Producing Large Herringbone Gears by the End-milling Process at the Woodard Machine Co.'s Plant in Wooster, Ohio

By FRED R. DANIELS

THE service required of transmission gearing in steel rolling mill machinery demands that the gears be so designed and machined that they will withstand the heavy loads and severe stresses encountered, and at the same time have a smooth action in which the meshing teeth will have a continuity of engagement. This type of smooth-action transmission has been approximated by what is known as "stepped" gearing, in which two gears are placed side by side on a shaft, with the teeth of one member opposite the spaces in the other.

It was soon recognized that the best type of transmission was the double helical or herringbone gear drive, but the difficulty that has usually been experienced in the machining of this type of gear has been one of the greatest hindrances to its more general use. When the herringbone gear is made in two parts, each being a helical gear of opposite hand to the other, the teeth may be cut by any convenient means and the halves securely fastened together after cutting. Modern developments in helical gear cutting, however, have made it possible to cut what is known as the Wuest type of herringbone gears by hobbing, running the cutter past the center where the teeth of opposite helical angles meet. One-piece herringbone gears may be cut in this manner without encountering the difficulties that formerly restricted the use of herringbone gear transmissions. In the Wuest type of gear, the teeth on opposite sides of the center line are staggered an amount equal to one-half the circular pitch.

The present article describes the method of cutting a one-piece herringbone gear by end-milling and without staggering the teeth of opposite halves of the gear. A special form of end-mill is used, and the teeth on one half of the gear are completely cut before the position of the gear is reversed to cut the teeth on the opposite half. The equipment employed is illustrated in Figs. 2, 3, and 4.

Objections to the End-milling Process

A number of objections have been raised to the practice of cutting teeth by the end-milling process, one of which is

Fig. 1. Semi-shrouded Rolling Mill Herringbone Pinions machined by end-milling

that the flutes of the cutter become clogged with chips, resulting in the tool becoming overheated. Another objection frequently brought forth is that the tool is so comparatively small that the cutting edges are subjected to excessive wear, the result being an incorrectly formed tooth. These objections, it will be seen, can be overcome. The end-milling process is the only one by which integral shrouded or semi-shrouded herringbone gears can be machined satisfactorily. It may be that this fact accounts for the amount of research which the Woodard Machine Co., Wooster, Ohio, has put forth in developing a method for end-milling these heavy gears that would produce entirely satisfactory results and that would withstand the arguments that have been advanced against the use of the end-milling process for machining gear teeth.

The obvious purpose of shrouds and half-shrouds is to furnish added strength, and on straight-toothed gears to eliminate end play of gear and pinion. For shrouded herringbone gears, the end-milling process is the only one practicable. Although the helix angle generally used for herringbone gears is 23 degrees, gears having greater helix angles than this, up to 45 degrees, are conveniently cut by the end-milling process, and an angle of about 30 degrees has proved very satisfactory.

Cutting Teeth in a Steel Mill Driving Gear

The practice in the shop of the Woodard Machine Co., in machining rolling mill machinery transmission gears, is to plane gears having a circular pitch of more than 5 inches and to end-mill those of less circular pitch. This article will cite two examples of finishing rolling mill transmission gears, one employing the end-milling process, and the other using the planing method. It is claimed that the objections commonly raised to the use of an end-mill for cutting gear teeth have been overcome by designing the tool so that it has a special form. Fig. 2 shows one view of the machine used in end-milling a 15-foot driving gear for one section of a 12-inch continuous strip mill. In service, this gear transmits a normal load of about 600 horsepower through a pinion, the ratio of the gear to the pinion being 8 to 1. The gear has 160 teeth, 20-inch face, a helical angle of 30 degrees, and a circular pitch of 3.534 inches. The teeth are not cast, but are cut from a solid blank in two operations. The gear is a steel casting with a carbon content of 0.35 to 0.45 per cent.

The planer style of table and the worm-gearing for revolving the gear are driven by a 25-horsepower reversing motor, the transmission of which is shown in the foreground. The table is driven by a rack meshing with a worm on the drive shaft, the end of which is shown at *A*. This shaft is set at an angle with the direction of travel of the planer table. It is driven through spiral and bevel gearing by a secondary drive shaft. This secondary drive shaft may be driven directly by the motor, when the planing process is used, or through the reduction transmission and selective speed gear-boxes when a slow feed is required for the milling process. This secondary drive shaft also drives, through gearing and helical change-gears, splined shaft *S*, Fig. 4, which actuates the worm by means of which the spindle and faceplate are rotated. The speed may be varied for machining gears of different diameters by selecting suitable change-gears for driving worm-shaft *S*. The worm drives the faceplate by means of a sector arm *D*, Fig. 3, attached to the lower side of collar *C*.

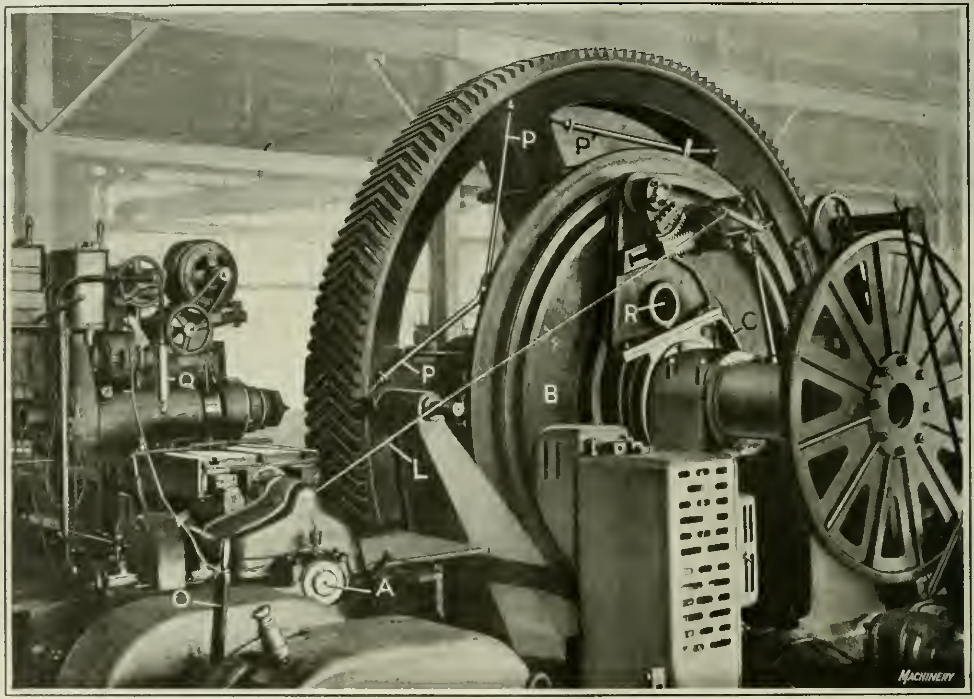

Fig. 2. Set-up of Machine used in end-milling the Teeth in Large Herringbone Driving Gears

Air-operated Clamping Device

The locking arrangement by means of which the faceplate is released during the indexing of the gear is also shown in Fig. 3. This is a view from the rear of the machine, and gives a good idea of how the indexing and clamping of the work are accomplished. On the upper slab portion of the collar *C* is bolted an extension arm *E*, which carries an air cylinder *G*, the piston of which is extended in the form of a double-sided rack *F*, which rides in a suitable slide.

At the extreme end of this extension arm there is an arm *H* which carries a segment. The segment arm *H* is fitted with a bronze nut which, acting on the thread of bolt *I*, draws the square head of the bolt which rests in the circular T-slot *J* in faceplate *B*, up against flanges in the faceplate slot, thus securely locking the faceplate to the oscillating worm. This is accomplished by air cylinder *G* acting on segment arm *H* through rack *F*.

After the faceplate has thus been locked to the drive shaft, the worm and sector arm *D* may be engaged so as to rotate the gear past the cutter the amount demanded by the angularity of the teeth, which in this case is tan 30 degrees (helix angle) × 10 inches (one-half face width), or approximately 5¾ inches. After machining each tooth, the faceplate is released by opening the air valve, and the indexing device is engaged. The lever that operates the referring to both Figs. 2 and 4. The latter illustration is a view from the opposite side of the gear and shows the type of end-mill used to better advantage. It will be noticed that a portable motor-driven grinding wheel *A* is located in a convenient position relative to the cutter-spindle, so that the end-mill may be dressed as it becomes dull. When grinding the cutter, the contour of the cutting edge is not touched by the wheel, the front clearance angle only being ground. Burrs produced by grinding the cutter may be smoothed off by lightly stoning the outer cutting edge, but not to such an extent that the contour of the cutter will be affected.

Reference to Figs. 2 and 4 will enable the method of attaching the work to the faceplate to be seen, as well as the use of auxiliary pipe-jack supports *P*, which withstand the turning moment in both directions and thus aid in assuring

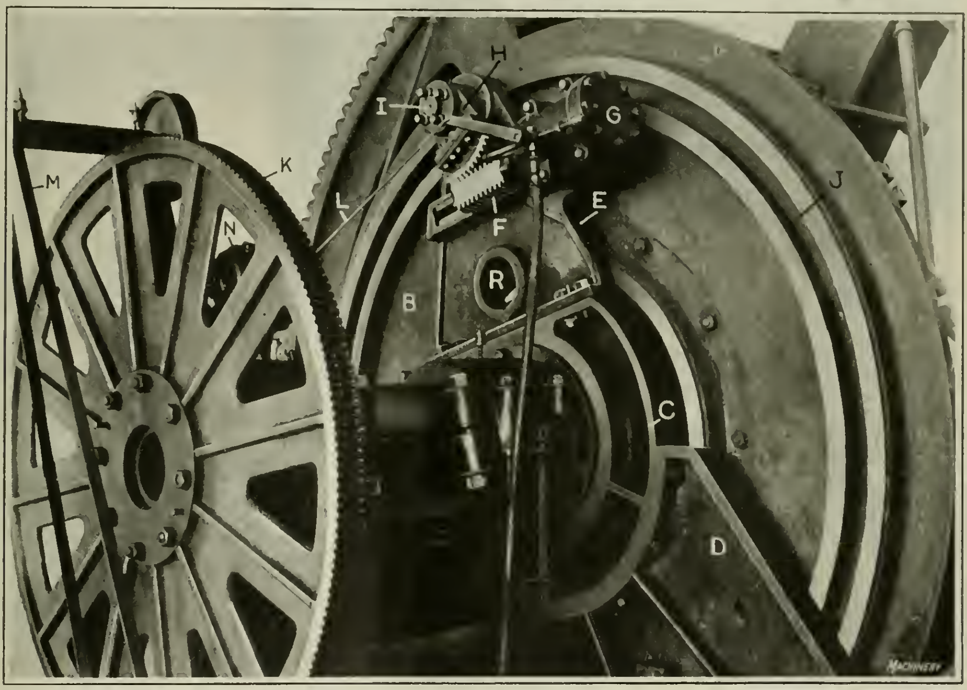

Fig. 3. Air-operated Device for clamping the Faceplate to the Driving Shaft of the Machine, and Indexing Mechanism

air valve of the cylinder is connected by rod *L* to the operator's station, as may also be clearly seen in Fig. 2.

Indexing Mechanism

The indexing mechanism consists of a worm and a worm-wheel *K*, Fig. 3, and a slip pulley drive. The worm is carried on the lower end of an arm located adjacent to the inner side of gear *K*. The worm-shaft carries the slip pulley which is driven through a belt *M* from the pulley shown just above the worm-wheel, and the motor *N*, which also is attached to the previously mentioned arm and which oscillates with it during the operation of the indexing mechanism. The switch for the indexing motor is located at the operator's station, as are also all other controls for the feeds and speeds of the machine.

The pendent switch *Q*, Fig. 2, which controls the main motor, is furnished with a cable so that the power may be quickly reversed or switched off without requiring the operator to leave his station. The milling head is equipped with hand controls for the regulation of the cutter, and motors for rotating and feeding in the end-mill, as may be seen by a positive drive for the gear. A support for the hub of the gear is provided by the swinging arm *D*, Fig. 4, which is clamped over the end of the gear hub by a turnbuckle screw, as shown. This arm carries a roll at *C*, so that the gear is not only free to revolve, but is also provided with a suitable outboard bearing.

Two cuts are required for machining these gears. In this particular instance, the cutter revolves at 210 revolutions per minute during the roughing cut and at 160 revolutions per minute while finishing the teeth. Although the speed of the cutter is decreased for finishing, the feed is the same in both operations, the rate being approximately 1½ inches per minute.

Sequence of Operations

The sequence of operations in machining a tooth on one side of the gear is as follows: The feed of the planer table is first engaged by means of the pendent switch *Q*, Fig. 2, which also results in revolving the faceplate and gear at the proper speed, as determined by the selection of the change-gears for the segment worm-shaft. In the present

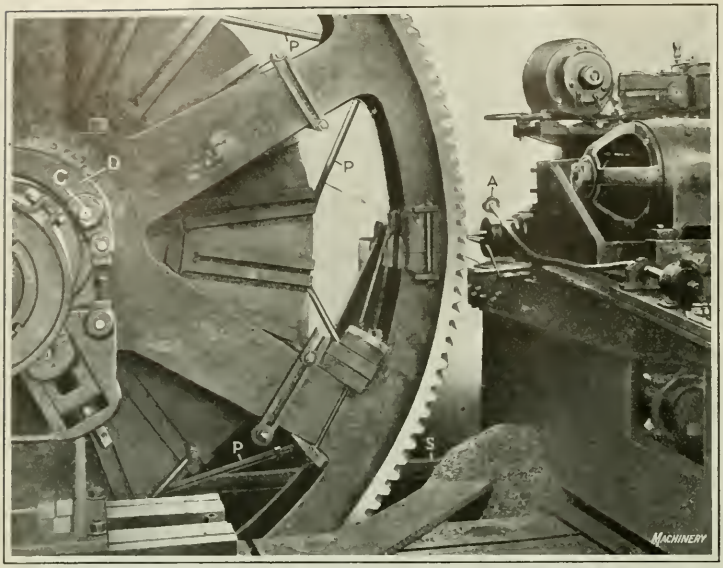

Fig. 4. Opposite Side of Gear illustrated in Fig. 2, showing the End-mill and the Method of attaching the Gear to the Faceplate

case, the gear ratio would be such as to rotate the gear a peripheral distance of approximately 5¾ inches while the table is feeding horizontally about 11½ inches. After the cutter has advanced to the center of the gear face, and the cut is completed, the driving motor is reversed, so that the end-mill travels back in the space just cut at a greatly increased speed, and the faceplate locking device oscillates backward in anticipation of the indexing movement. The motor that drives the cutter is then switched off, after which rod *L*, which controls the air cylinder valve, is operated to release the faceplate from the driving shaft of the machine. The indexing motor may then be switched on by means of the switch convenient to the operator's station. As soon as the faceplate has been indexed back a distance equal to the circular pitch, the air-operated segment-and-rack clutch is again engaged, the driving motor switch *Q* for traversing the planer table and rotating the faceplate, thrown in, the end-mill driving motor switched on, and the cut started.

After all the teeth on one side of the gear have been cut, the end-mill is moved to the opposite side and the operation continued. In Fig. 2, all the teeth on one side have been finished, and on the other side they have all been rough-cut except two. In the finishing operations, any inaccuracies in roughing are rectified, the tool used being of substantially the same design as that used in roughing.

For gears of smaller diameter the outer ring of the faceplate, which is attached with bolts, may be removed so that it will not be in the way, and the same segment gear *H*, bolt *I*, etc., (Fig. 3) are mounted in hole *R* and the opposite side of the rack is utilized.

Reference was made in the early part of this article to the particular advantage of the end-milling process where shrouded gears and pinions are to be cut. Although the gear shown in the illustrations referred to is not of the shrouded type, it is evident that cutting the teeth with semi-shrouds or full shrouds would not introduce any radical change in the machining procedure.

Planing Blooming Mill Pinions

The gear planer shown in Fig. 5 is the same type machine as shown in Fig. 2, except that the milling head has been replaced by a planer head, mounted on the same table. Here the work is a cast-steel gear, with a carbon content of 0.30 to 0.35 per cent, containing fifteen teeth of the stub involute form. The circular pitch is 7.33 inches, the helical angle, 25 degrees 25 minutes 21 seconds, the pitch diameter, 35 inches, and the width of face, 34 inches. It will be noticed that for this particular gear, a faceplate is not employed, a substantial collar *A* being used instead, in which one turned bearing end of the pinion enters and is secured by set-screws. The arrangement for indexing the pinion is the same as that previously described, except that the locking device is not used and a worm-wheel segment *B*, of shorter radius, takes the place of the large segment *D*, Fig. 3. The other end of the pinion is supported in a roller bearing having a swinging arm, roller, and turnbuckle arrangement which is similar to that employed in supporting the larger gear, as shown in the illustration Fig. 4.

Referring to the planer table, it will be seen that the tool-holder block *C* may be set at the proper angle to agree with the helix angle of the pinion to be cut, being rocked to the desired angle by means of segment gear *D* and hand-wheel *E*. The spring-operated clapper-box *F* is carried on the block *C*, which may thus be swiveled in the cradle fixture *G* in which it is carried, by means of gear *D*, as already stated. The arrangement is quite clearly shown, and the advantage of swiveling the tool *H* is that it does not become necessary to regrind the tool to machine teeth of opposite helical angles (except to maintain a good cutting edge) but only to change the angular position of the tool. At the time that this work was photographed, no cuts had been taken except the preliminary lining up cuts, which show faintly in the illustration at the tops of the teeth.

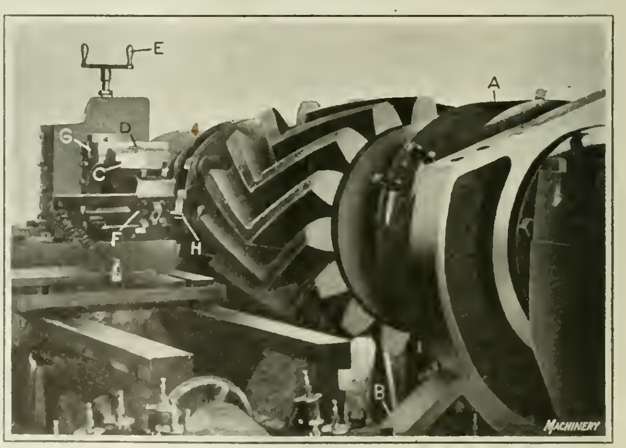

Fig. 5. Cast Pinions of Large Pitch planed on a Machine of Similar Design to that shown in Fig. 2

Lapping and Running-in Machine

By A. B. BASSOFF

Of the various methods employed in fitting automobile engine bearings, it is probably safe to assume that the "running-in" and lapping processes offer the greatest opportunity for improvement along lines tending to increase production and accuracy. Lapping and running-in are two distinct methods, and the incorrect application of the term "lapping" to what is strictly a running-in operation often results in misunderstanding. A lapping operation consists of grinding to size the surface to be finished, by the use of a lap charged with an abrasive; while a running-in operation consists of assembling two parts that are to run together, then applying a mixture of oil and an abrasive, and running the parts thus assembled until they are ground down to size or until the required smoothness of finish is obtained by the action of the abrasive particles in the oil. Both of these methods are employed to obtain the fine bearing surfaces required to eliminate vibration and noise and to insure the proper functioning of engine parts that operate at high speeds.

In running-in bearings, one of the assembled members may be rotated by power while the other is held stationary, but experience has shown that in most cases the best results are obtained by rotating one of the parts by hand. The reason for this is that the workman can change the direction of rotation and also give the work a slight reciprocating movement. The oscillating and reciprocating movements are nearly always employed when performing a lapping operation by hand, and this doubtless accounts for the incorrect application of the term "lapping" to what is actually a running-in operation. When the work is oscillated by hand, the workman can tell by the "feel" if the surfaces are not being finished uniformly, and he can control the oscillating and reciprocating movement to grind down the high portions.

While bearings fitted in this way are in most cases superior to those finished by other means, the method is not all that could be desired. In fact, it is considered a slow expensive process, and it requires the services of skilled workmen. It is also evident that the personal factor makes it impossible to obtain absolutely uniform results.

Function of Lapping Machine

In order to expedite the various lapping and running-in operations, and to provide a means whereby uniform results could be obtained, the writer designed the machine here described. The results obtained with this machine are superior to those obtained by hand lapping, even when the machine is operated by an unskilled workman. The installation of the machine not only made it possible to eliminate one department, but also released twelve skilled workmen from the tedious work of lapping, so that they could be employed on other work. The principal function of the machine is that of imparting to the work an oscillating and a reciprocating motion such as would be employed by a skilled workman.

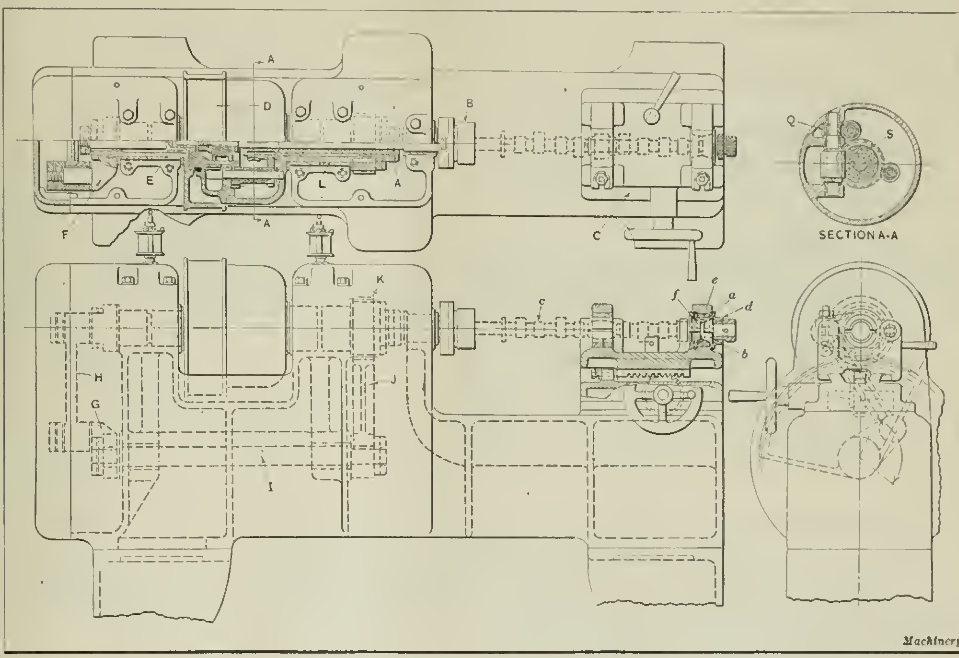

Fig. 1. Lapping Machine which imparts Oscillating and Reciprocating Movements to Work

Referring to Fig. 1, it will be noted that the oscillating movement is imparted to the work through shaft *A*. This shaft is equipped with a chuck *B*, which is designed to permit rapid insertion and removal of the work. One end of the work is supported in tailstock *C*, which is provided with hinged caps that can be swung back to receive the work, or tightened in place over the work-holding bushings by means of eye-bolts as shown. The diameter of the holes in the cap bearings is sufficiently large to accommodate bushings adapted for supporting the largest work to be lapped.

In some instances, one of the cap bearings may be used to hold a lap or a bearing which is to be run-in with its mating shaft. However, for most lapping operations a special lap-holding stand such as shown in Fig. 3 is employed. It will be noted in Fig. 1 that the tailstock is fitted to the machine by a dovetail slide provided with a rack and pinion adjustment operated by a handwheel. In operating the machine, the workman first throws back the tailstock bearing caps and locates the work in place, after which it is gripped by chuck *B*. The lapping or grinding compound consisting of a mixture of oil and abrasive particles is then applied to the surfaces to be lapped and the machine started. The lapping motion imparted to the work consists of a rotary movement first in one direction and then in the other, with a slight overlapping or advance at each oscillation, and a sliding or reciprocating movement parallel with the axis of the work. The rotary motion with the overlapping stroke brings different points of the work and the lap into contact, thus keeping the work round, while the reciprocating motion prevents it from becoming ringed or grooved.

Design of Oscillating Mechanism

The head of the machine has two housings between which is located the flanged pulley *D*, which is driven from a countershaft in the usual manner. This pulley is machined from a steel forging, and has a stem *E* to which is keyed the crank-arm *F*. The entire unit revolves between the two housings of the machine head, all end thrust being taken care of by the thrust collars shown. Crank-arm *F* is connected with crank-arm *G* by a connecting-rod *H*. Crank-arm *G* is keyed to shaft *I* as shown. At the other end of shaft *I* is keyed a sector gear *J* which meshes with gear *K* on the oscillating sleeve *L*.

Oscillating sleeve *L*, which is machined from a steel casting, carries the large end gears *M* and *N* (Fig. 2) which are cut from one piece, as well as the other cluster gear *O*. Gear *M* meshes with gear *P*, which is doweled and screwed to pulley *D*. The spiral gear *N* drives spiral gear *Q*, which is shown in the section *A-A* keyed to the shaft on which worm *R* is held. Worm *R*, in turn, drives worm-wheel *S* to which are keyed sleeve *T* and gear *U*. Cluster gear *O* receives its motion from gear *U*, which is keyed to sleeve *T*. Cluster gear *O*, in turn, drives sleeve *V* which carries the roller *W* located in the groove in cam *X*.

The upper crank *F*, Fig. 1, has a smaller radius of throw than the lower crank *G*, the result being that when the pulley makes a full revolution the lower crank oscillates but does not revolve. The ratio of the gears is such that for each revolution of the pulley the oscillating sleeve makes one revolution in each direction. The worm-gearing, consisting of worm *R* and worm-wheel *S*, Fig. 2, is self-locking, and therefore carries the work-driving spindle *A* (which is keyed to sleeve *T*) around an equal number of revolutions plus the amount that the worm-wheel sleeve is advanced by the epicyclic gear train. This advance constitutes the overlap which has been found necessary, and equals one-quarter revolution for each revolution of the pulley, so that when the pulley makes four revolutions, the work oscillates an amount equivalent to five revolutions in each direction.

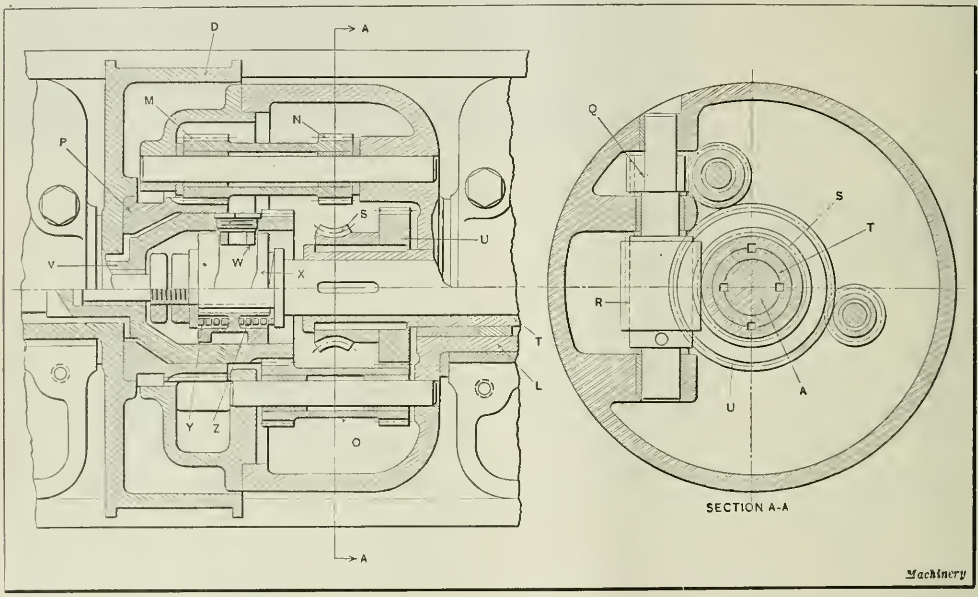

Fig. 2. Oscillating and Reciprocating Mechanism of Lapping Machine

Design of Reciprocating Mechanism

The sliding movement is obtained through the drum cam *X* in the following manner: It will be seen that sleeve *V*, which carries roller *W*, cannot slide endwise, whereas the drum cam *X* is keyed to the work-spindle in such a way that it is free to slide on the latter member. As the drum cam revolves the springs *Y* and *Z* are alternately compressed and released, thus producing pressure on the spindle *A*, which acts first in one direction and then in the other. The spindle is also free to slide in sleeve *T*; consequently, as soon as the pressure becomes greater in one direction than in the other, the spindle will slide in its supporting bearing in the direction in which the greatest pressure is exerted. It was found that more satisfactory results were obtained when the sliding movement was transmitted through cushioning springs instead of by positive means. This construction also permitted an even pressure to be exerted on the lapping compound in the case of the running-in operation on the conical bearings of the work.

The gear ratio is such that the drum cam *X* makes a complete revolution once in every twenty revolutions of the pulley as this ratio has been found to give the best results. It should be mentioned that the bearings on the main shaft and the oscillating shaft are not split. This construction was decided upon, as it permits the removal of the entire operating mechanism from the machine as a unit. It will also be seen that there are only two oil reservoirs on the machine, lubrication being effected by a system of leads and ducts, which prevents the possible burning out of bearings and damage to other parts of the mechanism.

Method of Holding Work

Since the work must float back and forth with the spindle, it is necessary that it be rigidly attached to the spindle. It is also necessary that the chuck or whatever means is employed to hold the work to the spindle should be quick-acting. Chucks of different kinds are employed to hold various types of work, the one shown in Fig. 1 being typical of those commonly employed. Referring to Fig. 4, which shows the construction of this chuck, it will be seen that the chuck is composed of a body which is held on the spindle and driven by a tongue. In this body are located three fingers *A*, which swing on pins *B*. These fingers are forced outward by springs *C*. The outer ends of the fingers bear against a sleeve *D*, which slides on the outside surface of body *E*. Sleeve *D* is normally forced outward in the position shown, by spring *F*. The sleeve is prevented from dropping off the body by set-screw *G*, which fits into a slot in part *E*. In loading the work, the operator simply slides sleeve *D* back, thus allowing the fingers to open outward against the recess or counterbored section of the sleeve. This permits the work to be readily inserted or removed. Releasing the sleeve closes the fingers and holds the work securely to the end of the spindle. Two large pins, one of which is shown at *H*, extend into holes in the end of flange *I* on the work, thus providing a positive drive. It will be noted that there are few working parts in the chuck, and that although it is easy to dismount it for the replacement of worn parts, the wearing surfaces are so well protected from dust that they should have a long life.

Types of Work Lapped

While this machine has not been employed or fitted up for internal lapping, it will be evident that it is adapted for this kind of work as well as for external work, provided suitable equipment is employed. Although the machine is employed for finishing a great variety of bearings, some of the more common operations for which it is used are lapping or running-in camshaft bearings, lapping timing gear shafts, crankshafts, and piston wrist-pins. These illustrations are representative of the automobile industry, but the nature of the machine is such that it is suitable for lapping almost any kind of round work. The running-in operation on the cone bearing of the camshaft, which is shown in heavy dot-and-dash lines in Fig. 1, is performed in order to obtain the required fit between the conical surfaces of bearing *a*, held in the tailstock of the machine, and the conical bearing collar *b*, held on the camshaft *c* by means of nut *d*. A mixture of oil and emery is applied to the bearing surfaces as a grinding compound. It should be understood that cone *b* is a separate piece, and is keyed to the camshaft when the latter is assembled in the motor. When in the lapping machine, a spacing collar *e* is placed between cone *b* and the fixed cone *f*, so that there is a small space between cone *b* and bearing *a*; then when the tailstock is properly adjusted the reciprocating motion imparted by cam *X*, Fig. 2, will bring the surfaces to be ground into contact, rotate the shaft first in one direction and then in the other, and release the parts from contact at regular intervals. For grinding the cone bearing *f*, it is only necessary to advance the tailstock toward the head of the machine the proper amount by means of the handwheel, and then repeat the running-in operation previously described.

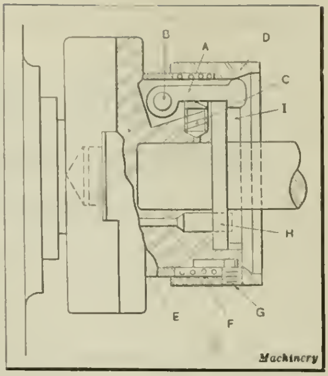

Fig. 4. Special Chuck for holding Flanged Shaft

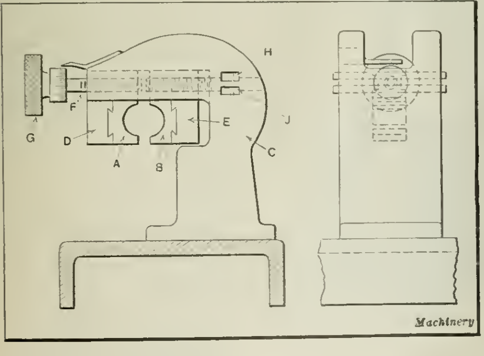

Fig. 3. Stand for holding Laps

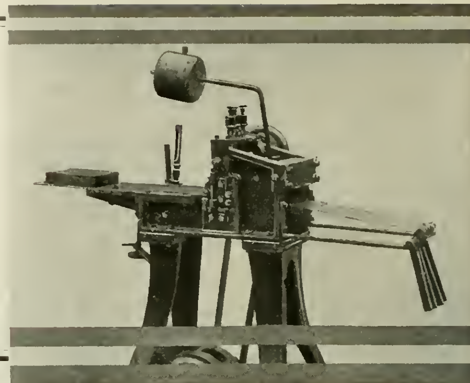
In lapping straight bearings, a stand such as shown in Fig. 3 is employed to hold cast-iron laps *A* and *B*. The stand *C* consists of a tool-steel forging having a T-slot in which blocks *D* and *E* may be adjusted by means of screw *F*, which is provided with right- and left-hand threads. A knurled nut *G* having graduations reading to 0.0002 inch is attached to the end of screw *F*. The jaws *D* and *E* are lapped all over, as is also the slot in which they are fitted. Taper blocks *H* and *J* are employed to take up wear and to make any transverse adjustment of the screw that may be necessary to center or locate the laps properly.

* * *

In a recent address by Mr. Hoover relating to world trade, it was pointed out that the reparation payments exacted from Germany must have a profound effect upon the economy of the whole world. Germany is to pay to the Allies $500,000,000, plus 26 per cent export duty, or, say, a minimum of about $750,000,000 a year. As she is left without much gold, foreign property, or foreign business earnings of consequence, these payments must be made mostly by the sale of manufactured goods outside her borders. But beyond the reparation payments, she must also sell sufficient goods abroad to buy her imports of food and raw materials. Any calculation based on the pre-war trade of Germany implies an enormous increase of her pre-war exports. In view of the export duty and other payments, she must produce these goods for about one-half our production cost in order to take our markets. Such an increase in exports must be in manufactured goods, and until the world consumption grows, these must be marketed in displacement of the goods of other industrial nations. We shall certainly feel the effects of this flow of goods that must be produced if she is to make reparation payments. On the other hand, Germany must take more raw materials from us for this purpose. However, the crowding in the market of German exports will affect her immediate neighbors more than us, for 80 per cent of her market must lie in Europe itself.

Punching Storage-Battery Insulating Sheets

By CHARLES O. HERB



THE necessity of developing a single-purpose machine for performing some operation for which no machine on the market is adapted frequently confronts a manufacturer. The present article deals with a machine designed, patented, and built by the Commercial Truck Co., Philadelphia, Pa., for punching rows of narrow slits in the hard rubber sheets used for insulating purposes in the electric storage batteries employed in driving the motor truck manufactured by this concern. This machine has proved satisfactory in every respect, and is here described because it is believed that some of the mechanical principles incorporated in its design may be of interest and value.

Use of the Hard Rubber Sheets

In the storage batteries mentioned, wooden plates are placed between the negative and the positive metallic plates, and sheets of hard rubber are placed between each wooden plate and a negative or a positive plate, as the case may be. An idea of the manner in which the rubber sheets are punched may be obtained by reference to Fig. 2, which shows the full width of a sheet but only a portion of the length. The sheets are actually about 8½ inches long, 5¾ inches wide, and range from 0.015 to 0.025 inch in thickness. It will be observed that there are 22 rows of slits, the slits being 0.009 inch wide, 3/16 inch long and spaced thirty-two to an inch. There is approximately 0.022 inch of rubber between each slit in a row, and the unpunched rubber remaining between each row is about 1/16 inch wide.

The function of the slits in the rubber sheet is to permit the electrolyte to filter through to the various plates, but it is essential that the holes be of such a size and shape that the chemical salts from which the electrolytic solution is obtained are not carried through the rubber sheets with the solution. Prior to the use of slits of the type shown, circular holes were used in the rubber sheets, but these were unsatisfactory because, in order to obtain the same amount of filtering area, it was necessary for each hole to have approximately the same area as one of the present slits, and circular holes of such a size permitted the electrolytic salts to seep through. In designing the machine for punching the slits, it was evident that if the operation was to be performed on an economical basis, it would be necessary for the tools to be operated at a high speed. A view of the machine as finally constructed is shown in Fig. 1.

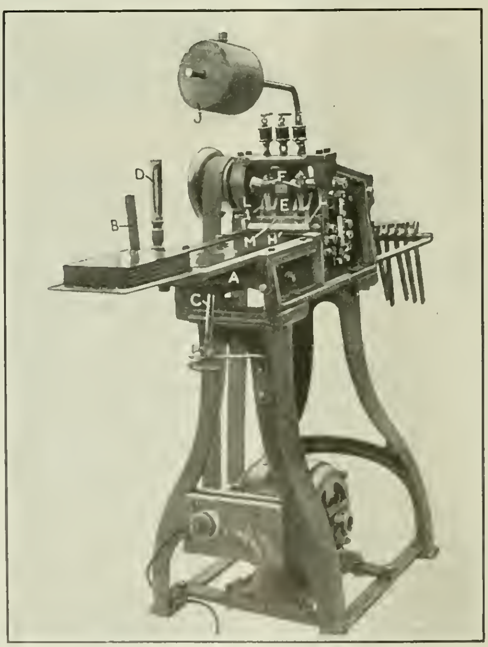


Fig. 1 Punching Machine developed for cutting Rows of Slits in Storage Battery Insulating Sheets

Construction of Punching Machine

The machine has a vertical ram, which reciprocates at a rapid rate. Attached to the lower end of the ram is a block containing twenty-two blades that pass through a stripper plate and into corresponding slits in a die beneath, during which movement a series of slits is produced in a rubber sheet. One of the problems encountered with the machine was that the sheets would crack and break when the punch blades came in contact with them, due to the brittleness of hard rubber. This difficulty was overcome by including a water chamber in the construction of the machine, the water in which is heated to a temperature of about 150 degrees F. The sheets are passed over the upper surface of this chamber prior to being fed through the machine, with the result that the rubber becomes sufficiently pliable to permit the successful performance of the punching operation. It will be evident that it is necessary to advance the rubber sheets a certain amount during each ram stroke and to keep them stationary while being punched. This intermittent movement is obtained by the provision of a mechanism to be described later.

The water chamber for preheating the rubber sheets is indicated at *A*, Fig. 1. It is filled by means of pipe *B* which is closed with a cap after sufficient water has flowed into the chamber. Provision is made for draining the chamber when the occasion demands. The chamber

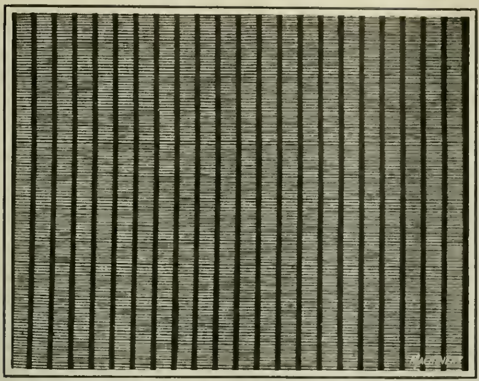

Fig. 2. Hard Rubber Sheet slit by Punching Machine shown in Fig. 1

is heated by means of gas-burner C which is connected to a gas supply line. The temperature of the water in the chamber can be ascertained at any time by reference to thermometer D. The illustration shows a pile of sheets lying on the sheet-metal bracket extending in front of the water chamber and two sheets lying on the water chamber. Ram E to which the punch-holder is attached is reciprocated up and down by means of two cranks F mounted on a horizontal crankshaft having a throw of 0.10 inch. This crankshaft is made of chrome-nickel steel, heat-treated, and it carries near the left-hand end a pulley connected by a belt to the pulley of the driving motor bolted on the bar supports at the bottom of the machine.

This motor is of 1/2 horsepower, and is connected to a lamp socket; it operates at the rate of 1750 revolutions per minute. As the ratio between the motor and machine pulleys is 6 to 7, the crankshaft rotates at the rate of 1500 revolutions per minute, the ram reciprocating the same number of times. A flywheel mounted on the left-hand end of the crankshaft beyond the pulley insures uniform operation of the ram. The crankshaft is mounted in a large Hess-Bright ball bearing where it extends through the left-hand frame, while other bearings support the crankshaft at the right-hand end and at the center.

Ram Support

A unique feature of the machine is that the ram does not operate in slides, as in common types of punch presses, but instead is supported by the outer ends of four parallel springs. Three of these springs may be seen in Fig. 3 at G. The photograph reproduced in this illustration was taken with one side of the machine frame removed, to permit the method of attaching the ram to be easily seen. The back ends of the springs are secured to the tying member of the machine frame at the rear. By this arrangement a rigid construction is obtained. It is evident that with this design the punch blades actually traverse in an arc rather than in a directly perpendicular path. However, the radius of the arc in which the blades operate is so great, and the distance that they enter the die openings so small, that the horizontal movement of the blades in the die is negligible and no difficulty arises from this source.

Intermittent Feed Mechanism

Attention has been called to the fact that it is necessary to move the rubber sheets a certain amount during each stroke and to hold the sheets stationary while being punched, so that the slits will be properly spaced. This movement of the sheets is obtained by four rollers, two of which are placed in front of the die and two at the rear, the four rollers being rotated intermittently. Three of these rollers are shown in Fig. 3 at H. The intermittent movements are obtained through the mechanism on the right-hand side of the machine which may be seen in Fig. 1. On the right-hand end of the crankshaft is a collar having a projecting pin that successively engages each of the six teeth of a Geneva gear mounted on a parallel shaft directly below the crankshaft. The duration of each engagement is sufficient to cause the Geneva gear to be rotated through an arc of 30 degrees, and during the remainder of a revolution of the crankshaft the Geneva gear remains stationary.

Helical teeth cut on the outer end of the shaft on which the Geneva gear is mounted mesh with a helical gear on the upper end of a vertical shaft. This vertical shaft also carries a helical gear at the lower end, which meshes with teeth machined on a horizontal shaft. On each end of the horizontal shaft, in turn, is mounted a helical gear, and these gears drive a gear on each of the lower rollers H, Fig. 3. The upper roller in each case is driven by another gear meshing with the one on the corresponding lower roller. Thus, ten helical gears, a Geneva gear and a special collar are contained in the intermittent gearing. The reduction obtained by this gearing is such as to give the rollers and sheets the required movement. One advantage secured through the employment of helical gears in this mechanism is that, although the fine rubber punchings may in some way be carried to the gearing, the sliding action of the teeth of the various gears in those of their mates is such as to cause the punchings to be easily worked out, and so they do not cause clogging. A cover is provided for this gearing, but this was removed at the time the photograph was taken.

Maintaining Friction between Feeding Rollers

A certain amount of friction must be maintained between the two rollers in each set to insure that the rubber sheets will be moved with the rollers. This friction is secured by means of counterweight J, Fig. 1, which is attached to a bent rod inserted in a suitable holder on shaft K, Fig. 3. Long projecting fingers also mounted on this shaft extend forward and rest upon wooden strips L, Fig. 1, which are hollowed out to suit the upper rollers on which they lie. By swiveling the counterweight rod from the position shown, the weight is brought to the rear of the machine and the fingers previously mentioned are raised. This removes all pressure from strips L so that they and the upper rollers may be quickly taken out to permit an inspection of the punch and die.

As the finished rubber sheets pass through the rear rollers, they are conveyed on ribbon belts, as shown in the heading illustration, to the back of the machine. The conveying

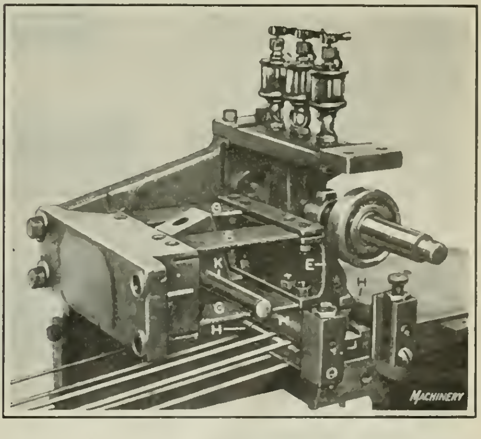

Fig. 3. Method of supporting the Ram on the Free Ends of Four Flat Springs

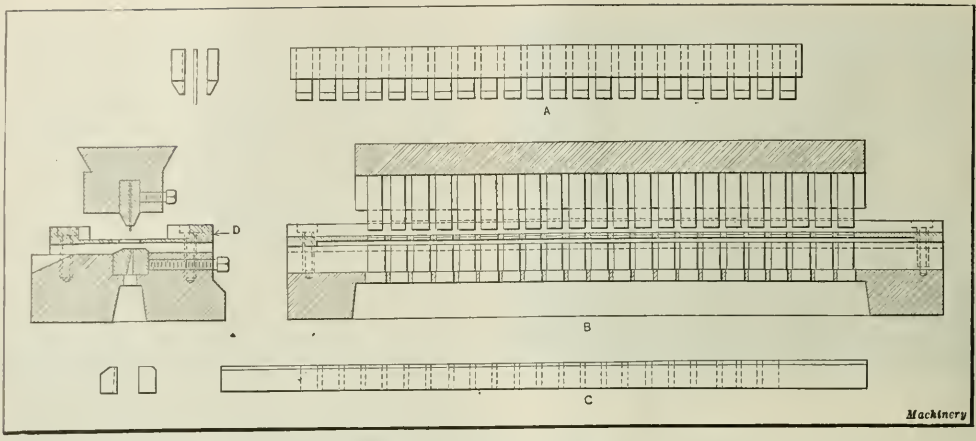

Fig. 4. (A) Punching Blades and their Strips; (B) Arrangement of Punch and Die Parts on Machine; (C) Die Strips

ribbons are driven by means of the lower of the rear set of rollers, which are grooved for that purpose. At the end of the machine, the ribbons pass over small pulleys mounted on weighted brackets which hold the ribbons taut. It will be noticed that lubricant is furnished to the various bearings by means of sight-feed oilers.

Punch, Stripper Plate, and Die

The construction of the punch, stripper plate, and die used on the machine is illustrated in Figs. 4 and 5. In Fig. 4 at *B* these parts are shown in the manner in which they are assembled on the machine. The punching blades are held in place by two steel strips that have fingers extending almost to the lower end of the blades as shown at *A*. The surface of one of the strips in contact with the blades is flush the entire length, while the contact side of the other strip has recesses milled to suit the width and thickness of each blade. The strips and blades are held together in the punch-holder by twenty-two set-screws as shown at *B*, and at *A*, Fig. 5. By clamping the blades individually in this way, each one may be adjusted independently of the others.

The punch-holder is secured to the ram of the machine by means of the dovetail tongue at the top, the rear side of the dovetail, that is, the side on which the set-screw heads are placed, being supported by a corresponding slot in the ram. The front dovetail surface is supported by the gib *M*, Fig. 1, one side of which is machined to suit. By this arrangement the punch-holder is securely held to the ram in a way that permits its ready removal. The stripper plate *D*, Fig. 4, is attached to the upper surface of the die-block and is so machined that not only the punch blades extend through its openings, but also the supporting fingers of the strips which hold the blades.

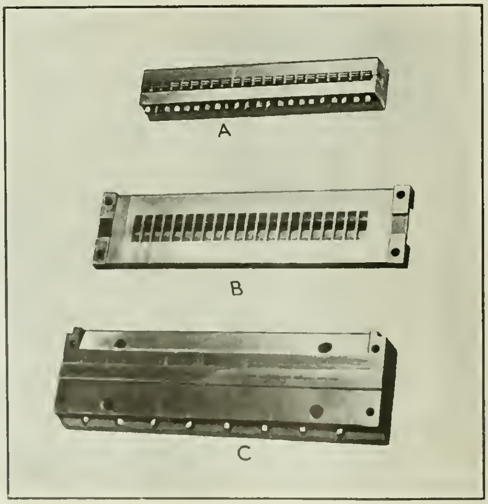

Fig. 5. (A) Assembled Punch-holder; (B) Under Side of Stripper Plate; (C) Die Strips assembled in Die-block

The openings of the stripper plate are hollowed out on the under side as shown at *B*, Fig. 5, so that the rubber sheets will not be stripped along the sides of the slits, but rather at the ends. By employing this principle, the narrow sections of rubber left between the slits in a row do not become torn, as would otherwise be probable. The die consists simply of two long strips as shown at *C*, Fig. 4, which are held in the die-block by means of set-screws as illustrated at *B*, and at *C*, Fig. 5. One of the strips is flat on the side which comes in contact with the punch blades, while the corresponding surface of the other is milled out to suit the blades. The punchings are forced through the die and fall into a receptacle beneath.

The punch-holder and die strips are made of a water-hardened non-shrinkable tool steel. An average of 2500 rubber sheets is punched before it becomes necessary to regrind the punching blades, which means that about 700,000 holes are punched by each blade. The long life of the blades is attributed to the rigid manner in which the machine ram is operated, and to the construction of the punch, die, and stripper plate.

MEETING OF AMERICAN ENGINEERING COUNCIL

The next meeting of the Executive Board of the Engineering Council of the Federated American Engineering Societies will be held at the Cosmos Club in Washington, D. C., September 30. The most important business coming before this meeting will be the election of a president to succeed Herbert Hoover, who resigned when he became Secretary of Commerce. Special attention will also be given to the extension of the employment service, and the question of licensing and registering engineers. Plans are also being made for a general engineering meeting, to be held in conjunction with the annual meeting of the American Engineering Council some time in the latter part of January. At this meeting such topics will be taken up as the elimination of waste, licensing of engineers, a governmental department of public works, and other subjects of importance.

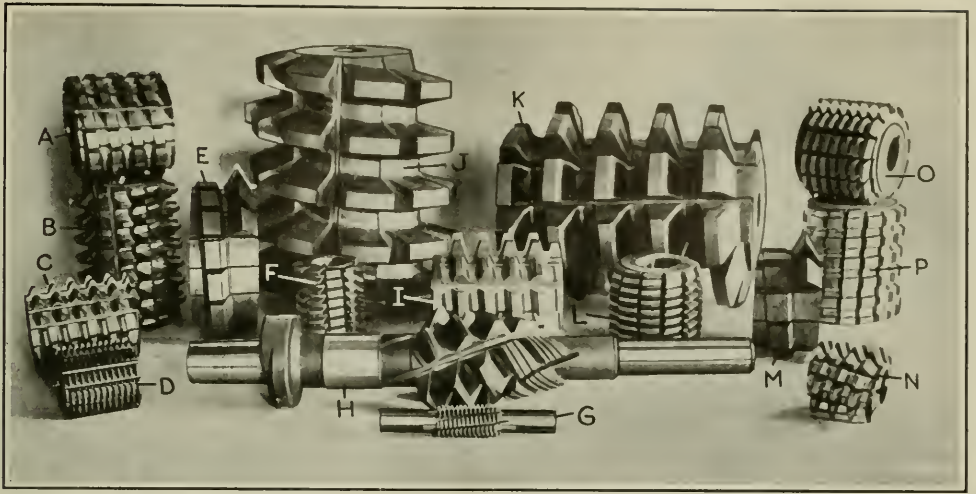

Fig. 1. Collection of Different Types of Hobs

Inspection of Involute Spur and Helical Gear Hobs

Testing the Accuracy of Hob and Tooth Parts—Hobbing Test—First of Two Articles

By CARL G. OLSON, Chief Engineer, Illinois Tool Works, Chicago, Ill.

EVERY user of hobs is interested in methods which will help him, when a new supply of hobs is received, to determine quickly if these tools are made with the accuracy required for his work. The purpose of this article is to point out and explain practical ways of conducting the inspection, whereby definite conclusions may be quickly reached. Broadly speaking, the inspection of hobs consists of determining whether or not orders have been correctly interpreted, and whether the hobs are made in accordance with the specifications given in these orders. The correctness of the type and size are first checked. Then the tooth parts are carefully gaged and examined before making the final test of cutting sample gears.

Type of Hobs

The term "type of hobs" refers to whether they are made for spur and helical gears or for other hobbed work, whether they are single or multiple threaded, straight or helically

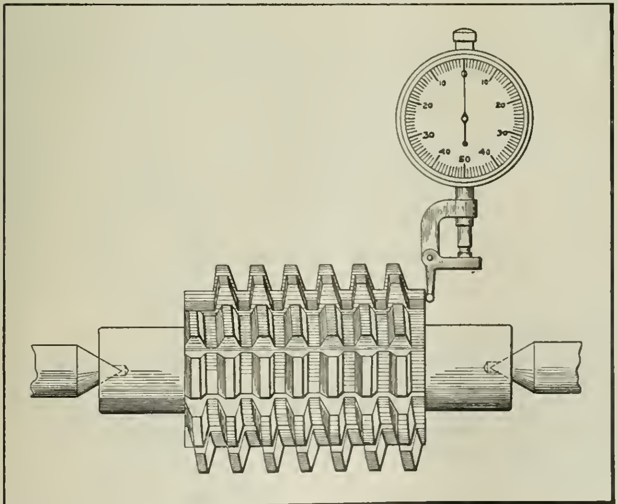

Fig. 2. Testing Accuracy of Hob at End of Arbor

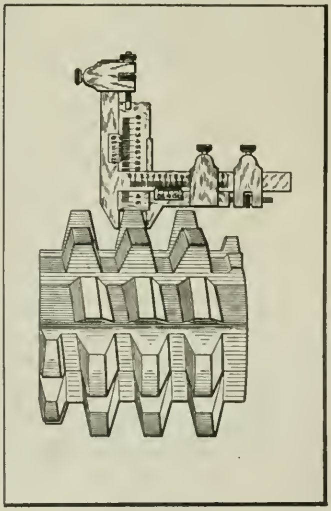

Fig. 3. Calipering Dimensions of Hob Teeth

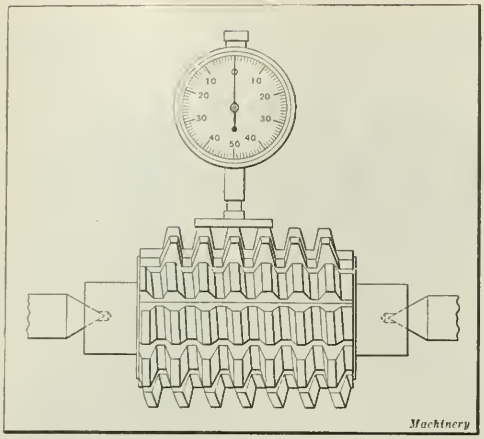

Fig. 4. Testing Eccentricity of Hob Teeth with Indicator, after sharpening

fluted, whether they have an arbor hole or shank, and whether they are intended for the roughing or finishing of gears. Several types of gear hobs are shown in Fig. 1, the letters referring to various types as follows: *A*, spline shaft hob; *B*, right-hand spur gear hob with hooked teeth; *C*, silent gear sprocket hob; *D*, standard straight-gash spur gear hob; *E*, Gould & Eberhardt type stepped-tooth worm hob; *F*, spur gear hob with helical flutes; *G*, shank type of hob; *H*, worm-gear hob used on machine equipped with tangential feed mechanism; *I*, spur gear hob; *J*, left-hand hob for helical gears; *K*, right-hand hob for helical gears; *L*, spur and helical gear hob with tapered end; *M*, Gould & Eberhardt type stepped-tooth worm hob; *N*, double-thread worm-gear hob; *O*, special spur gear hob; and *P*, spline hob.

Size of Hobs

The diameter and length of hobs of standard pitches, used on the various makes of hobbing machines, are given in the hob manufacturers' catalogues. These measurements do not usually require precision, but the cutters should be true cylinders at the points of the teeth, and the ends should be perfectly parallel and at right angles to the axis of the hobs. The accuracy of these conditions may be inspected by the methods shown in Figs. 2 and 4. The face and ends of the hob are checked with an indicator, while the hob is held on an accurate arbor, and is turned on true centers.

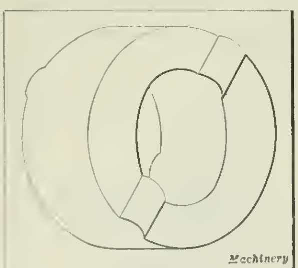

Fig. 5. Form of Equalizing Collar

Tooth Parts

The dimensions of the teeth in hobs are the same as the corresponding dimensions in racks and gears. The thickness of the teeth at the pitch line is equal to one-half the circular pitch; and the width of the space between the teeth, measured on the pitch line, is also equal to one-half the circular pitch. Therefore, the spacing of the teeth, measured between corresponding points, is equal to the circular pitch. The gear tooth caliper, shown in Fig. 3, is a convenient tool for checking the dimensions of hob teeth. In diagrams *A* and *B*, Fig. 6, is given the interpretation of the notation of the tooth parts, and also dimensions for 1 diametral pitch. Complete tables of tooth parts may be found in MACHINERY'S HANDBOOK.

Hobbing Test Gears—The Final Proof

After a hob has passed a general inspection, the final proof of its quality is determined by the perfection of the gears it will cut. To produce a good gear with any hob, it is necessary that the hobbing machine be kept in proper condition and that the setting up be carefully done. In preparing a machine for making a test, it is very important for the spindle bearings and the slides of the machine to be carefully adjusted, and for the gears governing the ratio of the spindles to mesh properly. The gears must not be too tight, as this will cause vibration in the machine. All minor adjustments and precautions necessary to care for a machine properly should be observed. The hob and gears are mounted on their respective arbors in the machine, after these parts have been carefully tested to ascertain that they are true. The shoulders on the arbors, as well as the ends of the collars and the nuts, must be perfectly true. A frequent test of these points of precision should be made, as illustrated in Figs. 8, 10, and 11.

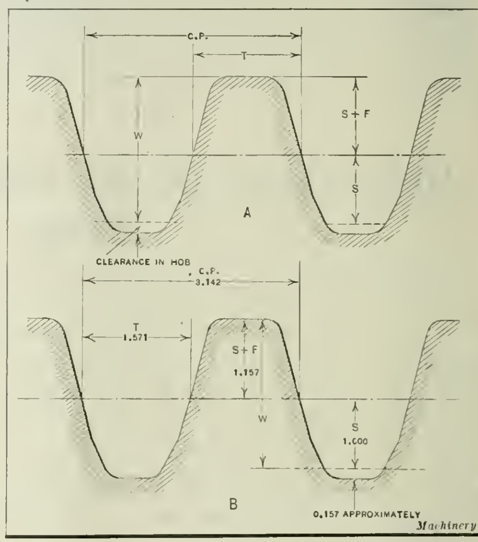

Fig. 6. Notation of Tooth Parts and Dimensions for 1 Diametral Pitch

The collars next to the hob on the arbor should be ground perfectly true inside and outside, and should fit the arbor exactly. When this is carefully done, the indicator may be used directly on these collars, on each side of the hob, as shown in Fig. 12, to determine whether or not the arbor has sprung in tightening the nut. The gear blanks, Fig. 9, should also be tested with an indicator after tightening the nut of the work-arbor. If it should be found, after these precautions have been taken, that the parts do not run perfectly true, the cause may be looked for in the accumulation of minute errors in the different parts; and when this occurs, the trouble is difficult to detect.

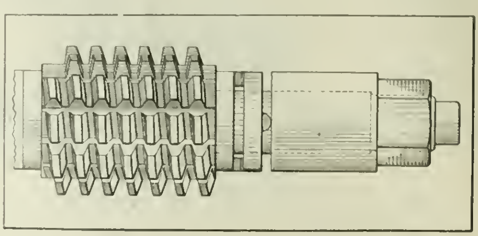

Fig. 7. Application of Equalizing Collar of the Type shown in Fig. 5

Equalizing collars are sometimes used to overcome these difficulties, one of which is illustrated in Fig. 5 and shown assembled on the arbor in Fig. 7. These equalizing collars are made with ridges on each side, the ridges on one side being located at right angles to those on the other side of the collar, as shown in the illustration.

In cutting test gears, it is best to take a roughing cut and a finishing cut, with only a slight amount of stock left for finishing. The proper depth is obtained by measuring the root diameter, after taking the roughing cut, subtracting from this the finished root diameter, and then feeding the hob in an amount equal to one-half the difference so obtained. This measuring is done with a vernier caliper or a micrometer. If the gears have an odd number of teeth the measurements may be taken from the root of one side to the outside of the opposite side; and by making the necessary allowance for the depth of the cut, the diameter may be found. The gears are ordinarily inspected by the use of master gears, but when no master gears are kept for this purpose, two gears must be cut for making the tests. The following article in this series, which will appear in October MACHINERY, will describe the methods and equipment used in making the involute test, the jump test, and the roll test on involute gears.

ENGINEERING EDUCATION IN UNITED STATES

Statistics compiled from the reports of eighty-one engineering colleges located in thirty-six states show that at present there are over 12,000 students enlisted in mechanical and an equal number in engineering courses, 8600 in civil engineering, 6500 in chemical engineering, 2400 in mining engineering, and 6500 in miscellaneous special engineering fields, making a total of over 48,000 students registered in engineering schools. Fourteen of these colleges have more than 1000 students, the highest figure being that of the Massachusetts Institute of Technology, with 2747 students. The next in order are the University of Michigan with 2212; Purdue University with 1845; Cornell University with 1825; and the University of Illinois with 1818.

Demonstrating Machine Tools

By HOWARD W. DUNBAR, Sales Manager, Grinding Machine Division, Norton Co., Worcester, Mass.

THE old adage "He who serves best profits most" is probably reflected more in the machine tool industry than is generally admitted. One of the essentials in the sales program of every successful machine tool builder is to render service to his customer, not in the sense of doing the things for him that are a legitimate part of his own, everyday routine work, but by giving the customer help in the truest sense of the word, when help is needed; and this can best be done by aiding the users of machine tools in getting out of them the most there is in them. It is better policy by far to show a customer how he can do more work with the equipment he has than to encourage him or influence him to buy more machines; because sales based on such encouragement or influence do not build up good-will for the concern, and this, after all, is one of the greatest assets that any machine tool manufacturer can have.

There are three distinct points that should be taken into account by a demonstrator in carrying out demonstration work in a customer's shop: (1) He must thoroughly instruct the user of the machine tool in obtaining the best results from the machine by its proper operation and care—this is to render real service. (2) As a result of this service he should try to impress on the customer the value, efficiency, and suitability of the machine tools that he is demonstrating, and to firmly impress the name of his concern upon those with whom he comes in contact, as one that stands for quality and integrity in machine tool building. (3) He should collect data and facts relating to the service given by the machine and its productive capacity. Such data later will prove of great value in increasing the service that the machine tool builder can render to this and other customers.

Service visits should not be limited to responses for calls for help. When a machine tool manufacturer has once established friendly relations with a customer by the demonstration of a machine, he can maintain cordial relations by calling for the purpose of inquiring concerning the operation of the equipment. This kind of attention has a double value. The machine tool builder learns of proposed plans for expansion that may mean additional business, and the customer learns that the service the machine tool builder renders is not of a temporary nature, but really permanent.

Instructing the Users of Machine Tools

With the sale of most machine tools in these days there is practically a tacit understanding that a demonstrator will be sent to the customer's plant to see that the machine is properly installed, instruction given to operators in its proper functioning, and a demonstration made to prove the ability of the machine to produce according to stipulated representations or guarantees. The majority of machine tools today are sold on the basis of their ability to produce certain quantities of work in a given time and of predetermined quality. On all new types of machines, wherever a definite guarantee is made, it is important to assist the customer in this way, both in order that he may obtain from the machine the very best results, and in order to safeguard the interests of the machine tool manufacturer.

Some customers show a tendency to take advantage of this willingness of the machine tool builder to render service. The fact that this service is available sometimes makes it too easy for the customer to call for assistance when it is really not required. When, for example, a concern is a large user of a certain type of machine tool, it is quite unnecessary for the manufacturer to go to the expense and trouble of sending a demonstrator with any additional machines that he may be furnishing to his customer, and there is no object in making an offer of a demonstration in such a case.

Sometimes the customer asks and actually requires services beyond those that may legitimately be given to him without cost. In that case an arrangement should be made whereby a demonstrator is sent to perform the specific work outlined, but the demonstrator's time and expenses should be charged for at a nominal rate. For example, suppose a concern should order several sets of spindle boxes for machines that had already been in operation for a number of years, and should request the machine tool builder to send a man a distance of several hundred miles to install and fit the boxes. In cases of this kind service rendered to a customer should be charged for, and the customer should not expect to be given such service for nothing.

Establishing a Reputation

If a machine tool manufacturer is always ready to furnish a customer with the proper kind of service, if he is always ready to lend a helping hand, and if through capable demonstrators he is able to prove the ability of his machines to produce accurately in quantity and continuously, it is inevitable that this kind of service will reflect credit upon his concern and ultimately lead to more business. Every machine tool manufacturer should endeavor to gain a high reputation for the kind of service that he gives. This can only be done by rendering a service that does not savor of patronizing, but the kind that helps a customer out of a tight hole when he needs help the most. Experience has proved that there is no easier way of securing orders than by following this policy. No hard work or extravagant promises are necessary to obtain a new order. It comes naturally and surely, if proper service and demonstration have been given in connection with former sales.

Service visits should not be limited to responses for calls for help. When a machine tool manufacturer has once established friendly relations with a customer by the demonstration of a machine, he can maintain cordial relations by calling for the purpose of inquiring concerning the operation of the equipment. This kind of attention has a double value. The machine tool builder learns of proposed plans for expansion that may mean additional business, and the customer learns that the service the machine tool builder is prepared to render is really permanent.

The Collection of Data and Facts for Future Use

In order to assist in the development of the business, and to enable the highest type of service to be rendered constantly, it is necessary that data be collected and returned to the home office of the machine tool builder, where it should be recorded for future reference. This data should cover results in regard to production; questions relating to the best kind of tools to be used; and anything that may be of value in the future in selecting the proper equipment for a similar job, either in the same plant or elsewhere. By collecting and recording such data the demonstrator himself acquires a valuable fund of knowledge, which assists him in his work; and the home office becomes a clearing house for information relating to performances that will be of the greatest value in developing new business.

It is evident that a demonstrator will also make it a point to study the performance of competitive machines, noting what they are doing, and particularly observing wherein they may excel his own, so that by making proper suggestions, steps may be taken to overcome any failings or shortcomings that may exist in the equipment being built by his own firm.

In order to facilitate the work of recording such data as may be collected in connection with the demonstration of machines in a customer's plant, forms should be provided so that the demonstrator can merely fill in information relating to speeds and feeds, depth of cut, production per hour, etc. These blanks should be filled in as completely as possible; but if certain data are not known, it could simply be noted on the blank by filling in the word "unknown," or, if the exact data were not available, but the demonstrator should judge the condition to be that met with in average shop work, he could fill in the word "normal." In all cases where data of this kind are given, a statement should be made as to whether the work is done by the demonstrator or the customer's own operator.

At the completion of each demonstration, the demonstrator should also submit a report to the home office, setting forth, in a brief statement, the work done and the production obtained. A special form ought to be provided for this purpose, and the report should be signed by the customer's superintendent or foreman, so as to indicate that the machine has been demonstrated to his satisfaction.

The Attitude of the Service Man

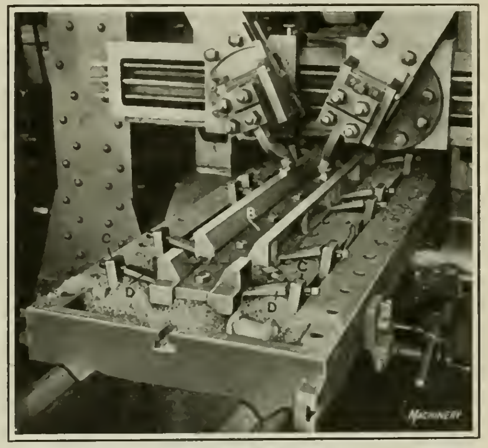
The attitude of the service man has much to do with the creation of a favorable impression of the service being rendered. Very often a customer calls for help when he is unable to correct a fault, simply because he is not looking in the right place for the cause. The service man or demonstrator should in all cases examine all the facts, and should accept no statements without having convinced himself of their accuracy. Erroneous statements are often made through lack of knowledge of the construction of the machine or by mistaken or erroneous assumptions. In investigating all details for himself, the demonstrator, of course, must use tact, but the acceptance without question of the user's statement of the cause of some unsatisfactory performance is likely to lead to delay in finding the remedy and to confirm the impression of faulty construction or design. As an example it may be mentioned that when unsatisfactory results are obtained in the use of a certain cam grinding equipment, it is natural to place the blame on the grinding of the master cams. As a matter of fact, the real cause of the difficulty is nearly always the alignment of the centers, speed of revolution, grade of wheel, or similar simple errors—something that is entirely in the hands of the customer's own operator.

Tendency to Overdo Demonstration Work

It may not be out of place to emphasize again the point that a great deal of needless expenditure of time and money results from offering the services of a demonstrator when the customer does not need his help. Some machine tool builders have on their quotation sheets a statement to the effect that when the machine is set up or ready for use a demonstrator will be sent to instruct the customer's operator without charge. While it should be understood that such service is available, it is hardly necessary to have this accompany every quotation. The services of a demonstrator will be furnished without charge in case the customer needs it, but many needless trips will be saved by not making this offer except when it is clear that there is a good reason for sending a demonstrator.

PLANING SLIDE GIBS FOR WOOD MOLDING MACHINES

The accompanying illustration shows a Niles-Bement-Pond planer equipped for finishing the slide gibs on a wood molding machine. This planer is used in the Pratt & Whitney Co.'s plant. The chief point of interest in connection with this operation is the provision made for setting up the work and locating the tool-heads so as to plane the slide gibs at the required angles. At the front end of the planer table, there is a templet *A* which has two inclined faces that match the contour of the surfaces that have to be planed on the work. In setting the tool-heads, it is the practice to locate the points of the cutting tools on these two inclined templet faces and to adjust the angles of the heads so that the tools may be fed along and kept constantly in contact with the templets. In addition to their use for setting the tools, these templets constitute a means of checking the accuracy of the finished surfaces of the work, the reading of an indicator in contact with the templet being compared with that of an indicator in contact with the finished face of the work. In this manner the planer operator can easily ascertain whether the job has been finished to the required form.



Application of Tool-setting Form in planing Irregular shaped Pieces

There is nothing of special interest in regard to the setting up of these castings for planing. It will be noticed that extending back from templet *A* there is a bar *B*, the sides of which are carefully finished to make them parallel, and as the inside vertical faces of the work have already been planed, they can be located against these parallel sides of the central portion of the fixture. Only the front end of the planer table is shown, but it will be apparent that the work is comparatively short and that a string of pieces is set up at each side of the parallel bar *B*. The ends of the first pair of castings at each side of this bar will be seen just back of the points of the cutting tools.

The method of clamping the work is quite simple. It will be seen that stops *C*, carrying clamping bolts in their upper ends, are placed in the table T-slots; and that fingers or so-called "butters" *D* are inclined downward, so that the pressure of the clamping bolts on these fingers serves the double purpose of pushing the work against parallel bar *B* and of holding it down on the table. On this job the depth of cut is ¼ inch, with a feed of 3/16 inch per table stroke, and a cutting speed of 35 feet per minute.

* * *

The French Government is encouraging the use of tractors for agricultural work, and granting loans for the purchasing of tractors and tractor material.

PRESS EQUIPMENT FOR FASTENING AND CLOSING PERFORATED CAN CAP

By S. A. McDONALD

The equipment employed on a horn press for securing a cap on the neck of a talcum powder can, and at the same time closing the sprinkling holes so that the powder will not sift out is shown in Figs. 1 and 2. The top of the neck fits loosely in the hexagonal-shaped cap, so that the latter may be moved around sufficiently to bring the perforations out of line. The horn press used for the fastening and closing operation is equipped with a hexagonal turret operated by a Geneva wheel which receives its motion from the brake end of the crankshaft.

The holder *A*, Fig. 1, has a hole through the shank, and a spiral threaded stem *B* is babbitted in place in this hole. On the end of the stem is a pad *C*, having a recess at *R* which fits loosely over the hexagonal-shaped cap. A ring *D* is secured to the punch, which acts as a guide for the pad *C* and the leather-faced pressure pad *E*. It also contains the trip-lever *F*, which engages the catch-screw *H* to hold pad *C* up until the end of the up stroke is nearly reached.

Six work-supporting horns like the one shown in the lower view, Fig. 1, are secured to the hexagonal turret, each of which has a tapered mandrel *J*, on which the expanding

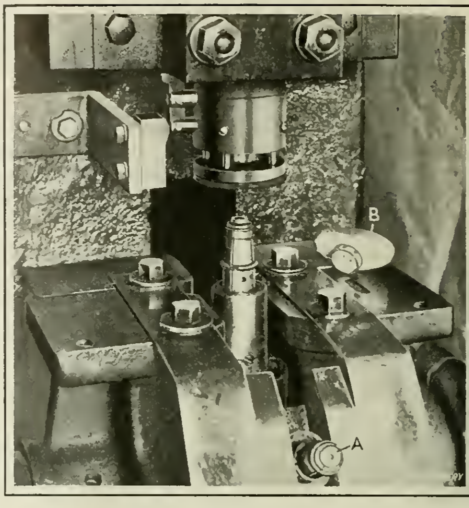


Fig. 2. Press equipped with Device shown in Fig. 1

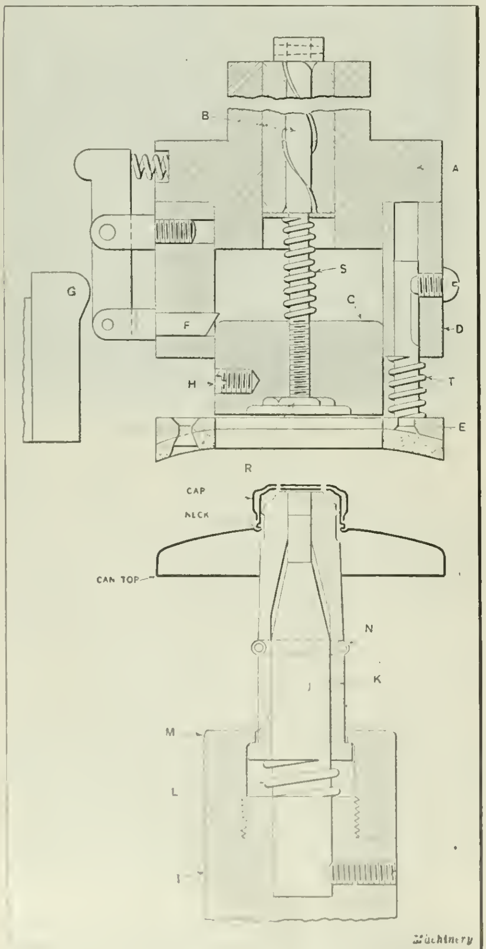

Fig. 1 Device for fastening and closing Perforated Can Cap

beading sleeve *K* slides. The spring *L* holds the sleeve in the upper position, and the nut *M* limits its upward travel. The small spring *N* serves to collapse the expanding sleeve. The trip-bracket *G* is attached to the body of the press by another bracket, as shown in Fig. 2. The operation of the device is as follows: When one of the turret tools or horns comes to the lower position shown at *A*, Fig. 2, the operator places an assembled can top, neck, and loose cap on the end of the expanding beading sleeve *K* of the horn in the position indicated in Fig. 1. At the next stroke of the press this horn comes under the punch, and when the punch descends the top and cap are located in their respective pads.

On the further descent of the punch the two pads stop, but the holder continues to descend, compressing the springs *S* and *T*, so that the pad *E* grips the can top while the pad *C* revolves, thus twisting the cap and closing the holes. When the pad *C* comes in contact with holder *A*, the spring *L* is compressed by sleeve *K*, and as the latter member slides down on the tapered mandrel *J*, it is expanded so that the bead sinks into the neck. This enlarges the neck so that the cap cannot be pulled off, but is free to revolve as far as the hexagon forms in the top will permit.

On the return stroke of the press, the pad *C* is retained or held up in the punch by means of the trip-catch *F* until its lever strikes the trip on the bracket *G*. Meanwhile, the pad *E* holds the can top down on the sleeve *K* so that the cap is free from the pad *C* and will not be turned to open the holes in the perforated cap. As the holder continues upward the trip releases the pad *C* and it spirals down to its lower position. The pad *E*, having traveled as far as its retaining pins will allow, moves upward, leaving the assembled work on the top of the now collapsed sleeve *K*. At the next stroke of the press, the assembled parts are carried in back of the press, where they tip off into a chute. One of the assembled parts is shown on the knee of the press at *B* in Fig. 2. As the operation is a continuous one an operator can assemble about 25,000 parts per day of eight hours.

* * *

Machinery manufacturers in Indianapolis are planning to take a large part in the Indianapolis Industrial Exposition, which will be held October 10 to 15, at the Indiana State Fair Grounds under the auspices of the Indianapolis Chamber of Commerce. Space has already been taken by more than 400 of the 781 different lines of manufacturing located in Indianapolis.

The British Machine Tool Industry

From MACHINERY'S Special Correspondent

London, August 16

BEYOND an improvement in the tone of inquiry, it cannot be said that the condition of the machine tool industry has altered since my last month's letter. There have been instances of orders booked for heavy machine tools, and some of the makers of these, particularly in the Manchester district, have been able to work full time. Judging from the latest of the inquiries received, there is a probability of a greatly increased trade with Japan, and not only there but in other prospective foreign markets much is being done to stimulate trade by improvement in British catalogues and other aids to sales. The absurdity of sending descriptive matter in a language that cannot be read by the potential purchaser is now recognized. Nothing is helping the overseas trade more than the cooperative trading policy, whereby firms act together as one concern in everything except the actual manufacture of products, and here they each agree to keep to that class or type of machine tools with which they have had the most experience.

Demand for Machine Tools in Domestic Market

There is a phase of the automobile industry that is bound to react favorably on the machine tool and small tool trades. Some of the makers who have previously confined their efforts to the production of the more luxurious cars are now interesting themselves in light cars that appeal to a much wider class of users; taking into account the many other concerns that cater for this trade there is no doubt that keen competition will call forth the most rigorous investigation and recasting of production methods. In the Birmingham district, there is some demand for machine tools for the brass trades, while in most districts it is clear that the small tool trade is quickly recovering. The Sheffield steel works are gradually returning to full activity.

It is reported that an order for 45 large locomotives. 2500 cars, and 12,000 tons of rails has been placed by New Zealand with British firms. A further order is also expected from the New Zealand Government for equipment for hydroelectric works, seven million pounds having been appropriated for that development. Some important Indian railway contracts have also been placed with British firms, and the low price at which the orders were taken points to an intention on the part of British manufacturers seriously to meet foreign competition. Part of the contract mentioned is for 135,000 tons of steel rails, and was taken at a price of about £10-2-6d (about $36.45 present exchange) per ton. This price is 15 per cent below Belgian quotations, but 3½ per cent above German quotations.

Imports and Exports of Machine Tools

Exports of machine tools in June show a small but welcome increase; the exports are valued at over £260,000 (about $936,000. present exchange) a figure that dwarfs the £40,000 ($144,000) value of imports. The fall in the value per ton of imported machines that was so strikingly pronounced in April and May was continued in June, the value per ton of both imports and exports being now about £150 ($540). This sudden fall in the import ton value from about £275 in only three months is very remarkable, and has occurred in a period during which the tonnage imported has remained fairly constant at a little over 200 tons per month.

During June no fewer than 246 lathes of a total value of nearly £100,000 ($360,000) were exported from Great Britain, while the most important items figuring in imports were 150 drilling machines of a total value of under £3500 ($12,600) and 78 presses, punches, and shearing machines totaling £17,600 ($63,360) in value.

New Developments in Small Tools and Special Machinery Field

The activity in the small tool trade is reflected in the large orders for twist drills being received by Tidswells Ltd., Ancoats, Birmingham. The methods used by this firm differ from those of other manufacturers in that the flutes are formed, and the backing off done after hardening. More uniform hardness is claimed and the number rejected is reduced, as naturally the plain round bar hardens with less distortion than a finished twist drill.

There are several plants requiring special machinery under construction for the quantity production of specific articles. One such plant is for the manufacture of door hinges; the equipment consists chiefly of special milling and drilling machines, and an output of 300 complete hinges per hour is arranged for. Another such plant is for the manufacture of sewing machines. These are designed to be made to sell at under 30s ($5.40) retail.

Prices of Materials

The uncertainty of material prices is having a detrimental effect on business generally. Users are buying only enough to just tide them over immediate needs. The iron and steel trade in consequence remains lifeless. Production of pig iron is negligible, smelters preferring to wait until they know what fuel prices are likely to be. Home supplies of pig iron are practically sold out, and weeks must elapse before furnaces can be got into regular production again. Meanwhile, many of our foundries are becoming familiar with foreign iron, where previously the practice has always been regulated by the employment of certain makes or mixtures of pig iron obtained at home. Modifications in their casting arrangements have been effected, so as to adapt them to imported material, and during the last three months Belgian iron, in particular, has made such rapid headway that it has established a position for itself from which it will be difficult to dislodge it.

The increase of about 5s (90 cents) per ton for coal is particularly unfortunate when the whole question of material prices hinges on this dominating factor. Everyone is agreed that nothing but substantial reductions in fuel charges can effect a lasting trade improvement and enable manufacturers to meet competition. Generally speaking, iron and steel prices have varied little during the last month, and the same is true of other metals.

REGIONAL MEETING OF THE A. S. M. E.

On October 3 to 4 a regional meeting of the American Society of Mechanical Engineers will be held in Cleveland, Ohio, with headquarters at the Hotel Winton, in the rooms of the Cleveland Engineering Society. Several papers will be read, and among others one by E. J. Lees, president Lees-Bradner Co., Cleveland, Ohio, on grinding and measuring involute gear teeth. The local sections and engineering clubs of the following cities have been invited to participate in this meeting: Akron, Buffalo, Chicago, Cincinnati, Cleveland, Columbus, Detroit, Erie, Rochester, Toledo, Indianapolis, Ontario, Pittsburg, and the Engineering Society of Dayton.

THE "NEARLY HUMAN" MACHINE

Automatic machines of various types constitute one of the wonders of this wonderful mechanical era. Some automatic machines are spoken of as being nearly human. If any deserve this attribute, surely the machines used in making watches do. Some of these machines are illustrated and described in the series, "Automatic Machines in a Watch Factory" now appearing in MACHINERY. The sudden stopping and reversing of rotation, the indexing of the work-holding turrets, the timing and reversing of compound slides, and the various other mechanical movements, each governed by pneumatic control in turn actuated by auxiliary cams and levers, give to these machines such range and accuracy that they seem indeed to be more human than mechanical.

More and more mechanical devices automatically perform all the purely mechanical operations involved in production; but it is in the tireless, restless, and progressive human brain that these highly ingenious machines must first be conceived and fashioned. The thinking must be done for them—every step worked out.

Nor does the invention of these wonderfully productive machines injure even the workers directly replaced. On the contrary they are released from tedious, monotonous manual routine to render more interesting and useful service in channels requiring greater skill and ability where the automatic machine is still a stranger. The worker himself is advanced by invention which thus alters the character of his service, and enjoys the fruits of invention and progress to an extent undreamed of by the wealthiest and most powerful of a century ago. What would Napoleon have given for the twenty thousand Fords, owned by working men, which operate in and out of the single city of Detroit on a fair Saturday afternoon!

* * *

THE EXECUTIVE'S UNDERSTUDY

Carnegie is quoted as having said that he considered himself a good executive because he could leave his job at any time without being missed. He had selected such men and built up such an organization that if he were temporarily absent, everything would proceed along the lines laid down. It is all too well known that this could not be said of a great many manufacturing organizations. Very often production is under the supervision of a factory manager or superintendent who personally attends to a great many details without consulting to any extent with assistants or department foremen. So long as the man entrusted with this work is on the job everything goes well; but too much dependence is placed upon his being constantly on the job; and if he takes to his bed with a long illness, goes on a vacation, or leaves for another job—any of which is likely to happen—confusion generally reigns for a while until someone else, after many mistakes, is trained for the responsibility.

Every organization should have an understudy working with every man who is holding a position of responsibility. The understudy should do the actual detail work, so as to learn all about policies and details, and be able, temporarily at least, to fill the position of his superior. This is the only way in which to give an understudy the training that he must have to permanently fill the position, should a change become necessary. Progressive and prosperous businesses often suffer greatly through losing the services of some executive who had no capable understudy.

In a small shop a single understudy would be sufficient. In a large shop it would be better to have a number of men trained under the direction of the chief executive. One large manufacturing plant has created an advisory board of assistant superintendents, half a dozen in number, to work under and in consultation with the general superintendent. The duties and responsibilities of each of these assistant superintendents are defined so that the foundry, pattern, and drafting departments come under one man; the die, tool, jig and fixture work under another; the assembling, shipping, bench, and repair work under another; all the production machine work under another, etc. By this method the general superintendent is relieved of a great deal of minor detail and can devote himself to the bigger production problems; while on the other hand, the men working directly under him become trained in handling executive problems. Should the factory manager take sick, die, or leave, there would be a group of trained men from whom the most capable could be selected to fill his place.

We have been so busy producing during recent years that we have almost forgotten how to train men for executive positions, but there is ample evidence that our manufacturers are awakening to the great necessity for regular and systematic attention to this very important organization problem.

* * *

TRADE SCHOOL EQUIPMENT

Generally speaking, machine tool manufacturers show very little interest in the equipment of trade schools. This field has been left largely to a few manufacturers specializing in machinery for trade schools, but it would be to the interest of the entire machine tool industry if trade schools were equipped with a greater variety of standard machine tools. Young men who receive their education in these schools pass out into active shop work, and many of them become executives later. They always remember the names of the makers and the characteristics of the machines used during their training period. For this reason alone it is decidedly to the interest of machine tool manufacturers generally to have their machines used in trade schools.

In selling surplus machine tools at 15 per cent of the purchase price to trade and engineering schools, the Government greatly aided many to obtain an up-to-date and varied equipment, and hundreds of machine tools that otherwise never would have found their way into such schools were thereby placed to the great advantage of engineering education. One town in the Middle West alone acquired $200,000 worth of these machines for its trade school at the comparatively small cost of $30,000. Some of these machines were new, and some very slightly used. But in cases where additional auxiliary equipment was required, the trade school authorities complain that they received little encouragement or help from the manufacturers, and that the makers were reluctant to give them the aid of their service departments. Ordinarily, buyers of second-hand machinery are not entitled to free service, but in the trade school where the future executive makes his acquaintance with the tools of the machine building industry, it is of lasting value for the manufacturer to have his machines operate satisfactorily.

The Present Situation and the Outlook

Summarizing the Views of MACHINERY'S Correspondents

THE many interesting letters in the symposium by practical business men published in July and August MACHINERY give a clear idea of the trend of thought in the machine building industry. The note of confidence, the definite constructive suggestions, the forward-looking attitude, the clear recognition and concise statement of the salient facts—all are equally significant. It is well worth while to glance again at the views so definitely stated; to note the quite unanimous opinion that improving business is just around the corner. Here are some quotations:

"I have been in the machine tool business for thirty years; I have seen its ups and downs periodically, but I have never lost faith in it."

"No one will believe that the human race is going to stand still very long."

"A good, healthy, reliable business that takes care of the normal requirements of our people is what we want and is what we are going to have in the near future."

"Do not overlook the thousands of new devices invented every year to replace hand labor, such as office appliances, household conveniences, sporting goods, toys, etc., all of which require machine tools in great quantities."

"We should not forget that in the long run everything points to the continually increasing use of machinery to replace manual labor in the factory, on the farm, and in the household. This calls for an increasing amount of machine tools, and the machine tool industry is always certain of its place in the economic structure."

"The most pressing needs of the industry are: the effecting of economies in our organizations, the still further perfection of design, and unfailing confidence in its ultimate future following the readjustment, when the resumed demand for things mechanical will inevitably be felt. This is no time for discouragement as to the future."

The following definite statements as to the return of more active business in the machine tool industry came from men of long experience:

"I am convinced that we have turned the corner and that before many months we shall have the definite evidence of another era of prosperity."

"The last three months of this year will probably be fairly good months in the machinery line. Beginning in January, 1922, I am looking forward to good, normal, healthy business which will probably last for several years."

"I believe there will be a gradual revival of business in the fall, and in a year from now the purchasing power of Europe may be enough improved to make the machine tool business in the United States about normal."

The keynote of many letters was the importance of using the present slack time to lay definite plans for the future—for improving the product so as to be ready for business when it resumes its full volume. Emphasis was laid on this, especially by men whose success in the machine tool field entitles them to more than ordinary attention:

"The present pause in the industry presents an excellent opportunity to make plans for the future. This is the time to bring equipment and methods up to date. The manufacturer who does this most effectually will have least cause for worry in the days of hard competition impending."

Definite opinions clearly expressed, straightforward advice, and practical suggestions—that is what the leaders in the machine tool industry gave to each other and to the industries in general in the symposium published in July and August MACHINERY. Manufacturing and selling problems must be solved, and the broad and candid exchange of ideas is now the most valuable form of cooperation in industry. This brief summary gives some of the salient points emphasized by responsible men now guiding their ships through the uncertain sea of business depression. The chief note is one of confidence and assurance.

"We all need a period of quietness in which we can check over our designs and our methods of manufacture. The machine tool builder who is not looking into the possibilities of specializing on some class of tools which will reduce the cost of production is losing a great opportunity."

"Increased production is obtained principally by or through efficient machine tools. Big opportunities are not far off for the machine tool builder who has a line of machines for intensive production, for when the tide turns it will be on greatly reduced cost."

"The manufacturer who makes a product of superior quality, and is prepared to give service, is going to reap a reward with the revival of business that is sure to come."

The reduction of production costs is the dominant thought in industry and will be in the years to come. It is also the dominant thought among the men who control in the machine tool industry. To quote from their letters:

"We believe that the words of Charles M. Schwab: 'Now is the time for the business-man to concentrate attention on the cost-sheet and not on the profit statement' should be given serious thought by every executive."

"The outstanding feature of the present machinery trade situation is the vital necessity for radical cost reduction."

"Cost cutting machinery and methods must be installed in both large and small shops of all industries in order that low production costs all along the line will permit of normal sales prices."

"A large number of concerns which manufacture in quantities are waking up to the fact that special machines and special tools will give them a much larger output per man-hour—sufficient to warrant the purchase of new and improved equipment."

"We are now entering upon a period of competitive production, in which the fittest to survive will be those who produce either better quality for a given price, or, by more efficient tooling, a satisfactory product at a lower price—or both."

The necessity for adequate publicity was touched upon by some of those who contributed to the symposium. Effective publicity is one of the sure factors of success, and has counted heavily with many of the leading manufacturers in the machine-building field:

"The very last asset a business man can dispense with, in these times of restoration, is his advertising program."

"The time to treat publicity matter as a side issue is past; and with a clear conception of the obstacles to be overcome, the results will more than justify the expenditure."

"Advertise and let the people know what you have, and do it now when they all have time to read your message. Don't do it with a splurge and then quit; you may quit just at the time when the man who wants your product has made up his mind to buy."

The quotations given are typical of the ideas expressed in most of the letters received. If space permitted, the number of extracts well worth repeating could easily be doubled. Every section of the country where tools and machine shop equipment are made was represented in this symposium. The selections sum up the conclusions for MACHINERY'S readers, and it will be interesting and doubtless stimulating to watch developments in the light of these authoritative opinions as to the Situation and the Outlook.

Instructions for Designing Fixtures

By H. P. LOSELY, Industrial Engineer, James E. Morrison Co., Detroit, Mich.

MANY tool-drafting departments make a practice of supplying checkers with instruction sheets enumerating all points on the finished design requiring checking. This is a good idea, but, why not give the instructions to the designer in the first place so that he may discover mistakes and omissions long before the drawings reach the checker? The instructions here presented have been compiled for the purpose of educating young designers of fixtures and reminding more experienced men of certain fundamentals which should be observed. These have been condensed into the seventeen major points shown in the accompanying list. The various points mentioned in the list will be dealt with more fully in the following, the same numerical order being maintained:

1. Examine the operation sheet to determine the condition of the piece prior to the operation for which the fixture is intended, and then draw the piece according to this actual condition. If the piece is unsymmetrical, take care to show it drawn to the correct "hand" and to scale; then check carefully before proceeding further with the design, as any errors in the scale of the drawing of the work, may cause the rejection of the whole design.

2. Pay attention to the condition of the surfaces or points from which the piece is located, and design the fixture to suit the tolerances allowed. If locating from a rough surface, design so that an adjustment can be made to suit the casting or forging. When locating from holes, note whether they are drilled or reamed and make the locating plugs to suit. If locating from rough- or finish-machined surfaces, note the limits allowed and consider the effect on the position of the piece.

3. Design the fixture so that the work can be readily inserted and removed, and leave ample clearance between the piece and any walls or other parts of the fixture. If the fixture is to be used much, do not hesitate at some extra expense in making the loading and unloading easier.

4. Make the clamping and supporting arrangements strong and stiff enough so that the pressure of the tool cannot move or distort the piece, and design the fixture so that it will withstand rough use.

5. See that the chips can get away from the cutting point without choking, and make the locating surfaces so that they can be readily cleaned before putting in the work. If cutting compound is to be used, it may be necessary to provide a retaining wall, and, if this is done, arrange so that the level of the wall will be at the right height, making an outlet at some point where the flow of compound will not be objectionable, or providing a pipe line to carry it back to the pump. In this case pay particular attention to avoiding pockets which will make it difficult to clean the fixture. If a retaining wall is not required and a heavy stream of compound is used, make an inclined surface or channel so that the stream will automatically wash the chips away.

6. All screws used in operating the fixture should have the same size of head so that one wrench will suffice for tightening the piece. If possible, avoid plain heads altogether and use wing-nuts, hand-knobs or plain heads with a heavy pin through them so that the screw can be tightened by a hammer-blow.

7. Make the operation of the fixture as simple as possible. Provide springs to bring clamps and levers back against the screws operating them; provide stops against which to run tools or open lids; use cams in preference to screws whenever practicable; and otherwise make the fixture so that the time consumed in changing the work is reduced to a minimum. On quantity production this is important, as the output of the machine may be greatly influenced thereby.

8. Avoid a complicated construction. While rapid operation is desired, frills are to be shunned, and any construction likely to get out of order or cause operating trouble, will never be acceptable to the shop. In any case, keep the cost of the fixture in proportion to the operation that is to be performed.

9. Look up the data of the machine on which the fixture is to be used and make the fixture to suit. See that operating clearance is provided, and that no interference with feed handles or the machine column exists. Check up the position of the tools and their range of action to see that the range of the machine feed is sufficient.

10. Make the base large enough for the fixture to be stable and free from any tendency to rock. Make the body, walls, and ribs heavy enough to insure rigidity, but do not make them excessively heavy, especially if the fixture is one which must be moved around.

11. If the fixture must be fastened to the table, provide ample facilities and such locating elements as keys in a milling fixture to fit the table slots, pads against which to set feeler gages, a machined circular surface to indicate the position of the faceplate fixture, etc.

12. Where a complicated casting would otherwise result, make separate brackets which can be screwed and doweled on the body. Remember, however, that the simplest bolting-

IMPORTANT POINTS IN FIXTURE DESIGN

1. Draw part to scale corresponding to latest blueprint and operation sheet.
2. Consider the condition of locating surfaces and the tolerances allowed.
3. Provide for the easy insertion and removal of work.
4. See that the piece will not be distorted by clamps or tool pressure.
5. Provide for the disposal of chips.
6. Do not require more than one wrench to operate the fixture.
7. Make a rapid-operating fixture.
8. Avoid a complicated construction.
9. Make the fixture to suit the machine.
10. Make a stable and rigid fixture.
11. Design to facilitate the set-up on the machine.
12. Make castings as simple as possible.
13. Use machine steel whenever it is economical.
14. Make sure that the tools can operate in the required position.
15. Picture mentally the whole operating process to see if all accessories are provided.
16. Use standard parts, castings, and stock material.
17. Consider the safety of the operator.

on job takes at least two hours' work in the tool-room to square up faces, drill, tap, and ream the required holes, and fit the screws and dowels, so that it does not pay to bolt on a separate piece to avoid one simple core. Wherever cores and loose pieces on the pattern can be avoided, choose the simple casting rather than the good-looking one.

13. Do not use a special casting for a piece which may readily be made from machine steel. On the other hand, if the making of a piece from machine steel entails a great amount of roughing out, it is better to make a pattern for producing a casting than to tie up a machine in the tool-room for a few hours.

14. Show the outlines of arbors, drill chucks, or any other small tools in the assembly drawing to make sure that there is no interference and that the distance from the table to the cutting point is within the range of the machine.

15. Consider the actual operation of the tools and fixture, and see that all accessories have been supplied. For instance, if support arms are required on a milling job, they should be shown in the assembly drawing, together with arbor collars and cutters. Furthermore, the list of tools to go with the set-up should be checked.

16. Use standard parts and castings whenever practicable, and when using machine or cold-rolled steel, consult the stock lists and design so as to utilize stock material with a minimum of machining. The designer should familiarize himself with the material carried in stock and listed in the drafting-room catalogue.

17. Have some consideration for the man operating the fixture. That the fixture should be designed so as not to endanger the operator goes without saying, although some designers neglect this point once in a while. On faceplate fixtures for a lathe or grinder particularly, do not omit a circular guard for covering any moving projections and provide against latches, etc., flying open. Supply ample clearance on all hand-knobs and levers so that the operator need not be particular in grasping them lest he scrape his knuckles.

* * *

TAXATION OF U. S. CITIZENS DOING BUSINESS ABROAD

The National Foreign Trade Council, India House, Hanover Square, New York City, has published a pamphlet entitled "The Unwisdom of Taxing the American Trader in Foreign Countries," containing an argument in favor of exempting Americans living and doing business abroad from taxes payable to the United States on income derived within the foreign country.

Citizens of the United States living and doing business in a foreign country are placed at a tremendous competitive disadvantage, because they are forced to pay to the United States a tax on income derived from their work and business in the foreign country. No country except the United States taxes its citizens living abroad on income derived from foreign sources.

It is true that the United States allows its citizens to credit against these taxes the total of all income and excess profits taxes paid to foreign countries upon income derived from sources therein, but this still places the American doing business abroad at a competitive disadvantage. On a business income of $500,000, the difference against the American trader, that is, the excess of taxes paid by him, may vary from $242,000 to $375,000. As an example, it is mentioned that there is a French concern in Manila handling American automobiles and tractors. In 1919 this company earned a net profit of $600,000 on which it paid a tax to the Philippine Government of $77,735, but paid no tax to the French Government. An American concern doing the same business in Manila would have to pay a total of $375,190 in taxes, or nearly $300,000—one-half of their net profit—in excess of what the French concern had to pay.

CONDITIONS IN THE GERMAN METAL INDUSTRY

Factories making the following lines of goods are reported to be well occupied: Locomotives, railway cars, shipbuilding, internal combustion engines, paper-making machinery, and woodworking machinery. All other industries are either working on stock or with reduced time. The iron and steel industry is in a critical position, and can sell only part of its production, in spite of the fact that it is short of raw materials, using in some cases cheap Spanish ores. By losing Lorraine and separating the Saar district from Germany, as well as separating Luxemburg from the customs union, Germany has lost 75 per cent of its ore supplies, 40 per cent of its blast furnaces, and 30 per cent of its steel and rolling mills. Prices have been cut 50 per cent without reducing wages, but it is stated that further reductions can be made only if the workers themselves voluntarily give up the legal eight-hour day. Up to the present time the workers have refused. On the first of April 887,000 men were reported out of work. A report issued by the Allgemeine Elektrizitäts Gesellschaft, covering plants employing 2000 officials and office people and 11,000 workmen, indicates that since 1913 wages, as expressed in marks, have been increased so that they are eight times what they were then.

News of the German Machine Tool Industry

Sondermann & Stier of Chemnitz have made an agreement with the machine tool works of Karl Wetzel of Gera and the Union Works of Chemnitz, according to which Sondermann & Stier will devote themselves entirely to boring and turning mills, and drop the manufacture of horizontal boring and milling machines, which latter line will be made a specialty of by the Union Works for machines up to a 3-inch diameter spindle, and by Karl Wetzel for machines with a spindle diameter of more than 3 inches. The three firms will also exchange all technical knowledge and experience with each other, have consolidated selling organizations, and will occupy a leading position in their branch of the machine tool industry.

Fritz Werner of Berlin-Marienfelde, employing at present 1000 men, is working exclusively on stock. The plant, however, is large enough to give employment to double the number or more. The foundries of these works have a daily capacity for 30 tons, all of which is not machine tool castings. The Fritz Werner Works are now manufacturing a large vertical milling machine. The Ludwig Loewe Co. reported for last year a net profit of 4,860,000 marks, and paid a dividend of 21 per cent. This company is now working exclusively on stock.

Very interesting tests are being carried out by the Berliner Präzisionswerke with the use of liquid air in relieving the internal stresses of tools, gages, and measuring instruments. It is said that the firm has obtained good results by chilling the material from which the tools are made to 80 degrees C. below zero.

Some interesting news comes from Austria. A prominent German leader in the iron and steel field has acquired an important interest in one of the large Austrian iron and steel works, which before the war produced 600,000 tons of pig iron and 500,000 tons of steel annually. Coke will be supplied from Germany, and it is expected that this transaction will mean a turning point in the whole Austrian iron and steel industry.

It may be of interest to note the varied lines of business to which the large number of German airplane manufacturers have turned. Taking ten of the leading of these manufacturers we find that they have entered such fields as the making of motor boats, electric railways, elevators, traveling cranes, locomotive and car repairs, bedsteads, milk separators, bicycle rims, driving motors for bicycles, motorcycles, agricultural machinery, domestic electrical apparatus, and furniture.

AMERICAN GEAR MANUFACTURERS' INSPECTION STANDARDS

At the annual meeting of the American Gear Manufacturers' Association, the following inspection standards were adopted as recommended practice:

Cylindrical Holes

Cylindrical holes up to 3 inches in diameter should be inspected with "Go" and "Not Go" plug gages, the diameter of the "Go" end being the same as the smaller limit specified on the customer's drawing, and that of the "Not Go" end, the same as the larger limit given. For holes between 3 and 12 inches in diameter, the gage should consist of two bars placed approximately at right angles to each other and held together by a handle, pressed through a hole in the middle of each bar. One bar should be made to the "Go" dimension and the other to the "Not Go" dimension. The length of the handle and the question as to whether the bars should be placed close together or at opposite ends of the handle will depend upon the nature of the work and principally upon the length of the hole. Holes larger than 12 inches in diameter should be inspected by means of measuring rods, inside micrometers set to vernier calipers, or a standard measuring machine. Gages should not be used after their wear has exceeded the limits on a customer's drawing.

Tapered Holes

Tapered holes should be inspected by means of taper plug gages, the quality of fit being determined by lightly coating the gage with red lead or Prussian blue. A full bearing should be shown. The proper depth of reaming or grinding of the hole should be indicated by means of a stepped shoulder located at either end of the plug, as the case may require, the height of the step and the relationship to the taper, agreeing with the limits specified on the customer's drawing.

Keyways in Holes

Single and multiple keyways in straight and tapered holes should be inspected for width by using "Go" and "Not Go" flat limit gages. For alignment and depth, a plug gage should be employed, the body diameter of which is the small limit of the hole and which has a key or keys, as the case may be, long enough to reach the entire length of the keyway. The width and height of the key gage should agree with the low limit specified. If the maximum depth is important, a similar gage should be used as a "Not Go" gage. This gage should have a key height equal to the maximum dimension given on the customer's drawing.

All keyways for Woodruff keys should be inspected by using a hardened gage similar in shape to the Woodruff key used, but slightly thinner than standard. A keyseated ring gage should be slipped over the key when the latter has been placed in the keyway. Two keyseats may be put in the ring gage to agree with the depth limits on the customer's drawing. For width of keyway, a "Go" and "Not Go" flat limit gage should be used, the dimensions of both ends of which should agree with the limits specified.

Shafts

Splined shafts should be checked for width of spline and root and outside diameters by "Go" and "Not Go" snap gages made to the dimensions given on the customer's drawing or with micrometers set to the same dimensions. For accuracy of spacing, a ring gage should be employed, which should have one portion of the hole ground to the minimum diameter of the keyways of the mating member, an annular portion at one end with a diameter of hole equal to the maximum diameter of the shaft body, and should be milled and ground away so as to obtain projections the cross-sectional dimensions of which will be the same as the minimum space allowed between the keys.

Inspection Standards for Shifter Grooves

Shifter grooves should be inspected for diameter by using a "Go" and "Not Go" snap gage, slightly thinner than the width of the groove and made to the dimensions specified on the customer's drawing. Shifter grooves may also be inspected by means of a micrometer. If a fillet is required at the bottom of the groove, a similar allowance plus a small amount for clearance, should be provided in the snap gage. A "Go" and "Not Go" flat limit gage, made to the limits specified on the customer's drawing, should be used for testing the groove width.

Small Sizes of Spur, Spiral, and Internal Gears

Small sizes of spur, spiral, and internal gears should be inspected on hand fixtures for pitch diameter, eccentricity, and irregularity of teeth. The fixture should be rigid in construction and have one stationary and one freely sliding head, the latter being so arranged that its movements will actuate a dial indicator. It is preferable to use a hardened and ground master gear of proved accuracy. The studs on which the work and master gear are mounted should be at right angles with the surface on which the sliding head moves and parallel with each other within 0.002 inch in a length of 12 inches. The diameter of the work stud should not be smaller than the low limit of the plug gage used in testing the hole in the work, while the stud for the master gear should be about twenty-five hundred-thousandths inch less in diameter than its hole. This fixture may also be used for determining the quality of tooth bearing.

For the determination of noise, a power-driven fixture should be resorted to, the requirements of which should be the same as for the hand fixture, except that it should be possible for one spindle to be rotated in either direction and the other spindle should be provided with a brake. No indicator should be furnished, and the movable head should be controlled by an adjustable screw having a micrometer collar. A clamping screw should be provided for locking the movable head. Master gears of 6 diametral pitch and finer should be true within an eccentricity tolerance of 0.001 inch. In disputes concerning eccentricity when master gears of proved accuracy are not available, a hardened gear with teeth cut away so as to have but one tooth in engagement at a time may be used by rolling it through the arc of contact and then ratcheting to the next tooth to be inspected.

Bevel Gears

Bevel gears should be inspected on hand or power-driven fixtures for quality, and on reversible power-driven fixtures equipped with brakes for noise. These fixtures should also be rigid in construction, and the belt pull should be downward rather than upward so as to seat the movable head, rather than to pull it away from the bearing surfaces. The spindles should lie in the same plane and be at right angles to each other within an error of 0.002 inch in 12 inches. With straight-tooth bevel gears, conical pointers may be used to ascertain whether the teeth are radial or not. The foregoing applies to such gears as are used in automotive constructions and not to the larger mill gearing.

Questions of tooth bearing should not be determined in the final assembly in case of dispute, but by inspection on proper test fixtures. The holes in collets or bushings for holding stem gears should be equal to the maximum shaft limit plus the smallest allowance which will permit the stem to be entered. A satisfactory way of testing the backlash of gears is by the use of standard feelers. The backlash of an individual gear may be determined by substituting a master gear of standard thickness of tooth and pitch diameter in place of the mating gear.

Other standards and recommended practices adopted at the annual meeting of the American Gear Manufacturers' Association will be published in coming numbers of MACHINERY. The association is doing a very valuable work along standardization lines.

LONG AND SHORT ADDENDUM BEVEL GEAR TEETH

Tables giving the proportions of 14½-degree teeth for long and short addendum bevel and spiral-bevel gears of ratios between 3 to 1 and 8 to 1, were presented at the recent annual meeting of the American Gear Manufacturers' Association by the bevel and spiral-bevel committee of the organization, and were adopted as recommended practice. These tables are given herewith, together with a description of the manner in which the values were arrived at. Long and short addendum bevel gear teeth are treated in the same manner as similar spur gear teeth, with the exception

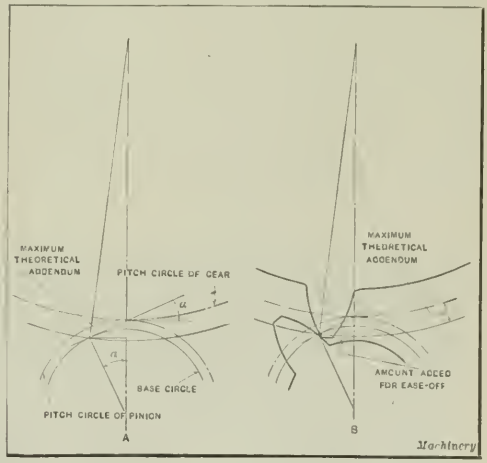
gear beyond the base circle of the pinion at the beginning and end of the theoretical arc of action is useless so far as tooth action is concerned. The first problem is to find the gear addendum which at the beginning of the arc of approach extends to the base circle of the pinion. This is known as the "maximum theoretical addendum." Values for this addendum to suit various ratios and for 14½- and 20-degree pressure angles are given in Table 1; these values were obtained by calculating the opposite side of the smaller of the two triangles of which *a* is the acute angle. The values given are for gears of 1 diametral pitch, and for any other diametral pitch they must be divided by it. Examination of the table will show that the values between ratios 3 to 1 and 8 to 1 do not change greatly, and for the sake of simplicity in preparing the tooth proportion tables, it will be assumed that there is no difference.

Table 2 gives the dimensions for 14½-degree plain bevel gear teeth. The addendum in each case has been obtained



Diagrams used in determining the Proportions of the Gear Tooth

by adding a certain percentage to the maximum theoretical addendum to provide an "ease-off." The view at *B* in the illustration shows graphically that unless this percentage is added, the tooth load on the gear at the beginning of the approach will lie along the very top of the tooth, which is a condition to be avoided. The circular thickness, that is, the thickness of the tooth measured along the pitch circle, was in each case obtained from a lay-out giving consideration not only to the strength of the tooth, but also to the width of the top. The tooth widths are sufficient to prevent a complete carburization, and consequent brittleness, in casehardening.

The values given in Table 2 are also for gears of 1 diametral pitch, and must be divided by the diametral pitch of the gears being proportioned. No table has been compiled for gears of 20-degree pressure angles, as the standard proportions, where the addendum is one-half the working depth, have proved satisfactory when the number of teeth in the pinion is not less than twelve. For ratios below 3 to 1, the percentages of change are so great, as shown in Table 1, that a lengthy table would be required to cover properly the proportions of gears of these ratios.

Table 3 gives the tooth proportions of 14½-degree spiral-bevel gears of ratios between 3 to 1 and 8 to 1, this table being also for gears of 1 diametral pitch. The values were obtained in the same manner as for plain bevel gears, with two modifications—the working depth of spiral-bevel teeth is 85 per cent that of plain bevel teeth, which are of standard depth, and the bottom clearance is 0.07 times the circular pitch instead of the usual standard of 0.05 times the circular pitch.

* * *

GREATER EFFICIENCY NEEDED IN RAILROAD OPERATION

If there is to be an early revival of industrial activity, the transportation system of the country must be placed in a position to obtain the same efficiency in operation as any manufacturer running his own plant. Only by so doing will it be possible for the railroads to reduce fares and rates; and such a reduction is necessary if we are again to have real industrial prosperity. In view of this situation the National Founders Association, in common with many other groups of manufacturers in the United States, recommends and urges that the agreements made during Federal control by the Railroad Administration be completely abolished. The Labor Board has ordered the cancellation of these restrictive rules, but has ordered the railroads to make new agreements with various union crafts. Leaders of these organizations are demanding that the new agreements be practically identical with the ones made during government control. Refusal of the railroads to perpetuate all these rules—which it is estimated cost the transportation interests of the country more than $300,000,000 annually—means that the Labor Board will be called upon to decide the question, so that there is danger, unless a firm stand is taken, that conditions such as prevailed during government control will be made perpetual.

It is further urged that jurisdiction over questions of wages, classifications, and working conditions be restricted to the individual railroad administration. Rules and regulations made by the Government during Federal control, continued in effect by the Labor Board, have standardized wages and rules on all railroads without regard to living conditions in particular communities or the rates of pay of employes of other industries doing similar work in these communities. Workers should be paid according to the service they perform, as they were before the Government took over the railroads.

It is also demanded that Congress immediately repeal the Adamson Law, passed under duress and unquestionably one of the most hampering pieces of legislation affecting a legitimate industry ever enacted at Washington. The Adamson Act was not really a law governing hours of labor, but was essentially a wage measure, sought by the union leaders as a way to increase the pay of certain classes of railroad employes. To repeal it would enable the railroads of the United States to save enormous sums annually without impairing their service or doing an injustice to any employe.

* * *

The total export trade of the United States to India increased 147 per cent in value from 1918 to 1920. The value of the metal-working machinery exported in 1918 was $1,251,662 and $1,374,068 in 1920.

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, August 11

There has been but little change in the industrial conditions during the last month. A slight improvement is noticeable in the automobile field, which is somewhat more active as a result of the reduction in the price of gasoline in France. The Renault plant is now producing 800 cars a month. A year ago 1200 cars a month were built, but the present output is considered satisfactory, as the firm is devoting part of its facilities to other branches of metal manufacture.

In the shipbuilding industry conditions are not as good as they were a year ago. One of the yards in the Loire-Inférieure district, established about a year and a half ago, has been closed down. The steel mills are still reducing the prices of materials. It was thought some time ago that the minimum had been reached, but that was not the case. A reduction of 20 per cent in the price of iron and steel is expected in Belgium in the near future. The German and Luxemburg metal manufacturers have made a further reduction in the price of steel bars.

As an indication of the price reductions, it may be mentioned that pig iron which was quoted last year at 650 francs (present exchange, $50.70) a ton, is at present marketed at 200 francs ($15.60) a ton, and a further reduction in price is expected. One of the steel companies is said to have sold pig iron as low as 150 francs ($11.70) a ton. In spite of these great reductions, there is but a small market, and furnaces are continually being closed down in the various iron and steel districts.

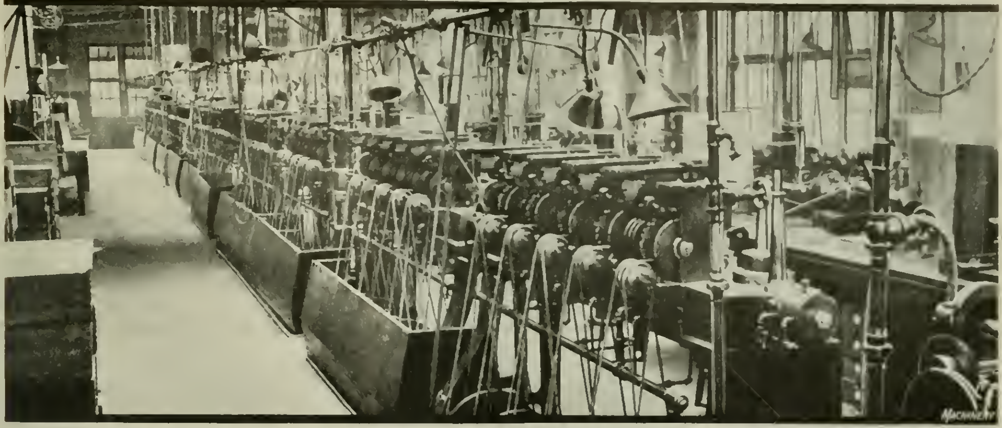
New Tariff Regulations

Early in July new tariff regulations were officially published. A general revision of the tariff rates will be made during the first three months of 1922, and the present rates quoted below are therefore only temporary. The rates published in the article entitled, "New French Tariff on Machine Tools" in June MACHINERY should be multiplied by the following coefficients: machine tools, 3.3; precision instruments, measuring instruments, and drawing instruments, 3; threading tools, turning, boring, and planing tools, and milling cutters, 3; vises, 4; drill chucks and drills, 4; wire-drawing dies, 4; files, 3.2; saws, 5; abrasives in pulverized form, 2.8; abrasive wheels, paper, and cloth, 2.7.

By employing coefficients that can be easily stated in this manner, an actual change in the figures designating the amount of the tariff in francs is avoided, the coefficient only being changed.

Labor Conditions

Although there has been no disturbances among the workers, the reductions in wage that have recently taken place in all the industries have not been accepted without protest. It is possible that the reductions have not been considered carefully enough in comparison with the actual reduction in the cost of living, and it is likely that with a return to normal industrial conditions some adjustments will have to be made again. The labor cost at the present moment is the principal production cost, amounting to a great deal more than the cost of materials. Hence, while six months ago the labor cost was one-sixth of the selling price, at present in many cases of manufactured metal goods, on account of decreases in prices, the labor cost has increased to one-third of the selling price. The Societe Alsacienne de Constructions Mecaniques at Grafenstaden, an important machine tool manufacturing concern, has closed its doors, as the men refused to accept a reduction of 20 per cent in wages; as a result, 2000 men are idle. In general, the principal metal-working concerns have reduced wages about ten per cent, in addition to the ten per cent reduction effected about three months ago.



Automatic Machines in a Watch Factory

Machines, Devices, and Methods Employed in the Plant of the Waltham Watch Co., Waltham, Mass.—Second of a Series of Articles

IN the first article in this series, published in August MACHINERY, automatic surfacing and drilling machines used in the manufacture of plates for watches were described, as well as a duplex type taper-turning and taper-boring machine. In the present article, additional types of automatic machines are illustrated and described.

Automatic Plate Recessing Machine

A seven-spindle automatic machine employed for producing the recesses in which the various watch wheels are set in pillar plates, barrel bridges, etc., is shown in Fig. 8. The work on which this machine is shown engaged is that of recessing barrel bridges. The shape of one of these parts may be seen at the end of the feed magazine *A*, and also at *B* in the assembly view of a watch, Fig. 1 of the first installment of this article. The eight carrier arms *B*, Fig. 8, are swung from left to right to position the work in the chucks, by an air-operated shaft which extends lengthwise beneath the machine, and which has rack teeth cut in it at intervals. The arms are oscillated by their gear connection to this rack shaft, the general construction being similar to that mentioned in August MACHINERY in the description of the plate roughing machine. Circular tools are used, which are mounted in tool-blocks supported on compound slides. The two slides *C* and *D* operate at right angles to each other, being actuated by levers *E* and *F*. Cams *G* control the lateral feed of the lower slide and the longitudinal or radial feed of the upper slide.

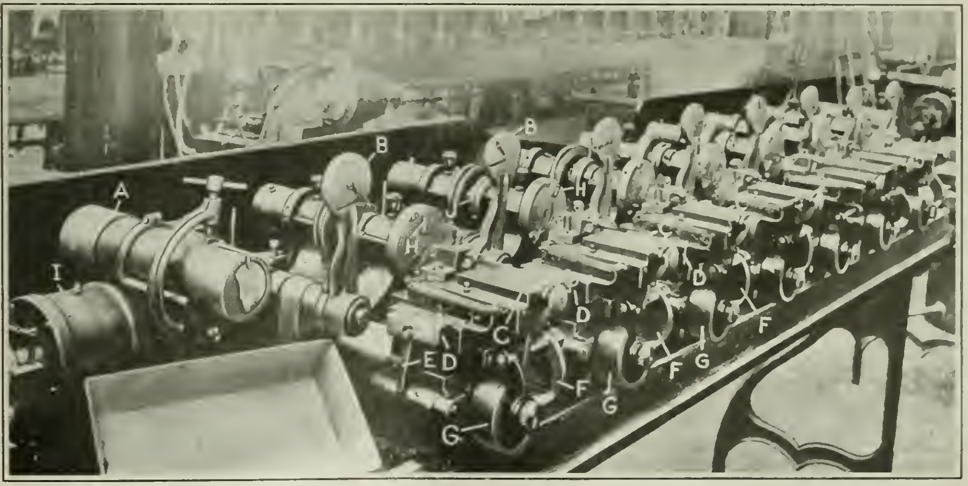


Fig. 8. Automatic Multiple-spindle Watch-plate Recessing Machine

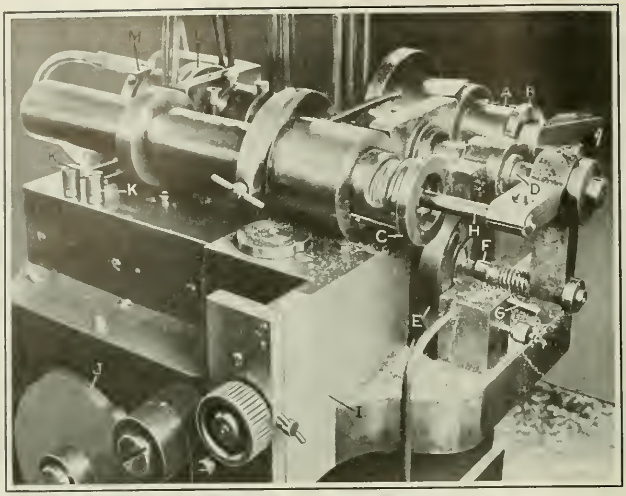

Fig. 9. Automatic Machine with Magazine Feed for turning the Rims of Watch Plates

When pillar plates are to be recessed, they are located in the chucks by dowel-pins, which engage the dial foot holes in the work. Incidentally, these three holes are used as a locating means in all operations performed on the pillar plates, if possible. The chuck is provided with spring jaws *H* for holding the barrel bridges, and obviously it is necessary to stop each spindle while being loaded from the carrier arms, in exactly the same position, so that the work will be located properly in the jaws. The abrupt stopping of rotation and the positioning of the spindles in the same angular relation to the work are accomplished by the operation of the air countershaft in conjunction with a one-tooth ratchet wheel and pawl. This ratchet wheel is located in front of the pulley and can be barely seen at *J*. As soon as the air which controls the direction of rotation is released and air is admitted to the opposite side of the countershaft pulley, the spindle is quickly stopped and reversed until the pawl which engages the ratchet tooth is dropped into place. The pawls are positively operated by the action of a cam.

The work passes from spindle to spindle for performing the various recessing operations, until it is finally delivered to the magazine at the opposite end of the machine. The work in the feed magazine is forced against spring jaws by air pressure, and these jaws are released by being forced radially outward when correspondingly located jaws on the carrier arms are brought into contact with them. The air then deposits the work into the carrier arm. After they have been swung into position in front of the spindles, the carrier arms are fed backward slightly, causing the hinged jaws *H* of the chucks to fulcrum and close over the periphery of the work and firmly clamp it in position.

The operations performed on a pillar plate are turning the recesses for the hour wheel and cannon pinion with tools mounted in the first tool-block; machining the intersect-wheel cap recess and its clearance with one tool at the second station; cutting the minute wheel seat at the third station; producing the recess for the third wheel at the fourth station; turning the recess for the minute pinion at the fifth station; machining the clearance for the minute pinion recess at the sixth station; and cutting the dial recess at the seventh station. The air cylinder through which the shaft that operates the carrier arms extends is shown at *I*, and the shaft carries a suitable stop arrangement at the end for placing the arms in a neutral position, this being the vertical position in which the carrier arms are shown in the illustration. The carrier arms occupy this neutral position after they have received the work from the station at the left of each arm, and remain in readiness to swing to the right, this movement occurring immediately after an operation has been completed and the work is ready to be passed to the next station.

Plate Rim Turning Machine

The machine shown in Fig. 9 turns the recess in the pillar plate in which the dial is located. Magazine *A* at the rear of the machine feeds the work into holder *B* by air pressure from within, and after being located in the holder it is held securely by three spring jaws. This holder and holder *C* are carried by a double carrier arm which rotates on shaft *D* to bring the work into position in front of the centrifugal three-jaw chuck *E*, from which position it is forced into the chuck by the spring plunger *F*. The tool *G* is then fed in to the proper depth, and the slide on which the tool-block is mounted is fed in radially to complete the recess or cup-section for the dial. The work is next picked up by holder *C*, which has previously swung into position, and transferred to the magazine where the finished work is deposited. The plates are forced from holder *C* by pin *H*, which is moved axially with shaft *D*. Both the pin and the spring plunger are carried by a two-arm casting attached to this shaft. As soon as the shaft is reciprocated outward, the carrier arm is again in readiness to oscillate 90 degrees and briug another piece in holder *B* into alignment with the centrifugal chuck.

The 90-degree movement of the carrier arm is obtained by a four-notch ratchet wheel, these notches being successively engaged by a spring-operated pawl which is disengaged by an air-operated piston-rod. The ratchet wheel is attached to shaft *D*, which is belt-driven, so that as the pawl is disengaged and a 90-degree turn of the shaft occurs,

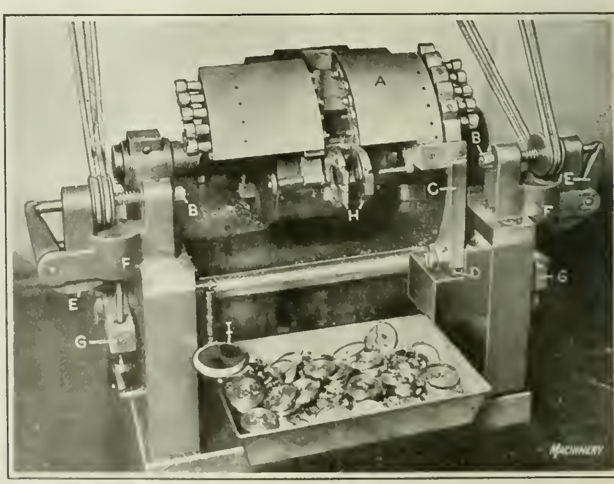

Fig. 10. Multiple Opposed-spindle Reboring or Uprighting Machine

the pawl will spring back into engagement and hold the shaft while the cut is being taken on the work. During this period the belt which drives the shaft and ratchet slips on pulleys *L*.

The cross-feed for the tool-slide *I* is actuated by cam *J* at the front of the machine, which controls the movement of a lever arm that transmits the motion to the slide. This lever has a ball-end which fits in a socket in the slide, allowing universal connection with the lever, which is required in producing the feed movement. The slide is returned to its normal position by the application of air. Shaft *D*, which slides but does not revolve, is guided at its rear end by a slotted finger *M* attached to it extending down with the slot riding over a square key. The knob shown at the front of the cross-slide is used to adjust the crosswise position of the slide when setting up the machine.

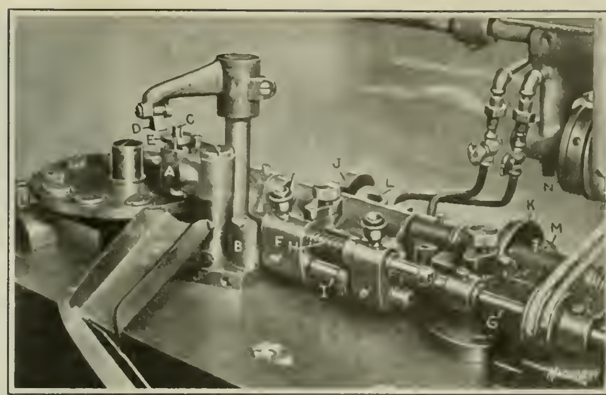

Fig. 11. Air-controlled Boring and Milling Machine for machining Clutch Clearance in Barrel Bridges

In some of the machines to be described, air tubes are provided of the type shown at *K*, for the direct application of compressed air to operative parts. In certain designs of machines it is often necessary to drill air channels through solid castings and direct the flow of air, in the manner most convenient, to the desired point. This method of utilizing compressed air in the operation of machines is novel and peculiar to those found in the Waltham Watch Co.'s factory, and it is this feature especially, rather than the cam-operated valve lever construction, to which attention is directed.

Uprighting Machine

The bench machine illustrated in Fig. 10 contains five pairs of opposed work-spindles which operate on opposite sides of the movement plates to bore the previously drilled holes in which the train wheel bearings are staked. This method insures that the holes will be absolutely normal with respect to each face of the plate. The spindles are carried in a swinging arm *A*, which is operated by a rack and pinion at the rear of the machine. This rack operates vertically by air pressure, swinging the spindle arm downward to bring the spindles successively into alignment with the driver at *B* at each end of the machine. The spindles are locked in the several operating positions by pawl *C* engaging with notches on the spindle arm. The pawl is operated by pin *D*, which is forced against the heel of the pawl by air pressure.

The driver spindles *B* are belted to an air-operated countershaft and are advanced axially to bring the clutch on each driver into successive engagement with the spindles, by means of a fulcrum lever *E* at each end of the machine. These two levers force the drivers forward when their lower ends are acted upon by air. The air cylinders are shown at *F*, and the application of air results in swinging the opposite ends of levers *G* into engagement with a feed-cam carried on the camshaft and located outside the frame at each end of the machine. The feed-cams, after each operation, permit the release of the driver clutch, this action being synchronized with the indexing movement of the spindle arm as it is swung downward by the rack-and-pinion construction previously mentioned.

The watch movement plates (which consist of the pillar plate with the various top plates assembled) are placed in a recess in one of the holders *H*, after which the two holders are brought together by air pressure and held in a vertical plane relative to the axis of the tools. After the various machining operations are completed, the work is ejected by a spring plunger shown to the left of one holder. This machine is semi-automatic, it being necessary after loading each piece by hand to depress the pedal *I* which engages a friction clutch connected with the driving gear on the camshaft of the machine. A quantity of these plates showing the number of holes that they contain may be seen in the foreground of the illustration.

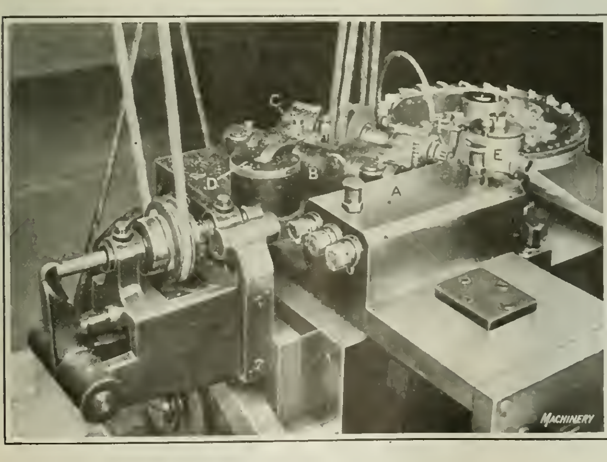

Fig. 12. Machine for centering, drilling, and tapping the Hole for the Hair-spring Stud in a Balance Cock

Dome Turning Machine

The operation performed on the machine illustrated in Fig. 13 consists of turning the diameter of the balance cock dome with an angular under-cut and boring a hole through the center, at a single setting. This insures concentricity between the hole and the turned circumference of the dome. The regulator arm is attached to this dome in the construction of a watch. This operation is performed after the plates have been assembled to the pillar plate, as shown at *A*. The assembled unit is located on the chuck *B* by spring jaws of the regular type, the location being such that a spacer bar *C* may be advanced to act as a support under the balance cock. This is a necessary provision because the unsupported end of the balance cock would not present a rigid enough surface to permit the operations to be performed with the required degree of accuracy. The air cylinder which operates this spacer bar is located at *D*.

The special feature of this machine is the means provided for readjusting the vertical height of the turning tool for each piece of work. An air-operated rack swings the spindle arm *E* to the right until spindle *F* is in alignment with the driver *G*. Spindle *F* is a locating spindle only, and is used for establishing the vertical height of the turning tool *H*. This setting is accomplished by feeding the driver *G* against the end of spindle *F*, which results in pushing the locating spindle down against the work and causing the yoke *I* to be raised or lowered slightly, in which new position the yoke spindle is locked in its bearing by an air-operated clamping device that binds a split collar *K* to the yoke shaft.

The feed mechanism is connected by a universal joint to the rear end of the fulcrum lever *J*, and as soon as the yoke shaft has been locked, the spindle arm is located in a new vertical position, from which the depth of cut employed in turning the dome is re-established. As soon as this height has been predetermined, the driver is raised and the spindle arm swung to bring the second or turning spindle into the operative position. At the completion of the turning operation, the spindle arm is again swung and the third or boring spindle is employed to machine the hole concentric with the turned dome.

The mechanism for actuating the feed is contained within the box casting which forms the base of the machine. It consists of an air plunger which actuates a bellcrank lever, bringing one end of the lever against the feed-cam; this air-actuated movement then permits the feed-cam to operate lever *J* and advance the cutting tools. This arrangement is known as a "permitted feed" movement. The tools are periodically set to the proper height in the carrier arm by a master gage of the disk type. This machine produces at the rate of 400 balance cocks per hour.

Balance Cock Drilling and Milling Machine

The automatic special-purpose machine shown in Fig. 12 centers, drills, and taps the hole for the hair-spring stud in balance cocks, and also mills a portion of the lug in which

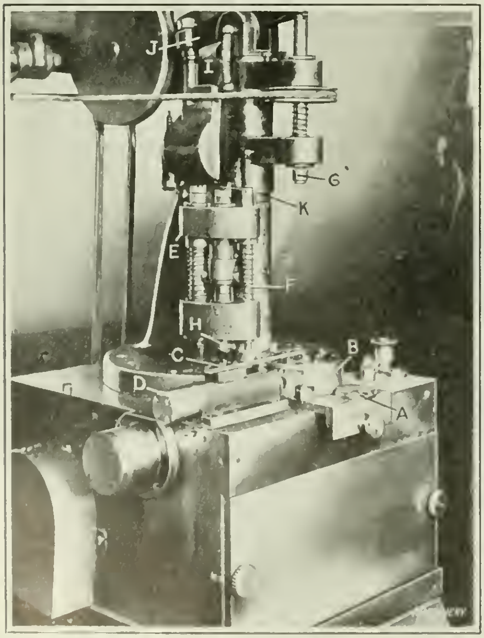

Fig. 13. Machine used for turning and boring the Dome on Balance Cocks

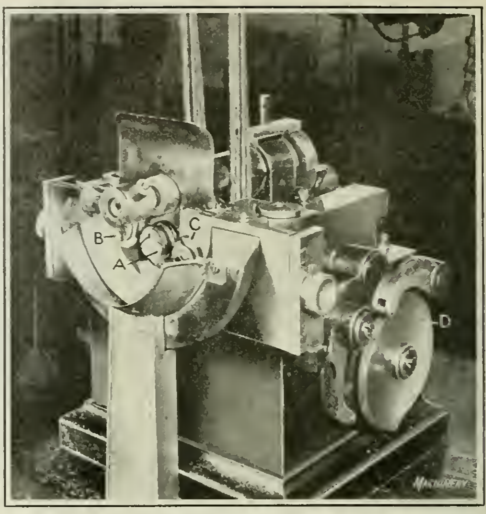

Fig. 14. Turning Plates to fit the Watch Case after assembling

this hole is machined. The balance cocks are located by pins on a turret which is revolved intermittently by a mechanism controlled by the work-carrier head *E*. This mechanism is contained within the machine frame and operates as soon as the spindles have finished working. The carrier spindle, as it revolves when another piece of work is to be picked up, trips a finger on the turret post within the machine, and this finger or lug carries a pawl which turns the turret by engaging a ratchet wheel also mounted on the turret stud. The work is picked up and swung into position and held thus during the several operations. The opening and closing of the jaw which is on the under side of the carrier head, is accomplished by a small pin extending vertically through the head, which is operated to contact with the end of the jaw by an air plunger actuated by a cam within the machine. When the work is being picked up, this plunger is depressed. A similar carrier head is illustrated at *A*, Fig. 11.

The three spindles of the machine are clutch-driven, and provided with a "permitted feed," the general construction being similar to that already described in connection with other machines in this series of articles. The feed-cam in this particular instance, however, has been designed to furnish a relief motion for the drill, but in other respects the mechanism is not radically different from the others. The tools, which project from the further end of the spindle-block *A*, are provided with three stop-pins for limiting the depth of cut, and when the slide moves crosswise to bring each spindle in alignment with the driver, an arm on the frame of the machine is swung over to act as a locating abutment for these stops.

The rear end of the cross-slide carries the swinging bracket *B* in which the milling spindle *C* has its bearing. This spindle is belt-driven and has a "permitted" radial feed movement which functions as follows: As soon as the three spindles have completed their work and the slide has advanced the milling cutter *F* into position for taking its cut, the projecting end of a lever attached to the camshaft of the machine is forced up by cam action and raises a stop-pin until it bears on the under side of bracket *B*, and acts as a steadier for the cutter during its downward feeding movement. The air cylinder *D* then causes the bracket to swing downward, thus feeding the cutter through the work.

A device for automatically stopping the machine if breakage of the drill or tap occurs is included in this machine equipment, and is located at the further end of the machine. There is a contactor, or piece of flat steel, against which the tools bear one at a time as the slide is fed forward to the next operative position. As long as contact exists between the tool which has just finished operating and the contactor, a steel magnet at the opposite end of the machine will act on the free end of a flat finger which is regularly reciprocated under it by cam action. As long as the tools continue to contact, the magnet will draw this lever up and over the trip which operates the air valve for shutting off the air to the countershaft. If the tools fail to contact, however, there will be no magnetism in the steel piece and the reciprocating finger will be permitted to trip the air valve and immediately stop the machine. The cam that reciprocates this flat finger is attached to the end of the regular camshaft of the machine.

Boring and Milling Machine for Clutch Clearance on Barrel Bridges

A machine for milling the winding pinion clearance and for boring the clutch clearance on barrel bridges is illustrated in Fig. 11. The work is loaded and located by pins on the turret of the machine. The work-carrier head *A* is swung from the position in which it is shown, to the right, until it is in a position to locate the work on block *B*. This movement is accomplished through the medium of an air cylinder on the left-hand end of the machine having a plunger on which teeth are cut to engage a segment gear and operate the take-up and retainer pawls. The work is picked up and held by the jaws in the carrier head, and is deposited on block *B* and held in this position until the machining of the work has been finished. The carrier head, with the work, then swings backward to the left, and when it reaches its foremost position a step on the vertical stud *C* is depressed by the swinging triangular trip *D*, past which the stud cannot travel without being depressed. Depressing this stud causes the collar *E* to force down the pivoted jaws by means of which the work is held on the under side of the head, opening them and allowing the work to drop into a chute.

The spindle arm *F* carries two spindles, one for each operation, and these are driven by a clutch on the driver *G*. A "permitted" cam-feed motion is incorporated in this machine, the construction of which has previously been described. This spindle arm may be held stationary as required in the boring operation, or may be fed both independently of the driver when indexing the tools and with the driver when performing the milling operation. This is the special feature of this machine to which attention is directed.

The boring spindle is shown at *H*, and after the hole has been bored, arm *F* is swung upward by a combined cam and compressed-air movement, and the driver clutch brought into engagement with the milling spindle *I*. In this position finger *J* has swung downward into contact with the end of the air-cylinder piston; also finger *K* at this part of the movement is in contact with the piston of another air cylinder. The pistons in these two air cylinders *L* and *M* are operated in unison during the milling operation, and permit both the milling spindle and the driver to feed upward a distance of about 3/8 inch, which is the required amount for producing the clutch clearance on the work.

The spindle arm is returned to the position shown in the illustration by means of a spring, after which the work is picked up and deposited in a chute as previously described. The machine is driven from a worm and worm-wheel, by means of a camshaft which extends through the machine and carries the cams for operating the various air valves and the feed-cam for the spindles. The air countershaft is shown at *N*.

Plate Diameter Turning Machine

After the barrel bridge, pillar plate, and balance cock have been assembled to the pillar plate as shown at *A*, Fig. 14, the diameters of the assembled unit are turned on the bench machine shown in this illustration. Circular tools *B* and *C*, mounted on each side of the work-holding chuck, are employed, the slide on which these tools are mounted being reciprocated to bring the tools alternately into operation. There are four diameters turned with the two tools shown, and the feed movement is "permitted" by the use of compressed air, and is actuated by the cam *D* shown at the right-hand end of the machine. Provision is also made, by the application of springs and compressed air, for moving the work-holding chuck transversely so that the same tools may be used to turn two other diameters.

The third installment of this series of articles will be published in October MACHINERY, and will contain a description of an automatic watch pinion making machine, a wheel opening or reboring machine, and automatic machines for cutting teeth in steel wheels and for numbering watch plates, concluding with a description of the process and machine used for finishing the convex heads of watch screws.

METAL FATIGUE UNDER REPEATED STRESSES

The development of the internal combustion engine, the steam turbine, the automobile, and the airplane has made the study of the fatigue of metals of increasing importance. Much information relating to this subject was given in a paper by H. F. Moore and J. B. Kommers, recently read before the American Iron and Steel Institute. The failure of machine parts under repeated stress has come to be commonly spoken of as due to "fatigue" of the metal. The cause of such failure was at one time thought to be the "crystallization" of the metal. In the paper referred to, it is shown that the phenomenon is one of a breaking up of crystals rather than of their formation.

RESULTS OF STRESS TESTS

Part of Structure or Machine	Approx. No. of Repetitions of Stress in the Life of the Structure or Machine
Railroad bridge, chord members.....	2,000,000
Elevated railroad structure, floor beams	40,000,000
Railroad rail, locomotive wheel loads..	500,000
Railroad rail, car-wheel loads........	15,000,000
Airplane engine crankshaft..........	18,000,000
Car axles	50,000,000
Automobile engine crankshaft........	120,000,000
Lineshafting in shops................	360,000,000
Steam engine, piston-rods, connecting-rods and crankshafts..............	1,000,000,000
Steam turbine shafts, bending stresses	15,000,000,000
Steam turbine blades................	250,000,000,000

Machinery

The accompanying table, which gives some idea of the number of repetitions of stress in the normal life of various structural and machine members, was prepared from the data supplied in the paper referred to.

* * *

According to a recent Commerce Report, there was a total of sixty-seven foreign steamship lines maintaining regular routes from Hamburg, Germany, to the principal countries of the world, at the beginning of 1921. Among this number were represented several flags which seldom, if ever, had been seen in that port before the war. The nationalities represented, together with the number of lines of each, were as follows: English, 22; Dutch, 11; Norwegian, 6; French, 5; Belgian, 4; Italian, 3; Swedish, 3; American, 2; Danish, 2; and Japanese, 2. The remaining seven lines were of various nationalities.

Group of Brown & Sharpe Employes, consisting of Twelve Nationalities, being assisted in filling out Citizenship Papers

Industrial Americanization

Policy of the Brown & Sharpe Mfg. Co. in Assisting Alien Employes to Become American Citizens

By LUTHER D. BURLINGAME, Industrial Superintendent, Brown & Sharpe Mfg. Co., Providence, R. I.

WHILE Americanization work among the children through the public schools must be looked to as the most important means of assimilating the many peoples of as many ideals who come to our shores, it is believed that the adults in our industries must not be neglected, either in the matter of language, customs, or in the ideals of American institutions and government, if we are to reap the benefits and avoid the dangers resulting from promiscuous immigration. Various methods have been tried to reach and influence adults coming from foreign countries, but with only partial success, and in many cases with admitted failure. Even though free opportunities for instruction and guidance are offered and the way is made easy, it is the exception rather than the rule for such adults to take advantage of the opportunities that are offered, and it requires watchfulness and sometimes drastic action to keep their children in school until they reach the minimum age limit.

To stimulate an interest in school attendance on the part of adult aliens, various methods have been tried, among which are the offering of prizes, paying wages during the time of instruction, or imposing penalties in the way of discharge or lack of opportunity for advancement for those who would not accept the help offered. Even such inducements or penalties have often proved futile. There is a general feeling among those who have dealt with this question that Americans made under compulsion, or by the holding out of what may be classed as bribes, are at best poor Americans, and that while figures may thus be made to show much progress in Americanization the results are but skin deep and of little real value.

In one of his last public addresses Theodore Roosevelt urged strongly that only such immigrants should be allowed to enter this country as would agree to learn the English language and acquaint themselves with American ideals, that ample provision be made at public expense to give them the needed instruction, and that, if after a reasonable time they had not complied with the conditions, they be sent back to the country from which they came.

In the industries lies the greatest opportunity for doing effective Americanization work. Here the foreign-born come in contact with American workmen, and are given an opportunity to absorb American ideals. From their associates and those under whom they work they derive their ideas of what this country stands for, and whether they become loyal or otherwise depends largely upon their industrial environment. If the managements of industrial plants encourage steps toward Americanization in a manner that will promote a feeling that the service is given as a privilege and opportunity, rather than as compulsion, much can be done of a helpful nature along these lines.

Responsibility of the Industries for Americanization Work

It is in the industries where there is the greatest opportunity to deal helpfully with adult foreigners in Americanization work. Here they come in contact with American workmen and the use of the English language, and are thus given an opportunity to absorb American ideals. From their associates and foremen they derive their ideas of what this country stands for, and whether they become loyal or otherwise depends largely upon their industrial environment. If the managements of industrial plants encourage steps toward Americanization, and cooperate with the workmen in taking out citizenship papers, and in becoming proficient in English, etc., and if this is done so that the men will feel that the service is given as a privilege and opportunity rather than as compulsion, much can be done of a helpful nature.

To carry out such a program, it should be understood throughout the works that the officials of the company are behind the movement—that they consider it important and are undertaking it seriously. In the language of commercial men, they must "sell" the idea to the foremen, who, in turn, must be so instructed and enthused as to "sell" it to the men. The preliminary canvass of a plant to learn the facts regarding citizenship is likely to bring out some matters of surprise as to who are and who are not American citizens. Foremen and others in responsible positions, in some cases, are not citizens themselves. There will also be found a surprising lack of knowledge on the part of foremen as to the status of their men relative to nationality and citizenship.

Americanization Methods in a Machine Tool Works

In the winter of 1916-1917, the officials of the Brown & Sharpe Mfg. Co. were impressed with the importance of Americanization work, not only from the standpoint of developing an interest among alien employes in becoming citizens and of training them in the English language and American ideals, but also in order to know who might be trusted as being loyal and who might need watching when America entered the war, which then seemed inevitable. The campaign was inaugurated by giving a dinner to the foremen at the local Y. M. C. A. building. The foremen were invited by formal letters signed by the secretary of the company, so that in every way it was impressed upon them that the matter was important and that their cooperation was expected. The officials of the company sat at the head table with national representatives of Americanization work, and the situation was forcibly presented, both from the standpoint of the national movement and from the point of view of the company. The industrial secretary of the Y. M. C. A. was requisitioned to give active help in cooperation with shop officials in carrying on the campaign.

TABLE 1. PROPORTION OF NATIONALITIES APPLYING FOR CITIZENSHIP IN THE B. & S. PLANT FROM 1916 TO APRIL, 1921

Nationality	Number Becoming Citizens	Number Securing First Papers	Total
English	272	178	450
Scotch	72	82	154

No. Completing	13	2	8

Machinery

Following this meeting, a census of the factory was taken, through the foremen and clerks of departments, and an index made. Each card contained the name of an alien and stated whether or not he had been in the country and state a sufficient length of time to make application for first naturalization papers. If he had previously made an application a record was made of the date on which this had been done. A record was also made of those who had made application for second papers and were waiting for appearance in court, dates and other needed information being noted.

A notice was then sent to each man eligible for citizenship or for advancement in his steps toward citizenship, calling his attention to the fact, asking whether he desired to become an American citizen, and offering him help if desired. The majority replied "Yes," and for all such an appointment was made to meet a representative of the company during working hours, and be given assistance in making out his papers. The accompanying illustration shows a group of men of twelve different nationalities being helped in this work. About fifteen minutes time was required for each employe, and a special job number was issued to which this time was charged. The applicant was then directed to go to the Federal authorities, pay one dollar, and complete his application. Upon receipt of word from the Federal authorities that a man had done so, his card was filed in a "tickler" index dated two years later, showing the time at which he should make application for second papers. All cases pending, including those waiting for second papers, were filed in a similar manner and as the period was reached when they should take the next step, they were notified and the offer of help repeated.

Results Secured by the Method

Those declining citizenship were further interviewed by their foremen, and some induced to change their minds, but no pressure was brought to bear at the time if a man refused. The reason most often given by a workman for not becoming an American citizen was his intention of returning to his native country. There were also many who felt that while their native country was in the war, and America was not, it would indicate cowardice to renounce their allegiance to their mother country. Many of these took out their first papers as soon as the United States entered the war. One man refused to apply unless the company would pay the dollar fee.

In the first comprehensive campaign, the 1312 aliens then employed in a total force of about 6000 were all interviewed relative to citizenship, and all but 201 took steps toward citizenship for which they were eligible at the time. Many already had first papers and, the two-year waiting period having been passed, were eligible to become citizens at once.

Others having first papers were waiting for the expiration of the time limit so that they could apply for second papers. Over five hundred applied for first papers.

Classes in English and Citizenship

Following the first general canvass, language classes were started which were held during the noon hour, those in English being of two grades, the first for those who had little knowledge of the English language or were illiterate in any language, and the second for those who were more advanced. These were carried on under the Roberts system. Lessons were also prepared under such headings as "Getting a Job in the Foundry," "At Work in the Foundry," "At Work in the Paint Shop," etc., these being in the form of simple dialogues printed in English and in each language represented by a sufficient number of workmen. Evening classes in citizenship were being conducted in the city in which the plant is located and many employes took advantage of these. Literature was distributed to men preparing for citizenship, including the Constitution of the United States and leaflets telling of the requirements of citizenship, of our form of Government, and of some of the important historical events which should make a man proud to be a citizen of this country.

Statistics of Americanization Work

During the last four years about 2600 employes have been approached regarding citizenship. Of these, 2032 have made application and the company has a record of 861 having become full citizens. No doubt hundreds of others who made application through the cooperation of the company have completed their citizenship, but having left its employ there is no record available. Table 1 shows the number of men who applied for citizenship and the proportion of nationalities. It will be seen that more than half of those who applied were recruited from the English-speaking races, while a still greater proportion of those who have become full citizens are of those races. Of those still employed there are now 184 waiting for the time limit to complete their citizenship, and a recent report from the foremen shows 66 recent employes not as yet citizens who have not been reached but who will be in the near future. Adding to these a few of the old list who declined to become citizens because of being illiterate or too old to feel it worth while, gives a total of only 263 of the entire force not as yet full citizens, and most of these will become such within the next few months.

In the recent reduction of the force due to the depression of business, the policy was to lay off alien employes rather than American citizens, other things being equal, and in rehiring, this thought of giving preference to American citizens, whether native or by adoption, will be kept fully in mind, the employment department being especially watchful not to give preference to men who showed a disposition to be "slackers" and evade their evident duty when their native country or the land of their adoption was at war.

Aid of Public Schools in Americanization

During the winter of 1919-1920 a special effort was made in Providence to stimulate an interest among adult aliens in the study of English and in preparing for citizenship. Evening classes with competent teachers were provided in eight of the public schools, and classes in citizenship were also held at the public library. The industries of the city were asked to assist in arousing interest and securing attendance. The earlier efforts of the Brown & Sharpe Mfg. Co. to encourage attendance at noon-time classes had been but partially successful, it having been necessary to bring pressure to bear through foremen, and in various other ways to secure continued attendance. Therefore, in cooperating with the public schools, it was thought best to offer an inducement to a man to attend the English classes, even though it was believed that a desire to better himself by learning to speak and write English and by becoming an American citizen should be a sufficient inducement without holding out any further reward.

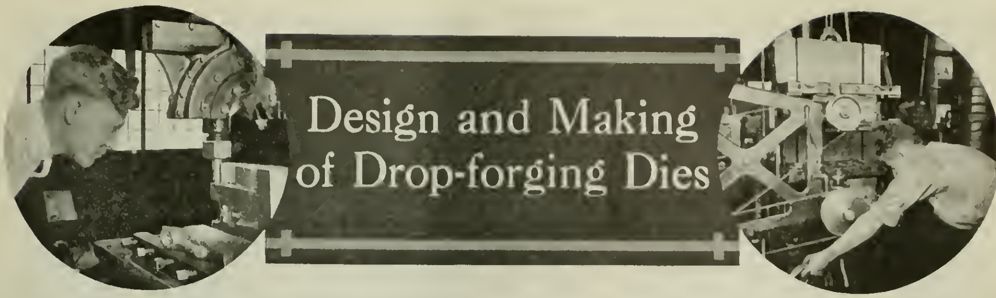
At that time a large proportion of the employes were members of thrift clubs and purchased thrift and war savings stamps in large quantities weekly. For this reason it was decided that the inducement offered should be prizes of thrift and war savings stamps. A thrift stamp was given for each session attended, provided a favorable report was received from the teacher as to faithfulness in attendance and in doing the required work at the school. This small inducement appealed to the men so strongly that the attendance jumped at once to a point much higher than had before been reached, and was so large as to cost the company during that winter nearly $700 in prizes. The gathering of these "coming Americans" to receive the prizes was an inspiring occasion. The meeting was addressed by the superintendent of schools and by officials of the company. To look into the faces of these men and see their interest, intelligence, and responsiveness, gave a feeling that they were assets to the nation, and that it is not always necessary to wait for the second generation in order to secure desirable citizens.

Of course, when the novelty of school attendance had worn off, excuses for absence and for dropping out gradually increased. Some of these are interesting, such as "going to see my girl," "sickness at home," and "too hard to learn." The record for the winter's attendance in English classes, distributed among eight of the city schools, is shown in Table 2. The attendance, it will be seen, fell off during the second term, but it is interesting to note that in each term about the same percentage (60 per cent of those starting) completed the course. In the citizenship classes no prizes were offered, and as a result, the enrollment was much less and the dropping off more noticeable. These statistics are also given in Table 2. It is no more than fair to state, however, that in the citizenship classes the small number in attendance at some of the schools led to abandoning the classes, so that those who would have willingly continued were forced to drop out. In both the English and citizenship classes some of the falling off was due to an increased amount of night work at the plant.

Summary

The loyalty of the force during the war, as shown by the large number of alien employes (133) who went into the service, largely in the United States Army and Navy, and the response of those remaining at the works to calls for financial help and other imperative demands of the war, can be traced, in part at least, to the influence of the previous Americanization work. Because of the situation created by the war, the activities here described to assist "coming Americans" would be fully warranted as an aid to America in the war, and its aftermath, yet this is but a small proportion of the benefits resulting—benefits belonging to times of peace—and a policy of undertaking such work can be recommended to all employers of alien labor.

Judging from past experience and the showing in other industrial plants, it is believed that an active citizenship campaign is needed to bring results, because but a small percentage of aliens will become citizens on their own initiative. Even those who go so far as to take out first papers often fail to take further steps—in fact, many were found whose first papers had become outlawed because of exceeding the seven years' period allowed, thus requiring these men to take out their first papers again and go through an added waiting period. While the war served as a special reason for carrying on an active campaign, the making of citizens permanently interested in and feeling that they are a part of our body politic is what will give lasting results. Such results can be obtained only by interest and enthusiasm on the part of the employer, coupled with systematic, sustained, detail work.



Design and Making of Drop-forging Dies

Methods Employed in Modern Drop-forging Plants—Second of Two Articles

IN the first article dealing with the design and making of drop-forging dies, published in August MACHINERY, all the factors entering into the design of drop-forging dies were discussed, including die materials; the proper grade of die steel, and the considerations entering into its selection; the importance of adequate draft, shrinkage, and machining allowances; the laying out of the die impressions; and the design and purpose of the fuller and the edger. In this article the actual making of the dies is discussed.

Sinking the Die Impression

Having selected the steel for the dies, according to the size and requirements of their service, and determined upon the location of the impression and the location and design of the fuller and edger, the next step is to follow out the machining operations in making these impressions. Two practices are followed in sinking the die impression, which may be broadly classified as all-mechanical and part-mechanical methods. In both of these methods, the machined surfaces must be finished by the usual hand work, although in the all-mechanical method the amount of hand work is greatly reduced. In general, the machines and methods used are those which can be most conveniently employed.

In Fig. 6 is shown a No. 6 Becker milling machine and the roughing mill employed in hogging out the fuller impression in a locomotive switch crank die. This die illustrates a case where, on account of the depth of edger *A*, the matching surface must be on the left-hand and the edger on the right-hand side, just opposite to the usual design. It has been stated that no matter how the die impression is produced, a certain amount of hand work, such as typing and riffling, is required and that the development of modern automatic machines has reduced the amount of hand work materially. For convenience in differentiating between the practices followed in sinking a drop-forging die impression, that method in which automatic machines of special design are employed has been termed "all-mechanical," although this expression is not literally correct, as considerable hand work is sometimes necessary on intricate designs, even when automatic machines are used.

Die-sinking Machines

One of these die-sinking machines is made by the Jackson Machine Tool Co., of Jackson, Mich., and is essentially a vertical milling machine provided with an additional head for cutting semi-cylindrical impressions, such as those by means of which a camshaft is drop-forged. The second head is commonly called a cherrying head, and carries a cherrying tool which is semicircular in shape and which has an oscillatory movement imparted to it through the mechanism of the head. On the completion of the cutting stroke of this oscillation of the tool, the tool is lifted from the cut and again lowered into the impression at the termination of the return stroke. Since the table of the machine is fed under the cherrying tool, it will be readily seen that a semi-cylindrical groove of varying length and radius can be readily machined. By employing tools of narrow width, it is possible to machine comparatively deep circular impressions to such a degree of accuracy that little, if any, typing is required. It is not probable, however, that the use of types for the more intricate cavities will ever be supplanted by this method.

An entirely different type of automatic die-sinking machine is manufactured by the Keller Mechanical Engraving Co., Brooklyn, N. Y. The principle employed in the design of machines of this company's manufacture is that incorporated in profiling machines. Instead of following an outline, however, a master pattern or model is employed which may be cast from an ordinary wood pattern or from a plaster-of-paris mold, or it may be built up from laminations corresponding to various sections of the forging and then machined. One of these machines is known as a duplicating type, and in this design the die produced is of the same size and shape as the pattern used. The work is

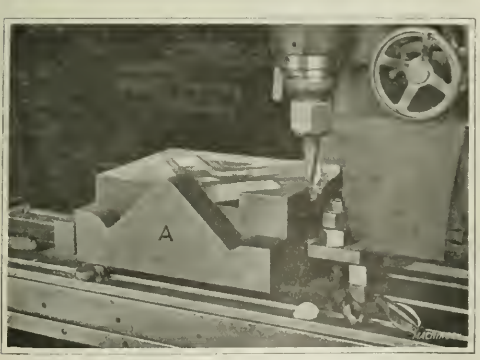


Fig. 6. Machining Impression in Locomotive Switch Crank Die

Fig. 7. Forging and Trimming Dies for Automobile Steering Arm

located directly in the machine without the necessity of laying out the impression, with the face of the die in a vertical plane. A rotating cutter carried on the lower part of a swinging frame is employed to remove the metal. The upper part of the swinging frame carries a tracer, which passes over the contour of the master model as the table on which the pattern is mounted traverses back and forth and feeds upward, thus guiding the outline machined by the revolving cutter. Means are provided for keeping the tracer point in contact with the contour of the master, and where particularly intricate dies are to be reproduced the chaser point is also revolved to facilitate following the rise and fall in the impression. The frame on which the revolving cutter and the tracer are carried is mounted on centers in such a way that it will swing freely outward and at the same time keep the tools in contact with the impression by the application of a suitably located counterweight.

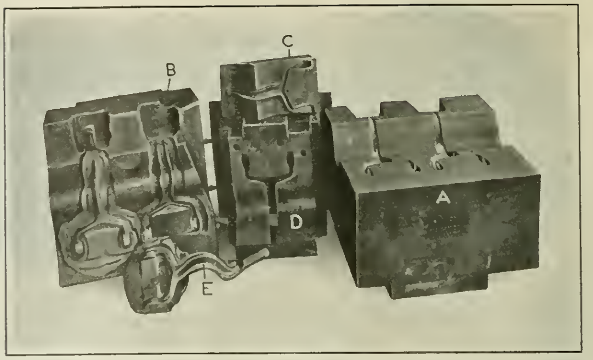

Fig. 9. Drop-forging Dies for Motor Truck Towing Hook

The reducing machine for die-sinking, which is also manufactured by the Keller Mechanical Engraving Co., employs the same method of establishing the contour of the impression, namely, a master model. With this machine, however, a different construction is employed owing to the fact that a larger pattern is used. It is stated that die impressions of an intricate nature can be more accurately reproduced when the master is larger than the die impression. Obviously this facilitates the manufacture of the master, and enables the delicately proportioned parts of the impression to be more accurately reproduced.

In this machine, two vertically revolving faceplates are employed, on one of which is attached the master, and on the other the die-block in which the impression is to be sunk. The tracer point (which may revolve or not as required) and the revolving cutting tool are adjustably mounted on a pivoted bar. This bar is so hung that it may swing freely in either a horizontal or vertical plane as the tracer passes over the master pattern. The relative distances of the two faceplates and the centers of the tracer and the tool from the end of the swinging rod on which these tools are carried establishes the amount of reduction. It will be obvious that in case the positions of the work and the master are reversed, an enlargement rather than a reduction will result, but for the manufacture of drop-forging dies such a setting of the machine would hardly be of advantage. In both of the machines which operate on the master model principle, the feed of the cutter and tracer is from the center of the pattern to the periphery, and suitable feed and speed changes are provided to correspond with the size of the work being machined. Machines of these types employ round-nosed cutters, ordinary end-mills, and in some cases cutters of special though simple design. Three cuts are often required, the end-mill being used to rough out most of the metal, and the intermediate and finishing cuts being taken with special milling cutters. The cherrying machine and the automatic profiling or duplicating machine are shown in the heading illustration.

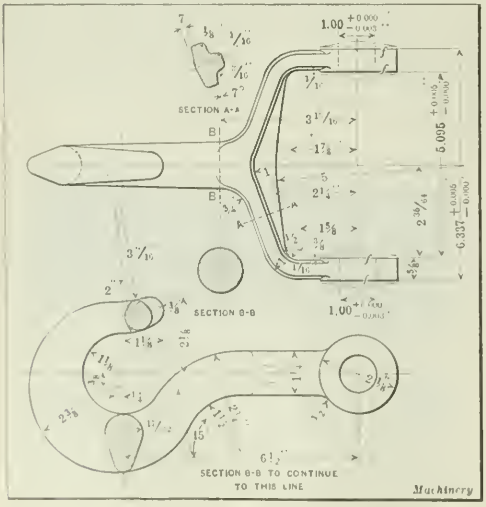

Fig. 8. Towing Hook, drop-forged in Dies shown in Fig. 9

Two-impression Dies

A second or finishing die is often required, as in the case illustrated in Fig. 7, because of an offset or bend in the forging. The automobile steering arm which is produced in the dies illustrated has a sharp offset, necessitating much more work in sinking the impression than would otherwise be required. Dies of this kind are known as locked dies, and in designing them there must be sufficient flat striking surface to absorb some of the shock produced by the hammer blows. This is a case where the all-mechanical method of die-sinking will result in a great saving of time and money. When the impression is to be laid out, it is apparent that a templet cannot be used owing to the offset. In such cases use may be made of a lead casting made from half of the first-impression die; this is bent to the proper offset, laid upon the face of the blocks which have previously been machined to the contour of the parting line of the forging, and circumscribed with a scratch awl.

Nearly every design of forging may be considered as a special case. It would therefore be impossible to attempt to cover all points in design except those that are most commonly encountered. Often the piece is of such shape and size that the first and finishing impressions can be made in one block, so that the forging will not require a second heating to complete it. In drop-forging eye-hooks in which the eye passes through the forging at right angles to the bend in the hook, this method can be employed. By producing a large lump of metal in the first-impression die, when the eye is subsequently to be forged, and then transferring it quickly from one impression to the other and turning it at right angles, the end through which the eye passes can be drop-forged while the part is still hot.

Another example where a two-impression die is employed to drop-forge a hook is shown in Fig. 9. These dies are used in the production of the motor truck towing hook shown in Fig. 8. The upper die is shown at *A* with the impressions partly completed, the lower member at *B*, and the trimming punch and die at *C* and *D*, respectively. The forging produced in the finishing die is shown lying in the impression, and the forging produced in the breakdown die at *E*. It will be noticed that a large amount of flash is produced in making the drop-forging, which must be trimmed off before

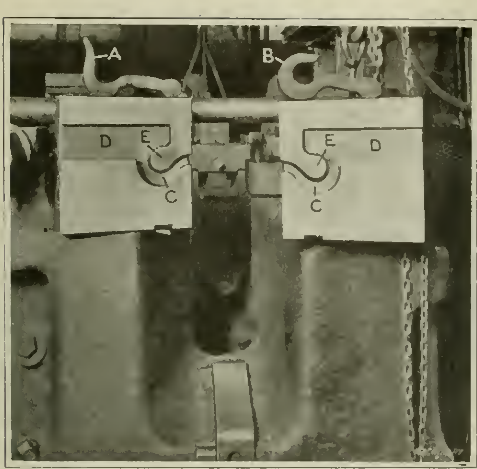

Fig. 10. Upsetter and Dies for bending Towing Hook

the end of the hook can be bent. This bending is a job for the upsetter or forging machine, and Fig. 10 shows the hook with the flash removed; the illustration shows the hook at *A* and *B*, before and after bending, respectively, resting on the upsetter dies by means of which the bend is produced. This is a view looking into the end of the machine. The end to be bent is held in the impressions *C*, with the tapered end in a vertical position, so that the bender which slides in channels *D*, may force the end of the hook around the center *E*. These dies are of comparatively simple design, and the method of making will not be gone into, as they cannot really be classified as drop-forging dies, although closely identified with the production of drop-forgings.

The method of making dies for drop-forging bronze, copper, and aluminum is not different from that already described. In finishing the impressions, however, much more care must be taken to produce a surface which will be free from all imperfections and tool marks. If this is not done, the forgings will be unsatisfactory and will cause difficulty in handling in the dies. Carbon steel die-blocks will be found suitable for this class of forgings.

Trimming Punches and Dies

In most cases the lead casting is employed in laying out the hot trimming dies, but for the cold trimming dies a forging is usually obtained and used as a guide in finishing the die opening. Two hot trimming dies are shown in Fig. 7, one for trimming the first-operation forging and one for the finishing operation. The die openings are cut in a plate which is attached to a bolster plate, designed so that as the punch descends, the hot forging may be pushed through and withdrawn from an opening under the die plate. In the case of trimming dies for cold work, the design is practically the same as that used for hot trimming dies, except that in hot-trimming the sprue is usually removed in a subsequent operation, while in cold work the entire scrap is removed at once. It will be evident that the openings at the front of the trimmers shown in Fig. 7 are for the passage of the sprues.

The steel for hot trimmers may be considerably lower in carbon than for cold trimmers. For cold-trimming, shear must be provided on the cutting edge of the die. For long, comparatively large work, and especially if the forging is of circular or of irregular section, this shear may be similar to a scallop. In such a case the shear should be located between the ends of the die opening. The punch should be formed on the face to conform with the shape of the forging, so that it will bear firmly on the ends and prevent the forging from being displaced when the press descends and forces it through the die. The punch and trimming die shown in Fig. 9 are good examples of tools of this kind. These are used for hot-trimming, the punch *C* carrying the form of the forging on its face, and being shaped to agree with the hook.

Shear for Trimming Dies

For flat work the cold trimmer should have shear provided from end to end of the die opening, but not enough to cause the forging to tip up at one end. The degree of inclination, or shear, commonly provided for cold trimmers is frequently expressed as a fraction of the thickness of the flash being trimmed; for example, one-half shear means that the inclination of the die face is equal to one-half the thickness of the metal to be trimmed. The shear may also be expressed as inclination of the face of the die in inches per foot, which is the more common method when referring to trimming dies. It does not matter whether the die has a straight shear or whether it has several cutting edges as in a scalloped shear, as regards the pressure required to trim the forging. The pressure, in pounds, required to force a forging through a trimming die provided with shear, when this amount is expressed as a fraction of the flash thickness, may be determined by the following formula:

$$W = \frac{ldf}{c}\left(t - \frac{dt}{2}\right)$$

When the shear is expressed in inches per foot of inclination, the following formula applies:

$$W = \frac{6dt^2f(2 - d)}{S}$$

in which W = pressure in pounds required to force forging through die opening;
l = length of cut (or distance around the die opening) in inches;
d = a constant varying from ¼ to ½—usually taken as 1/3 for cold steels;
f = ultimate strength of material, in pounds per square inch;
t = thickness of flash, in inches;
c = shear expressed as a fraction of the thickness of flash; and
S = shear expressed in inches per foot.

Shear expressed in terms of thickness of the material being cut is more commonly spoken of when referring to the shearing of plate stock.

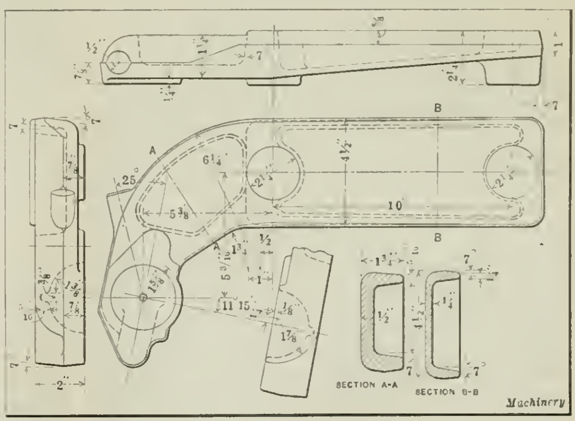

Fig. 11. Radius-rod Bracket for Motor Truck

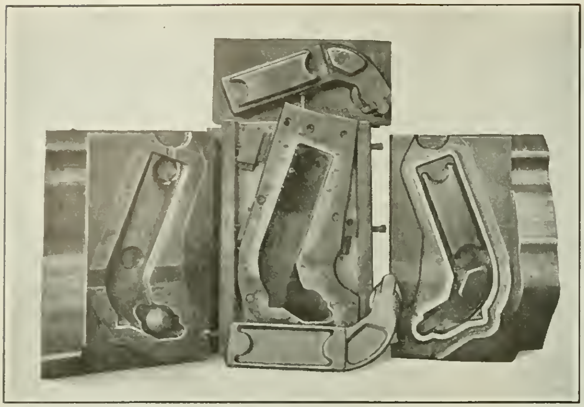

Fig. 12. Drop-forging Dies for Radius-rod Bracket shown in Fig. 11

Under favorable conditions from 10,000 to 12,000 drop-forgings may be cold-trimmed without regrinding the die, and this output is not dependent on the size of the work. Combination trimming punches and dies are sometimes used, if the quantity of work and its requirements should warrant the expense of such equipment. Liberal clearance should be provided for the die openings, in the under side of the die plate, to facilitate forcing the forging through the die opening.

The radius-rod bracket, Fig. 11, is forged from low-carbon steel in the dies shown in Fig. 12. The upper and lower dies are shown at the right and left, respectively, and the trimming die in the center with the punch resting on it. This hot trimmer removes the sprue as well as the flash, which may be done if the forging does not need to be restruck after trimming. This illustration shows how the die is located in the bolster plate and the adjusting screws by means of which it is aligned with the punch. The holes for the machine screws which fasten the die in place are enough larger than the heads of the screws to allow for adjustment. The face of the punch is shaped to seat evenly in the impressions of the forging. The forging is shown beneath the trimming die.

Much of the information contained in this article was obtained through the courtesy of the Union Switch & Signal Co., Swissvale, Pa., and J. H. Williams & Co., Brooklyn, N. Y. The next article in this series will appear in October MACHINERY, and will deal in detail with modern methods of heat-treating drop-forging dies.

LOW WAGES IN GERMANY

According to a recent item published in Commerce Reports, an investigation covering a total of 2,300,000 workers in the German metal-working industries shows that, figured in marks, 63 per cent of the workers get eight times the wages they received in 1914, 36 per cent from five to eight times, and the remainder less than five times the wages in 1914. When we compare this with the fact that, still using the mark as a basis of comparison, the cost of living in Germany has increased fifteen times since 1914, it will be readily seen that the actual wages of workers in the German metal-working industries are only from one-third to one-half the amount received in 1914. This is one of the reasons why German industry is able to under-sell other nations in the world's markets. Taking even the highest paid group of workers mentioned in this report, and comparing wages on a dollar basis, we find that they are less than one-half of what they were in 1914, and for the lowest paid workers in the same field they are not much more than one-fourth.

SENSITIVE MEASURING APPARATUS

By J. B. MORAN

The Bureau of Standards is now experimenting with an electrical measuring device which is sensitive to one two-hundred millionths of an inch. While this approaches closely its limit of measurement, it may be adjusted to make much more practical measurements. It represents the greatest advance in mechanical measurement that has ever been made. Credit for the origination of this method is due Professor Whidington of London, England.

Before describing the details of this new development, an example of its unusual sensitivity will be given. Referring to Fig. 1 two ½-inch steel rods *A* and *B* are solidly mounted on a steel base *C*. Attached to one of the rods is a small lever *D*, which may be adjusted vertically. A sliding pan *E* is arranged on this lever. It has been found possible to measure the outward bending of this rod when the infinitesimal weight of one milligram is placed in the weighing pan and the latter is adjusted 5 inches from the rod. At this point of adjustment it is computed that the rod bends outward at its uppermost end one two-hundred millionths of an inch.

The detection of this slight movement has been made possible through the use of the little vacuum tube used in radio work. A non-technical explanation of the functioning of the electrical circuits used should interest mechanical men even though they have no knowledge of radio work. In radio circuits, what are known as high frequency currents are dealt with. These are alternating currents that oscillate to and fro thousands or even millions of times per second. Fundamentally, they are the same as the alternating currents of low cycle used in electric lighting work. The radio currents, however, oscillate at a much higher rate.

Let us imagine that we have an oscillating radio current with a period of 100,000 cycles per second; that is, the current alternates 100,000 times per second. This rapid oscillatory current is generated by the little audion bulb or vacuum tube previously mentioned. Before going further it should be mentioned that such high frequency circuits are very sensitive to changes in capacity and inductance. By capacity, we mean electrostatic capacity which is represented by the condensers in the circuit. By inductance, we might say, roughly, the amount of wire in the circuit.

At the side of the circuit oscillating at a frequency of 100,000 cycles per second, let us set up another circuit exactly the same as the first one except that it oscillates with a frequency of 101,000 cycles. It must be understood that the human ear will not respond to frequencies beyond 10,000. For this reason the currents in both these circuits will be inaudible. When these circuits are placed in proximity to

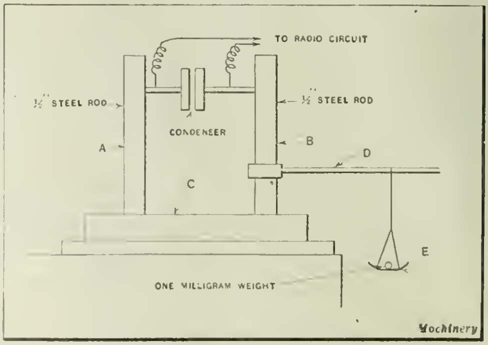

Fig. 1. Equipment used to show Sensitiveness of Measuring Apparatus

each other, however, the oscillating current in one will be superimposed on the other through the property of inductance. This brings about a very interesting result. There is set up in the second circuit what is called a "beat note," and this beat note will have a frequency that will amount to the difference between the frequency of the two oscillating circuits. In this case, the beat note will have an audible frequency of 1000 per second, which is the difference between the 100,000 cycle current in the first circuit and the 101,000 cycle current in the second circuit.

The slight change in the capacity of one of these circuits will change the frequency of the oscillatory current and therefore alter the beat note, which is the difference between the two frequencies. So sensitive are these circuits to changes in capacity that the slightest change imaginable will produce an audible effect in the telephone receivers of the second circuit. The actual measuring instrument used in this electrical device consists of two metal plates which represent the two contacting plates of an electrical condenser. Every change in the distance between these plates will change the capacity of one of the oscillating circuits and thereby produce a difference in the beat note.

Theoretically, a movement of one five-hundred millionths inch is measurable with the device, although one two-hundred millionths inch is the smallest measurement that has yet been made. The actual measurement is made by calculating or measuring the frequency of the beat note. The frequency of the beat note can be measured directly on a frequency meter and the reading of this instrument can be translated to linear measurement. With the proper constants and data available, the measurement of the movement of the plates of the condenser is possible. Of course, one two-hundred millionths inch is a measurement beyond the realm of practice, and this figure is mentioned only to impress the reader with the unusually high sensitivity of the apparatus. The natural expansion and contraction of all substances due to changes in temperature fluctuate so widely that such measurement would not be practical. For instance, with this device the expansion of a piece of steel due to the heat from a human body can be measured.

This measuring instrument is so sensitive that it will measure the deflection of a table top due to the weight of a fifty-cent piece. Fortunately the sensitivity of this electric circuit is adjustable within wide limits, and it may be brought down to a point where it will make practical measurements with absolute accuracy that are beyond the measurements attainable with any known means. If the difference in frequencies in the two oscillating circuits is made greater, the sensitivity of the device is altered accordingly, and comparatively large measurements may be made.

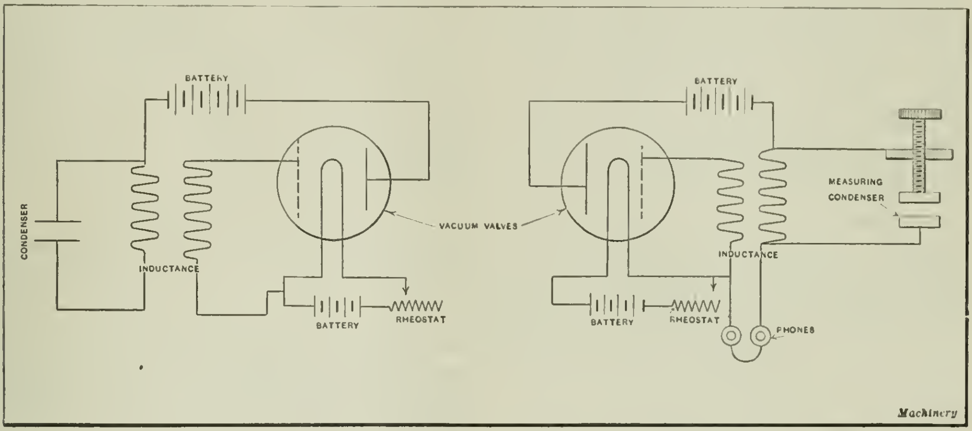

Fig. 2. Wiring Diagram of Electrical Measuring Apparatus

WROUGHT TUNGSTEN

In a review of the results of research work done to produce tungsten lamp filaments of great strength, prepared by Dr. Irving Langmuir of the General Electric Co., and published by the Engineering Foundation, 29 W. 39th St., New York City, many interesting facts relating to this remarkable metal are brought out. Until 1904, tungsten had been known for a century and a quarter only in its unrefined state. Its value as a hardening alloy for steel had been recognized and appreciated; but it was not until 1905 that the metal, mixed with paste and squirted through dies, had given the incandescent lamp its most efficient filament, although the brittleness of this filament caused great embarrassment to electric lamp makers and users alike.

For many years Dr. W. D. Coolidge, of the Research Laboratory of the General Electric Co., had sought a process for making tungsten ductile. The feat was regarded as almost impossible by metallurgists. To make any ordinary metal soft, it is heated to a temperature above its annealing point and then cooled to room temperature. This process, however, left tungsten as brittle as ever. It was eventually found that the only way to make the metal ductile was to mash the grains out into fibrosity and thus make it ductile while cold. This was accomplished by first heating the tungsten to a temperature below its annealing point and then mechanically working it with infinite care at a variety of degrees of heat, each less than the one preceding it, until it was at room temperature. A similar treatment would, if applied to ordinary metals, destroy their ductility.

A process was worked out which, if followed without the slightest deviation, stretched the grains out and the metal was made ductile; but if the working varied from this process, failure resulted. The tungsten would break at a stroke, when cold. Thus, after years of patient labor a triumph of far-reaching consequence in the field of research was attained. The filament produced had a startling tensile strength—about 600,000 pounds per square inch for wire 0.001 inch in diameter. It was so pliable that it could be wound into any form safely.

The tungsten filament has doubled the efficiency of incandescent lamps and provides a white light of far purer quality than any lamp heretofore known. It has provided new targets for X-ray tubes, phonograph needles fifty times as efficient as any that preceded them, better ignition contacts for automobiles, and many other new articles and improvements of old ones. Trained facilities for scientific study and experiment, a spirit of indomitable perseverance, and the facilities afforded by a completely equipped laboratory made this achievement possible.

Common Causes of Errors in Machine Design

Instructions and Standards—Convenient Form for Data—Attitude Toward Errors
Concluding Installment of a Series of Articles

By R. H. McMINN

THE present installment of this series of articles, which began in the January number of MACHINERY, concludes the discussion of the underlying causes of errors in machine design. In the eight articles presented, all the common causes of errors have been classified, and methods have been suggested for preventing the occurrence of each kind of error. The points dealt with in the present article include lack of concentration, reasoning from slight knowledge, systematic methods of applying knowledge, and attitude of employer and employe toward errors.

Systematic Methods of Applying Knowledge and Experience

The lack of a systematic method of applying one's full knowledge and experience is productive of many errors. A designer may have had wide experience, but he must use an orderly system to bring his knowledge to bear in producing the most accurate results in any particular design. Constant reference to a suggestive list of important factors which he has learned may partially determine design is safer than relying on memory to always consider these factors.

A draftsman should therefore tabulate for his systematic use the considerations which enter into the design of machines in general, and as he becomes acquainted with the design of any particular machine, he should tabulate any considerations applying especially to its design. This should be done right after he completes the design or checking of any machine and is most familiar with it. If after completing the making or checking of a drawing, he discovers an error by chance he should try to determine why it was not found by his regular routine system for preventing errors, and should try to incorporate in his system a method for discovery of that kind of mistake in the future without failure. In addition to using a definite system as a guide, he must always bear in mind that unless a machine or a single part to be designed is carried by the mind through all the surroundings with which the machine or part must come in contact, from raw material to operation, conditions affecting design may be overlooked.

Utilizing Experience of Entire Organization

The responsibility in eliminating errors in an engineering department does not rest entirely upon the individual. It should be the aim to have every bit of experience possessed by an organization go into all the methods of manufacture and into all the products, and this cannot be done without a thorough system. One phase of such a system should be in trying to prevent drafting-room errors. This cannot be done solely by constant admonitions to employes to be careful. The system should not be based upon an opinion concerning the accuracy that men of average ability ought to be able to maintain, but upon the discovery that all men are inclined to make errors. Many mistakes can be avoided by recognition of the mind's frailties and the erection of every possible safeguard against error. It should therefore not only be the endeavor to make drawings which are fool-proof for the shop and a machine which is fool-proof for the customer, but to adopt a drafting-room system which, as far as can be governed by methods and general practice, is fool-proof for draftsmen.

Instructions and Company's Standards

Important instructions given by the head of an engineering department to subordinates should be in writing. This not only gives less chance for forgetting or misinterpreting, but incites a tendency to more care in giving instructions as well as avoiding argument as to what they were. Giving full reasons for certain instructions not only may make them more readily understood, but may serve as a guide to a subordinate for future practice. It is often impossible for one receiving instructions to carry them out with the same degree of intelligence that might be used by the one who gave them, unless he knows the result to be accomplished.

A set of instructions consisting of company standard parts and practices, given to men at the beginning of their employment, greatly increases their initial efficiency and accuracy in drawing. Unless there also are written instructions pertaining to determining factors in the design of each type of machine manufactured by a concern, it is impossible for the whole experience of that company to go into each modification of the machine for particular cases, except when the smallest details come under the direct supervision of one man. This man must not only know all necessary facts relating to the design, manufacture, shipping, and erecting of the machine, but he must have a memory so faultless that he will see that no necessary consideration is overlooked in any machine being built. It is evident, in order to insure that he overlooks nothing, that he, at least, requires written data even though it be not for general distribution in the engineering department. If such information be made inaccessible to most of the draftsmen so it cannot so easily get into the hands of competitors, there is a question as to whether this will not prevent most of the men from attaining their maximum usefulness to a concern and thereby offset any possible benefits of secrecy. In as far as possible, it is well to have all useful information relating to one kind of machine grouped together where it will be examined by following a regular routine. If such a collection of data does not contain all the necessary information relating to a particular machine, it should refer to what the missing data is and where it can be found.

Advantage of Having Data in Convenient Form

Draftsmen will not always go to the lengths necessary to eliminate all doubts regarding a certain point. They realize that they are not expected to spend too much time on any one phase of work. Consequently the head of an engineering department should bear in mind that the easier it is to obtain information, the more likelihood there is of its being used. Therefore, data concerning stock material, kinds of machines in the shop, with maximum size of work that can be handled, limitations in foundry work, and maximum sizes and weights of parts that can be taken into all plant buildings and on all elevators and floors should be easily available. When a change is made in a plant standard or in the design of any standard machine all draftsmen affected should be informed. Likewise all other departments, such as estimating, sales, manufacturing, or any others interested should be notified. All old blueprints or other data affected should be corrected or withdrawn from the departments holding them. A single change may require an alteration in such a large number and so many different kinds of records that it is well to have a standard reference sheet listing all the records which may be affected, so that none will be overlooked.

Standard drawings and bills of material must be kept up to date or prominently marked out of date. In order that draftsmen may know definitely the reliability of any drawing which they may wish to use for reference, a list, kept constantly corrected, should give the serial numbers of drawings which can safely be referred to in designing any new machine. A report should be filed in the engineering department regarding the results of operation of each new type of machine built, as well as any special difficulties experienced during manufacture, assembly, shipment, or erection, to show how far a design may be taken as a precedent for future similar machines.

Adoption of Standard Practice

The engineering department should try to eliminate errors by perfecting the routine. Settled standards are a part of a concern's assets. Unsettled features are liabilities. As many things as possible should be settled once and forever —that is, things which could apparently be done in a number of ways with equal success. In order to dimension all parts in the best manner from the standpoint of clarity, and ease of laying out and measuring, every shop should adopt standard methods of giving dimensions on drawings of all representative parts with which it deals, such as gears, shafts, plates, bearings, etc., with instructions that the standard methods shall be followed as closely as practicable. Uniformity of practice should be followed to as great an extent as possible even in small things. Uniformity in the use of words, names, and abbreviations saves time and promotes accuracy. Small, apparently insignificant errors, such as mis-spelled words, should be weeded out to prevent their perpetuation. Changing the pattern number of a part already used promotes error. Changing a symbol number of a part having a certain size should be avoided: thus a certain size crane hook that has been known as No. 25 should not be changed to No. 26, as this invites confusion. Forms for use in the drafting-room should not have spaces too small. This necessitates the crowding of letters, making difficult reading, and promotes error.

Stress of business should not be allowed to interfere with an established routine any more than is absolutely necessary. When drawings are sent to the shop for the work to be started before all related drawings are completed, or when a drawing is sent out without checking, the probabilities are that something will require changing. Interruption of men by change to a new job before completion of another should be avoided if possible, as this disturbs continuity of thought. The amount of work required of men should be considered in its relation to accuracy, as an unreasonable demand will induce a tendency to take chances regarding doubtful points. Absolute harmony in the engineering department and throughout an organization should be sought, as an inharmonious atmosphere is disturbing to the closest attention to one's work.

Attitude of Employe Toward his Errors

When a drafting-room error is not detected until after a machine or part is manufactured, the men who made and checked the drawing are inclined to look for every possible circumstance that may help to exonerate them. But inwardly, at least, they should accept the full weight of responsibility. Each man should try to discover the fundamental law which was violated, so he may observe the law in future related cases, correct the mental habit which made the error possible, or improve his routine system to avoid similar errors.

Attitude of Employer Toward an Error

When an error involving a financial loss occurs, it is not wise for an employer to censure an employe severely who has a good past record of performance, on the assumption that the mistake was due to carelessness. A man may exert care to the limit of his mental capacity and experience, and yet may fail to detect an error in his work. In order to think properly along engineering lines men require equanimity. Severe censure, for a certain error probably lessens the liability of a man's failing to detect that particular kind of error in the near future, but opens the way for a multiplicity of errors along other lines, because of the mental disturbance that has been created in his mind. Unduly emphasizing the occurrence of an error not only destroys the enthusiasm of the individual who made it but that of his associates as well, and lowers the productiveness of all. The loss due to an error should be charged to an account called "Experience." In each case the employer should try to discover if the drafting-room system or data could be improved, and thereby lessen the liability for the recurrence of errors of that class.

* * *

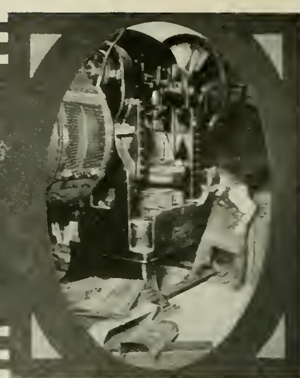
BUSINESS SECURED THROUGH GOVERNMENT DEPARTMENT AID

In a letter sent out by the Bureau of Foreign and Domestic Commerce, attention is called to the fact that the foreign representatives of the Department of State and the Department of Commerce who are engaged in trade-promotion work hear of the results of that work in only a few of the cases handled. Possibly only a small proportion yields results that can be measured in dollars and cents; and it may also be that some of the firms concerned do not wish to divulge the amount of orders received through the information given by consuls, commercial attachés, or trade commissioners. In order to encourage the men in the field to continue to increase their efforts, the Bureau of Foreign and Domestic Commerce asks any firm that benefits in any way from the services of the government representatives abroad to acknowledge this assistance either by writing to the Bureau of Foreign and Domestic Commerce, Washington, D. C., or to the official through whose effort some business may have been obtained. Any information contained in such acknowledgments will be considered strictly confidential.

* * *

According to a recent Commerce Report, a contract has been signed between the Bolivian Government and an American company for the financing and construction of a railway from La Quiaca on the Argentine border, to Atocha, Bolivia, a distance of 126 miles. This is the final connecting link needed to give La Paz, Bolivia, an all-rail route to Buenos Aires, Argentina.

Safety Devices for Power Presses



Guards and Safety Measures Provided for the Power Press Equipment in the Cleveland Metal Products Co.'s Plant, Cleveland, Ohio—Second of Two Articles

IN the first installment of this article, published in August MACHINERY, various types of gate guards were shown. In the present installment, additional types of guards, including the sweeping type gate guard, sliding guards, stationary guards, and guards for shears, will be illustrated and described.

Gate Guards of the Sweeping Type

A positive acting sweeping guard, attached to a Bliss No. 3½ toggle press, is illustrated in Fig. 9,,and its method of attaching to the machine, in Fig. 8. The machine is air-operated. The guard is operated by a stud which engages a cam-slot at the upper end, raising and lowering the guard as actuated by the toggle of the press. In Fig. 9 the guard is shown in its closed position, from which it will be apparent that when the ram of the press ascends the gate will swing to the left and expose the dies to view. This type of guard is of simple construction, and has proved very satisfactory in use. Referring to Fig. 8, there is a leather bumper attached to the guard at *A*, and if the operator's hand is in a precarious position prior to the closing of the dies, the guard will sweep the hand out of the danger zone. The construction of this device is so simple that further description is unnecessary.

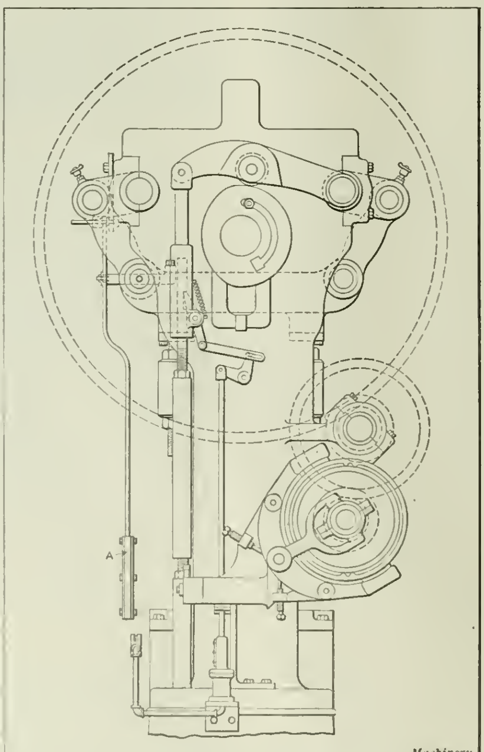


Fig. 8. Method of attaching Gate Guard of Sweeping Type to Toggle Press

Stationary Guards for Blanking and Piercing Work

The guard shown attached to the inclinable press in Fig. 10 consists of a framework and reinforced glass. This type is especially suitable for blanking or piercing operations; it permits the work to be observed without obstruction, and at the same time makes it impossible for the operator's hands to extend into the danger zone. The side arms by means of which this guard is attached to the machine are adjustable so that the guard may also be used on machines having a greater stroke.

Another type of glass stationary guard is illustrated in Fig. 12. It will be noted that this guard may be adjusted vertically as required, and that it gives a very clear view of the punch and die. This particular die is provided with an automatic stop so that the stock may be easily fed to the machine by the operator. Fig. 13 shows another type of stationary guard suitable for blanking operations. This guard is attached to the die in such a manner as to just enable the stock to enter, and the space is sufficiently small to exclude the operator's fingers. A guard of this type may be slightly modified in design so that it will entirely enclose the die. This guard is attached to the machine in a different manner from that shown in Fig. 12, but its construction is so simple that it may be applied in a variety of ways to suit the machine and the work.

Sliding Guard

A guard that is operated by a somewhat different arrangement from that used in other movable guards described in this article is illustrated in Fig. 14. This is a Bliss No. 76½ single-geared press. The guard operates on a track from which it hangs, and is advanced into its closed position, as shown in the illustration, before the ram of the press descends. With the gate open, the operator presses the foot-treadle down, which causes rods *F* and *E* to close the gate by means of lever *G* and to pull roller *D* from engagement with clutch drum *J*. Before roller *D* has been pulled down sufficiently to remove

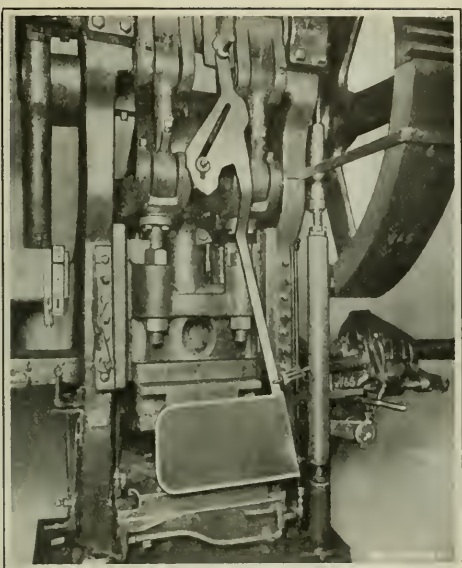

Fig. 9. Application of Sweeping Type of Gate Guard to Toggle Press

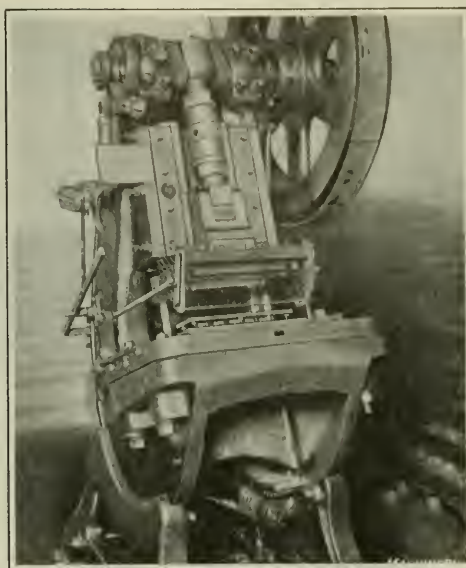

Fig. 10. Inclinable Press with Stationary Reinforced Glass Guard

it from contact with dog *H*, the lever *B* swings forward and locks itself under weight *C*. This constitutes a lock for the gate, the locking movement occurring just before roller *D* is pulled entirely away from contact with dog *H*. The clutch will not engage until roller *D* has been completely disengaged from dog *H*, at which time the press will trip. The gate is held in the closed position

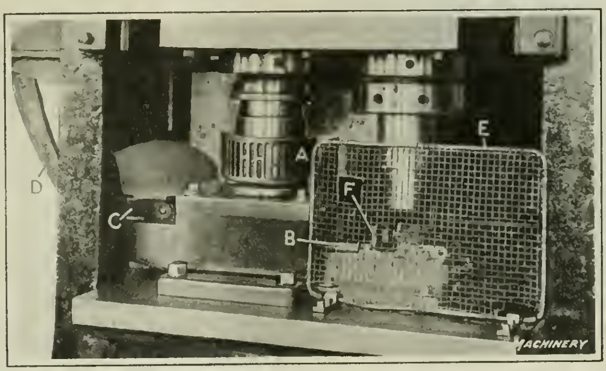

Fig. 11. Guard for a Double-action Press employed for Blanking, Drawing and Redrawing Operations

until the ram is about to be raised, at which time cam *A* operates lever *B*, permitting the weight to drop; this brings roller *D* into contact with the clutch drum *J*, and the clutch is disengaged as soon as dog *H* contacts with the roller. In the meantime, the raising of roller *D* has lifted the foot-treadle and returned the gate to the open position. It will be readily seen that the arrangement of

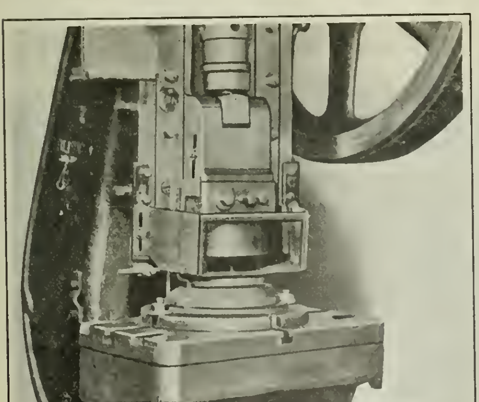

Fig. 12. Stationary Glass Front Guard which may be adjusted for Various Heights

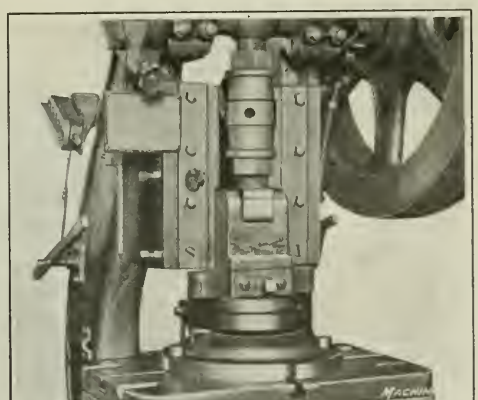

Fig. 13. A Type of Guard Suitable for Blanking and Piercing Operations

the levers that control the sliding of the gate is such as to make it improbable that the operator would slide the guard manually to expose the dies, for in so doing he would need to exert enough pull to lift the foot-treadle which is practically impossible to do, on account of the connection to the clutch mechanism.

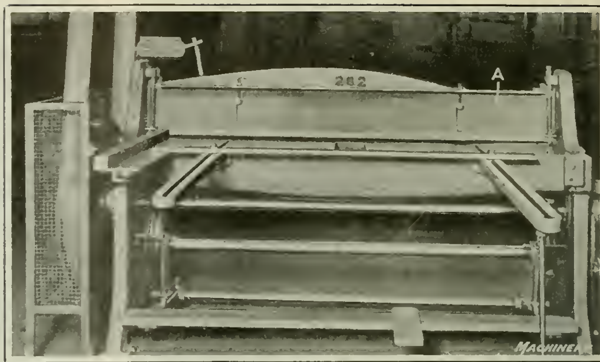

Fig. 15. Front View of a Square Shear with Guard attached to Arch Bracket

Stationary Guards for Double-draw Press

A Bliss No. 353 double-draw press, properly guarded, is illustrated in Fig. 11. The blanking and first drawing operation is performed by the punch and die shown at the left-hand side of the machine. The punch is protected by a stationary sheet iron guard *A*, which practically encloses the entire distance between the punch and the die, leaving only a 3/8-inch opening for feeding the stock under the guard. The partially drawn blank is pushed down into an opening in the die-block, where it is picked up by a pusher *F* on the end of reciprocating ram *B*, which may barely be seen through the hinged guard *E*. This pusher *F* is connected to link *C*, so that it may be

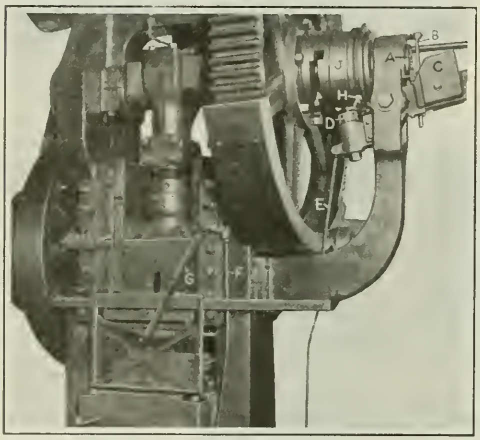

Fig. 14. Sliding Gate Guard, actuated from the Press Clutch

operated by lever *D* with each throw of the crank. It is rarely necessary to swing the guard *E* down, because the drawn shells do not need to be handled, for they are pushed through the die and deposited in a receptacle at the rear of the press. This guard may be readily swung forward however, as it is provided with spring hinges which hold it in an upright position against the frame of the machine. A combination of two guards such as this is very effective, and may be applied to blanking and redrawing dies of numerous types.

Guard for Shear

In the operation of the square shear shown in Figs. 15 and 16, provision has been made for guarding the shear blade so that the work may be cut rapidly without the possibility of the operator's fingers being injured. Only a 3/4-inch opening is allowed for stock between the bed of the machine and the guard when the arch bracket is raised. This prevents the operator's fingers from getting under the shear blade. Fig. 15 shows a front view of this machine, to the arch bracket of which a guard *A* made of channel iron, with elongated slots in it, is hung by means of bolts passing through the slots. This construction is very simple. As the shear descends the lower flange of the channel iron rests on the work and precludes all possibility of the fingers coming into contact with the blade. This arrangement does not curtail the output, but rather is an aid in increasing the speed at which the shear may be operated. At the rear of the machine, Fig. 16, a chute *B* may be seen attached to the head of the shear so that the stock may be fed rapidly under the blade and against a stop at the front without danger to the operator.

All power presses, shears, etc., in this press department are equipped with individual or group motor drive, to suit the machine lay-out, which is another feature adding to the general safety of the machine operators.

* * *

At the annual meeting of the German Machine Builders' Association (not the German Machine Tool Builders' Association, which is another organization), it was stated in the annual report that 700,000 men are now employed in the machine building industry in Germany, and that the association has 944 individual firm members with 40 additional branch works, representing over 550,000 employes. Since October, 1920, the monthly average has been 20,000 export orders distributed between the members of the association. The industry exported, in 1920, machinery valued at 6,000,000,000 marks (about $75,000,000 present exchange). There has been a decrease in the export business during the present year, and poor business conditions have been met with all around. The main subjects of discussion at the convention related to methods for holding Germany's export markets in machinery, and for producing more economically.

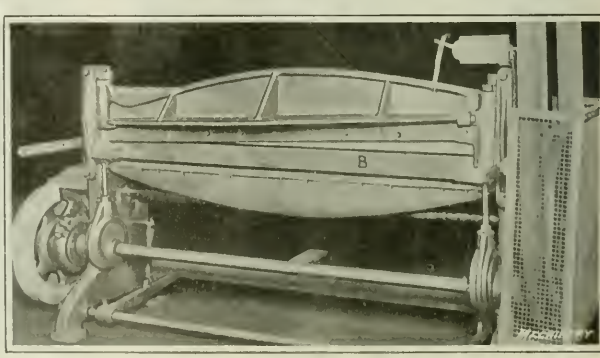

Fig. 16. Rear View of Shear illustrated in Fig. 15, showing Chute provided to facilitate feeding the Stock

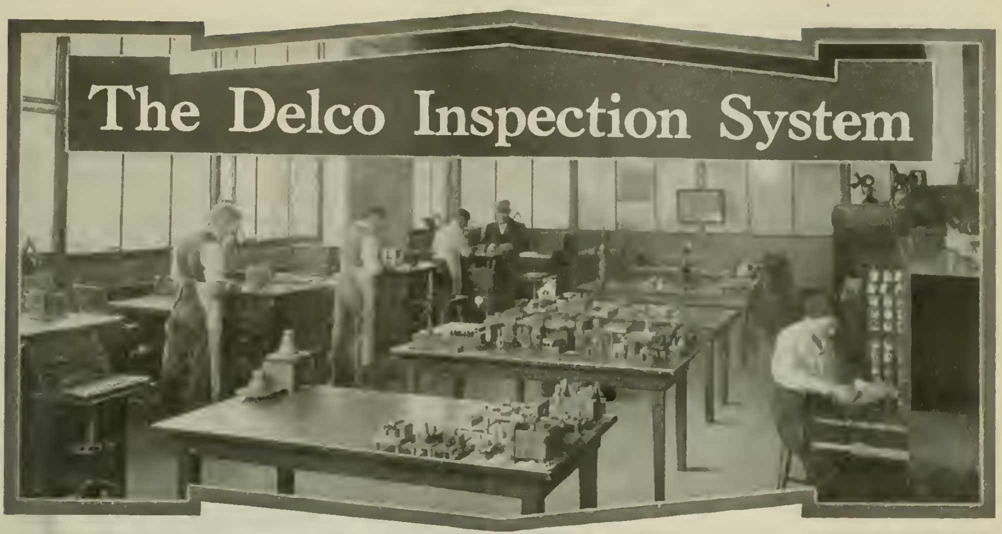
The Delco Inspection System



Typical Examples of Gaging Fixtures Used by the Dayton Engineering Laboratories Co. in the Manufacture and Inspection of the Company's Product—Second of Two Articles

By ERIK OBERG

IN the first article on typical examples of gaging fixtures, published in August MACHINERY, concentricity gages, gages for motor generator frames and distributors, and recess gages were dealt with. In the present article a number of additional fixtures and gages will be described, including a spring testing fixture, a gage for testing installation conditions of motor generators, amplifying gages, device for testing the spacing of ignition cams, plate gages for the automatic screw machine department, gear-testing devices, limit gages for rollers, etc.

Spring Testing Fixture

The spring testing fixture illustrated in Figs. 14 and 15 is used for testing the automatic advance spring on the distributor of a Delco ignition system. It tests the loads at two given compressions of the spring. For example, the spring is compressed to a height of 1 inch, at which it should register a certain load. It is then compressed to, say, 3/4 inch, at which it should register another definite load. The base of the device is a weighing scale, and the loads are registered on the dial of this scale. Referring to Fig. 15, *C* is a rack by means of which pressure is applied to the spring by rotating the handwheel. At the upper end of the rack there is a pointer *F*, which indicates on a graduated scale on rod *A* as the spring is compressed. The lower end of the rod rests on the platform of the scale so that it is free to move up and down with it.

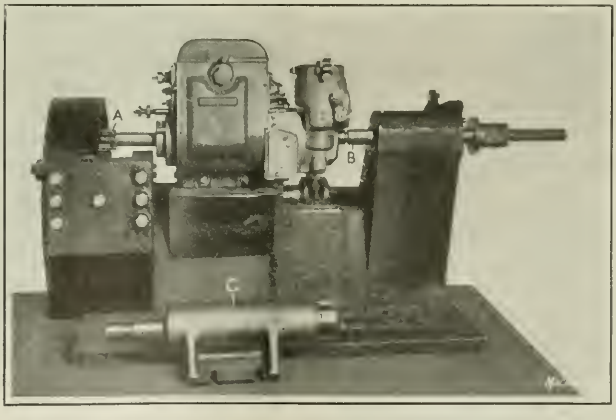


Fig. 13. Running-in Gage for testing Installation Conditions of a Motor Generator

In making use of the device, pointer *E* is first set to the correct graduated scale reading for the compression required. Rack *C* with pointer *F* is then moved down by means of the handwheel until the spring has been compressed beneath face *D* to the proper length. Then the weighing scale is read for the applied load. Rack *C* is then moved downward to compress the spring further, until pointer *F* coincides with pointer *G*, which has been set to the correct scale measurement, and the reading on the weighing scale indicator is again noted. It will be evident that pointers *G* and *E* can be independently adjusted to agree with any desired compressed lengths.

Testing Tension Springs

The auxiliary testing unit shown resting on the platform of the scale in Fig. 14 is used for testing tension springs by the aid of the device just described. The fixture, which is more clearly shown at *B* in Fig. 15, is set on the platform of the weighing scale so that surface *D* bears upon surface *H* of the auxiliary device. The spring to be tested is fastened to two projecting studs *I* and *K*, *I* being attached to part *H*, and *K* to the base of the auxiliary device. Stud *I* is then actuated by rack *C*, and the pull on the spring is transmitted through stud *K* to the platform of the weighing scale. It is evident that the application of the device is otherwise the same as that described for testing compression springs.

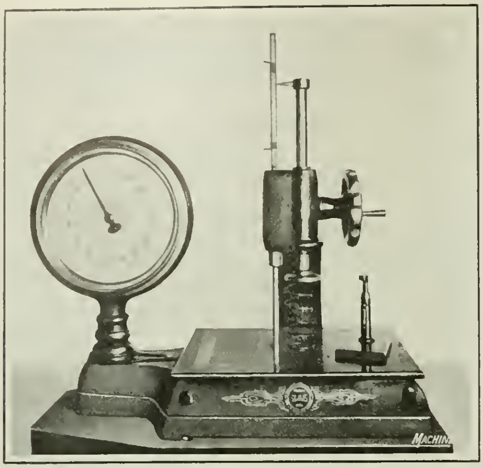

Fig. 14. Spring Testing Fixture

Gage for Testing Installation Conditions of a Motor Generator

The gaging fixture shown in Fig. 13 is employed for checking the relation of the center line of the armature of a motor generator to the center line of the crankshaft, and for detecting backlash between the armature pinion *A* and the

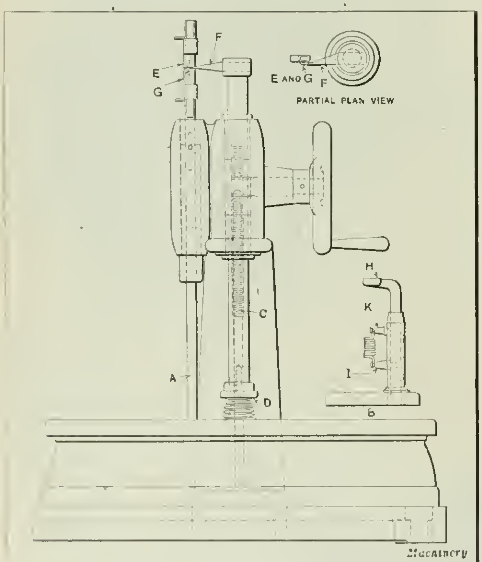

Fig. 15. Assembled View of the Spring Testing Fixture and Auxiliary Gaging Device for Coil Tension Springs

starting clutch gear. Also, when the motor generator is located properly in the gaging device, it is checked for gear noise, by running the motor generator as a motor from a storage battery. For testing the gaging conditions of the fixture, the master gage *C* is used, being mounted on the fixture with its shaft in the same relative position as that occupied by the armature pinion shaft. After the device has been located in this manner, it is replaced by the motor generator to be inspected. This fixture enables the actual installation conditions to be checked. The aligning gage *B* checks the center line of the coupling in the generator clutch with the center line of the pump shaft coupling.

Amplifying Gages

Figs. 16, 17, and 18 are views of three "American" amplifying gages—made by the American Gauge Co., Dayton, Ohio; these are used for the gaging and inspecting of different classes of work in the Delco plant, including practically all cylindrical work inspected in the grinding department. Fig. 16 illustrates the method of gaging cylindrical surfaces. An anvil is provided on which the work rests while it is rolled under the gaging point. A set-block gage is employed for first setting the dial of the amplifying gage to zero. This means of inspection provides a simple method of determining whether the work is within the required limits.

Fig. 17 shows the same type of gage applied to work held on centers for gaging the concentricity of the work in relation to the centers, and Fig. 18 is a similar type of gage employed for testing lobes of cams. One cam lobe after the other is passed under the gaging point, and the limits of accuracy are thereby quickly inspected.

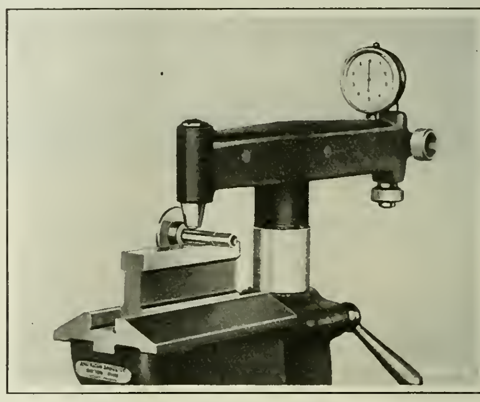

Fig. 16. Amplifying Gage for Small Cylindrical Work

Testing Spacing of Ignition Cams

Figs. 19 and 22 show an interesting device for testing the spacing of lobes or "breaking points" of cams for ignition distributors. The cam is secured on a central stud which

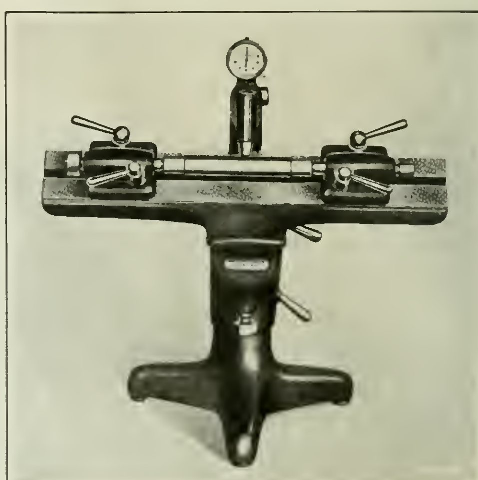

Fig. 17. Amplifying Gage used for inspecting Work held between Centers

is firmly fastened to the fixture. The dial *A*, which may be freely revolved, is mounted on a sleeve having a good running fit on the central stud. The dial is graduated around its outer edge in degrees. The fixture is provided with breaker arm *B* so that when the graduated dial is revolved, each lobe of the cam will cause the breaker arm to break contact and open an electric circuit, thereby extinguishing an indicating light. The cam is so set that the indicator points at zero with the breaker arm at the high point on one of the lobes and with the light out. As the dial is revolved about the cam, which is held tightly on the central stud by friction, if the lobes of the cam are accurately spaced, this is indicated by the fact that the light will go out at 45-, 60-, or 90-degree spaces, according to whether there are four, six, or eight lobes on the cam.

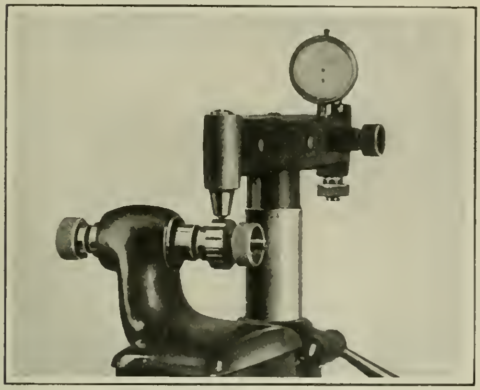

Fig. 18. Testing Lobes of Small Cams on Amplifying Gage

Plate Gages for Automatic Screw Machine Department

The examples shown in all the previous illustrations have been of inspection gages for the final inspection of assembled mechanisms and parts. A number of gages are used in the manufacturing departments both as working gages and as inspection gages that have a great deal of interest. One of these gages, shown in Figs. 20 and 21, is a plate gage for testing a shell after it has been finished in the automatics.

Fig. 19. Fixture for testing the Spacing of Lobes on Ignition Distributor Timing Cams

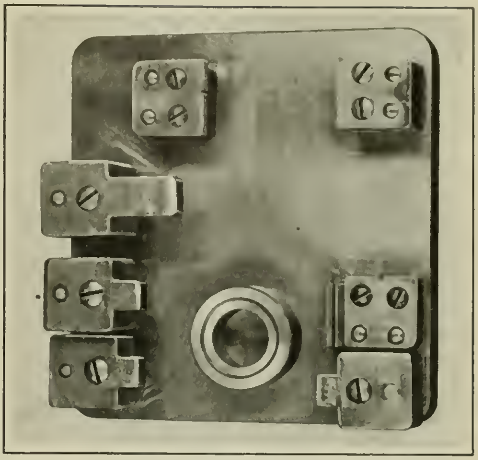

Fig. 20. Plate Gage for Inspecting a Clutch Shell

The fixture consists of a plate with a number of gage-blocks screwed to it, which constitute limit gages for different dimensions on the work. The center hole *G* of ring *A*,

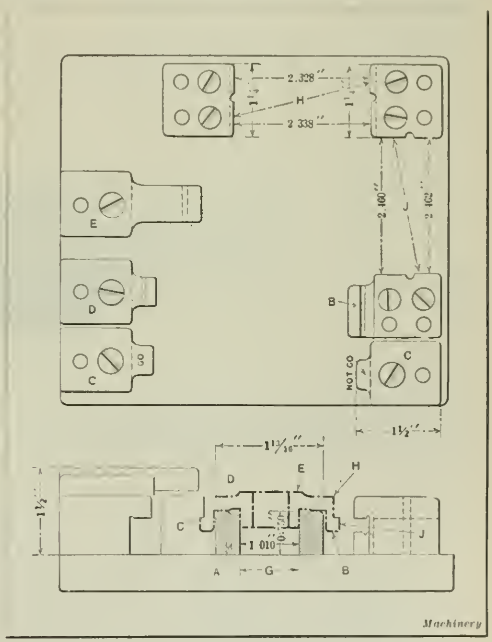

Fig. 21. Details of the Gage shown in Fig. 20

Fig. 21, is the "Go" size for the hub of the piece. The part, shown in dot-and-dash outline, is mounted on the gage-ring *A*, and is then slid under or between the various gages, as indicated by the corresponding letters in the elevation and plan view. The shoulder *C* in the elevation, for example, is gaged by the "Go" and "Not Go" gages *C* in the plan view; the shoulder *D* in the elevation by the limit gage *D* in the plan view; the face *E* by the limit gage *E*; the diameter *H* by the limit gage *H*; the diameter *J* by the limit gage *J*; and the surface *B* by the limit gage *B*. After the parts to be gaged have thus been moved around the gage plate and gaged on the various dimensions, plug gages are used to gage the center hole, thus completing the cycle of inspection operations. No further checking is necessary until other operations are performed on the piece. This group arrangement of inspection operations eliminates considerable inspection labor, and thus saves time.

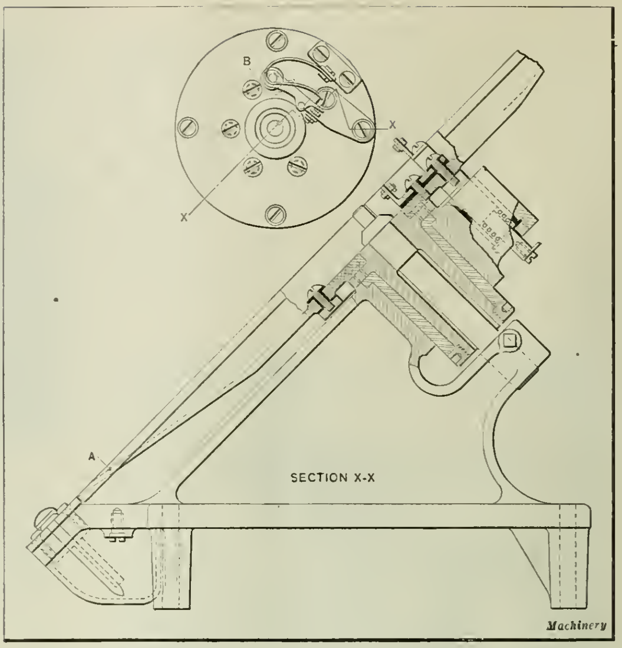

Fig. 22. Sectional View of Lobe Spacing Inspection Gage shown in Fig. 19

Gear Testing Devices and Clutch Roller Gage

Fig. 24 shows two simple gear testing fixtures intended simply for determining the free running qualities of gears. The fixture at the left is for spur gears, and the one at the right for spirals. The tooth thickness of the gear to be tested has previously been inspected, and the test for running qualities merely shows that the gears will assemble in the mechanism for which they are intended, without binding; that is, the center distance between the two studs on which the gear to be tested and the master gear are mounted during the test are placed at the minimum limit of the center distance in the frame into which the gears are finally assembled. The master gear used in the test, with which the gear to be tested runs, is made to the maximum limit of tooth thickness and outside diameter. In testing a gear in this way, there is absolute assurance of the free running of the tested gear.

The spiral gear testing fixture at the right tests the running qualities of spiral gears on the same principle as the spur gear fixture operates. The master gears both for the spur and spiral gear testing fixture are made soft, and are duplicates of the gears with which the gears being tested are to run, except that they are made to the maximum limits as already mentioned. To make sure that they represent in every way the actual working gears, they are cut on gear-cutting machines the same as the mating gears that will be assembled in the mechanism. These testing fixtures are used both for gears and for pinions, by simply changing the position of the masters.

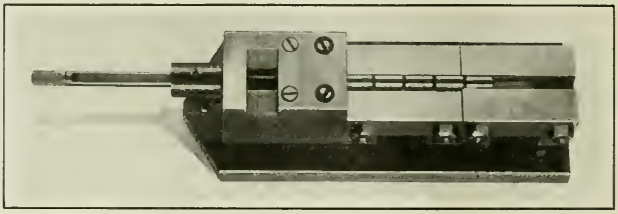

Fig. 23. Gage built up of Plates, which checks the Length and Diameter of Clutch Rolls

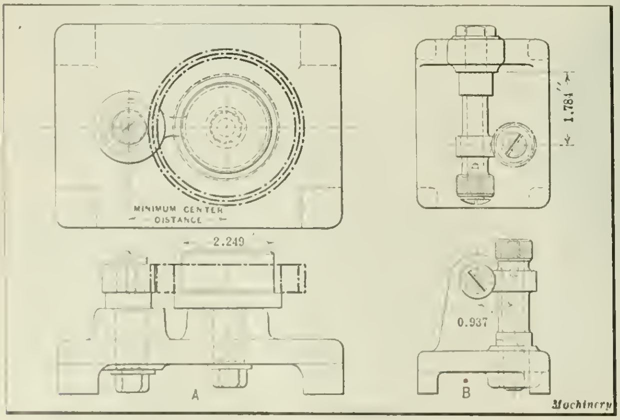

Fig. 24. Gear Testing Devices

A gage for checking lengths and diameters of rollers for clutches is shown in Fig. 23 and in the upper part of Fig. 25. This gage could be equally well applied to the testing of rollers for roller bearings or various other purposes. The roller is put into the gage in the receptacle shown at the left end in Fig. 23, and is then pushed through a hole and into a groove formed by gaging plates assembled on the baseplate. Block *A*, Fig. 25, permits the gaging of two different lengths of rollers, the block being removed or left in place, according to the size to be gaged.

The object of the gage is to prevent the passing of rollers that are too long, in which case they are unable to enter the gage at the receiving end. If the rollers are somewhat shorter than the opening in the gage, no harm is done; hence the gage checks only the maximum limit in regard to length. The roller, having dropped into the receptacle at the end, is pushed along by the plunger shown. If it is too small in diameter, it will drop through the opening at *C*, Fig. 25, which is set to the minimum limit. If it does not drop through here, it will pass along between the plates until it reaches section *D*, where it will drop through if it is within the maximum diameter limits. If it is too large in diameter, it will not drop through here, but will then be passed over the gage and ejected at the end. When worn, the gage parts at *C* and *D* can be readily removed, relapped, and replaced.

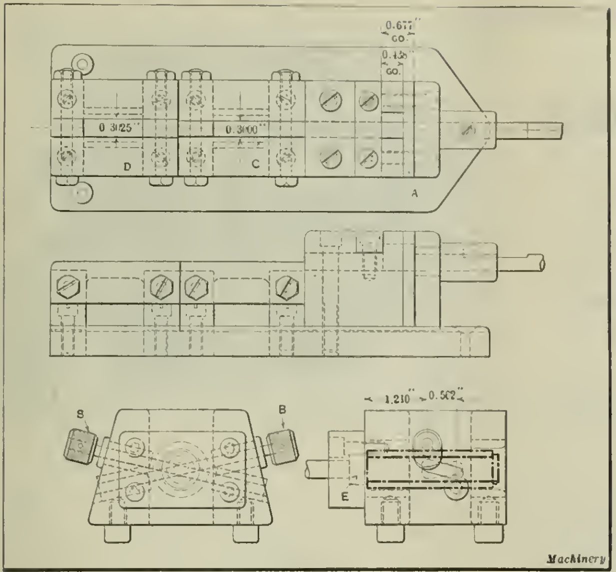

Fig. 25. (Above) Detail View of the Roll Gage shown in Fig. 23. (Below) Gage used for testing the Spiral Slots in a Sleeve

Testing Spiral Grooves in a Sleeve

An unusual type of testing fixture is shown in Fig. 26 and in the lower part of Fig. 25. These gages are used for gaging the location of two spiral grooves in a sleeve, the sleeve being shown in the upper part of Fig. 26. In this sleeve there is one spiral groove on each side that must have a definite relation to the groove on the other side. The relation of these grooves to the center hole of the shaft as well as to the outside diameter and ends of the shaft is also checked by this gage. To test this part it is passed through a hole in the gage, as more clearly shown in Fig. 25, where the sleeve is indicated by dot-and-dash outline, and pushed against a stop *E* at one end, which also acts as an ejector after the gaging. With the part in place, the two plungers *B* are pushed in. These must be able to pass clear through the spiral slots in the piece. The fixture shown in Fig. 26 is used for gaging spiral grooves and for additional gaging of the work. With this fixture the testing of the milled grooves at the other end of the piece is accomplished by means of plungers *C*. Plunger *D* is a "Go" and "Not Go" gage, which tests the length of the part.

THE RIGHT ATTITUDE TOWARD THE JOB

By WILLIAM C. BETZ

During the present business depression any man having a job should realize that it is to his advantage to do all in his power to produce work economically, because costs must be cut in order to bring back business. He must understand that wages will have to come down with other things. A man is injuring his own chances by nursing a grouch, lying down on his job, or criticizing the management because of the necessity of reducing hours of work, or wages, or both.

A great many workmen today apparently believe that manufacturers are holding up orders with a view to bringing down wages. To believe such statements is the height of folly, for surely no manufacturer would tie up his equipment while paying taxes, insurance, interest, and many other expenses which must be paid whether the plant is in operation or not. Any thinking man will find it impossible to believe that the firm should go on losing dollars in that way in order to gain cents.

The firm with which the writer is connected is doing everything in its power to obtain business to keep its steady and capable employes busy, and any man who has the least idea about business should be able to understand that no firm would refuse an order in these times. It is a case of the survival of the fittest, both as regards firms and individuals, in the machinery business for years to come, and the man that goes to work with a determination to produce better and cheaper than he has ever done before is the man who is going to be kept on the payroll as long as the firm can keep that payroll going.

It may be of interest to state a comparison of prices of goods manufactured in this country and in Europe. A firm in Milwaukee is making a certain device which it cannot sell, according to its own statement, for less than $120, and yet the best possible equipment is being used in its manufacture. A German firm, after paying transportation and tariff on an identical machine, sells it in the United States for $22.50. This should bring home to the American workman the necessity for cutting costs to the core.

It has often come to my notice that the men who are the most fault-finding about working conditions and wages and who deliberately lie down on the job, are the men who feel that a great injustice has been done to them when they are laid off on account of lack of work.

* * *

The oldest iron manufacturing plant in Austria, employing furnaces using wood charcoal, has been in operation for over six hundred years, according to a Commerce Report. This plant, which is located at Vordenberg, was forced to shut down three years ago by being supplanted by the larger furnaces at Donawitz which employ coke as fuel. As a result of the present difficulty of securing coke, however, work has been resumed at the Vordenberg plant where five carloads of pig iron per day are being produced at about the same cost of production as at the Donawitz plant.

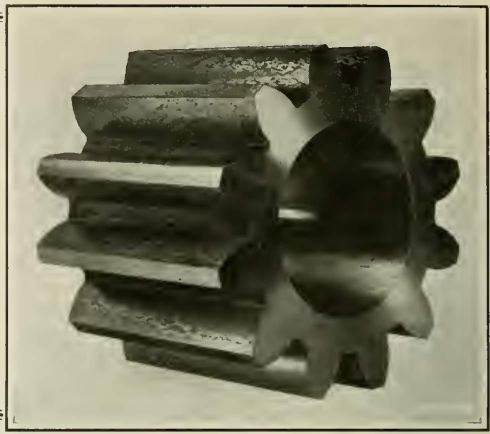
Principles of Maag Gearing

An Analysis of the Maag System of Gearing, Advantages that are Claimed for this Type of Gears, and Machines for their Production



THE main objective in choosing a curve for the profile of gear teeth is the fulfillment of the requirement that two toothed wheels, when meshed together, shall have the same relative angular velocities as two given disks would have if their edges touched and no slipping took place. Theoretically, a variety of forms can be given to the teeth of one gear from which complementary teeth can be determined for the other so that the required ratio is obtained. The curve obtained by rolling a circle of infinite radius on one of finite radius is known as the involute. Its advantages for tooth form are well known; not the least is the fact that the center distance between two meshed gears with involute teeth can be varied, so long as the involutes are in contact, without disturbing the constant relative angular velocity of the gears. The only requirement for maintaining this constant relation between gears is that at any moment the common normal to the contacting faces must, if produced, pass through the pitch point or point of contact between the imaginary disks.

Difficulties Encountered with 14½-degree Pressure Angle

With involute teeth, provided the center distance is maintained, these normal lines are always coincident, and the usual practice has been to so form the involute that this normal is inclined at 75½ degrees to the common center line of the gears, the pressure angle thus being 14½ degrees. The normal is tangent to two base circles concentric with the imaginary disks, the base circles being of the same proportionate diameters as the disks and of such size that the tangent touching each is at an angle of 75½ degrees with the center line of the gears. Other angles besides 75½ degrees have also been used as standards.

The strict adherence to a common normal or pressure angle of 14½ degrees brings with it endless difficulties in gears with few teeth, and all sorts of "corrections" have been suggested to overcome them. Since the base circles to which the common normal is tangent must be in a strict relation to the velocity ratio desired, it follows that, if normal proportions of addenda and dedenda are followed and one gear has very few teeth while the other has a large number, the base circle of the smaller gear will be very near to the pitch circle, while the base circle of the larger gear will be relatively further from its pitch circle. Since the involute curve cannot exist within the base circles, it follows that only a very short portion of the teeth of the small gear below the pitch circle will be of involute form. Another difficulty crops up since the crests on the tooth addenda of the larger gear sweep out more or less of the bottom of the teeth on the smaller gear, under-cutting them so that not only are the teeth weakened, but in gears with few teeth, part of the involute, short as it is, is also

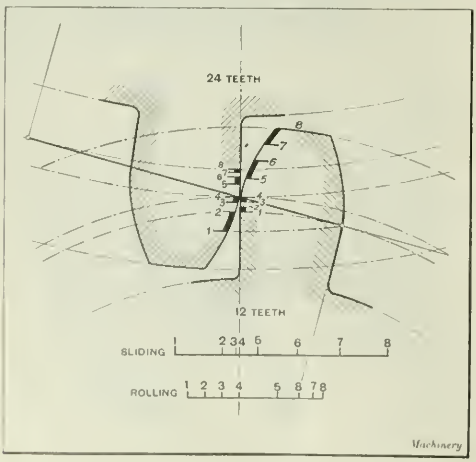


Fig. 1. Diagram showing Amount of Sliding and Rolling Contact on Gear Teeth having a Standard 14½-degree Pressure Angle

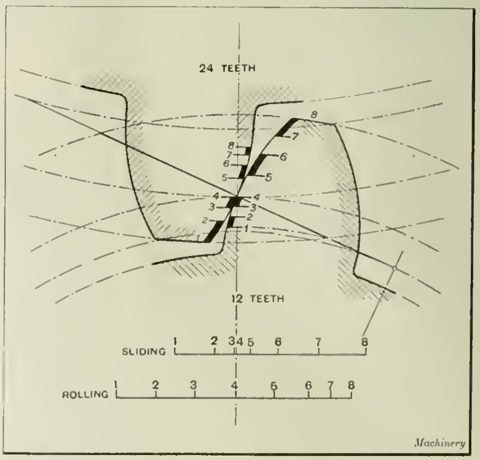

Fig. 2. Sliding and Rolling Contact on Teeth of Gears of Same Ratio as in Fig. 1, but with a Pressure Angle of 22 Degrees 55 Minutes

removed and, therefore, this important part near the pitch circle is of no purpose. For these reasons, pinions with a smaller number of teeth than twelve have not been recommended.

Effect of the Pressure Angle on the Shape of the Teeth

In Fig. 1 are shown teeth of a 12-tooth pinion and a 24-tooth gear in mesh; the common normal passes through the pitch point and is tangent to both base circles. The pressure angle is drawn at 14½ degrees. It will be noticed that in each case a large proportion of the tooth flanks is below the base circles, and therefore cannot be involute. This is especially the case with the pinion tooth. Fig. 2 shows teeth of gears having the same ratio but with the pressure angle and tooth proportions chosen to give a better shaped pair of teeth. In this case the pressure angle is 22 degrees 55 minutes. It will be noticed that a reduction in the diameter of the base circles improves the tooth shape, and it is interesting to compare the usefulness of these profiles with those in Fig. 1.

By dividing into three equal parts the profile of the pinion between the pitch and base circles (Fig. 1), and striking from the center of the pinion circular arcs from these divisions to the normal line, the position during rotation at which these several points will contact with the other tooth face may be determined. From the points located on the normal line, draw arcs about the gear center to the tooth flank of the gear. In this way the corresponding points of contact are obtained. Thus, points 1, 2, 3, and 4 on the pinion tooth contact at points 1, 2, 3, and 4, respectively, on the gear tooth. It will be seen that about one-half of the addendum of the gear tooth is useless. By dividing the addendum profile of the pinion tooth into four equal parts and proceeding as before, contact points 5, 6, 7, and 8 on the pinion tooth, and 5, 6, 7, and 8 on the gear tooth may be obtained. By proceeding similarly with the teeth shown in Fig. 2 the better utilization of the tooth faces in this illustration will at once be apparent.

Comparison of Sliding and Rolling Contact

Again, by comparing the distance between points 1 and 2, 2 and 3, etc., on each tooth, the sliding and rolling between the faces can be followed. For example, in Fig. 1 the distance between the points 1 and 2 on the pinion tooth is very short, while on the gear tooth it is comparatively long. The difference in length between these points on the two teeth is a measure of the sliding which will occur during action between these portions of the tooth profiles. The shorter distance represents the distance of the rolling contact. These measures so obtained are shown enlarged on the scale below the diagram; the same procedure has been followed in Fig. 2. The advantage of choosing a pressure angle and pitch circle position relative to the teeth, to suit the gears, is at once apparent. By maintaining a standard 14½-degree pressure angle and keeping to standard tooth proportions as in Fig. 1, about two-thirds of the tooth flank is useless, and the wear on the part that is used is increased proportionately. The sliding contact is reduced in Fig. 2 by about 11 per cent, and the rolling contact increased by about 75 per cent, while the thickness of the teeth at the root is as about 1.3 to 1 as compared with that in Fig. 1.

It has sometimes been the practice to improve pinions with a small number of teeth by keeping the pressure angle at 14½ degrees, and increasing the addendum and correspondingly decreasing the addendum of the gear, the dedenda being modified accordingly. With large gears and small pinions the results are not unsatisfactory, but such a compromise is of decreasing value as the number of teeth of the gears becomes less than about 40, since the improvement of the pinion is made at the expense of the gear teeth.

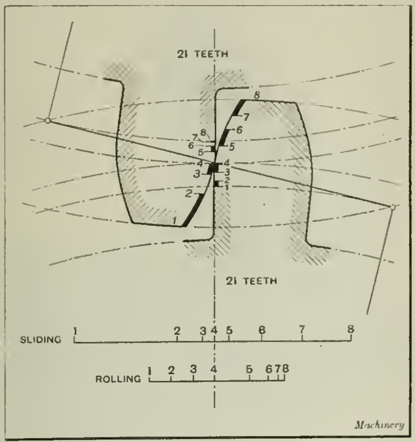

Fig. 3. Comparison of Sliding and Rolling Contact on Two Gears having 21 Teeth and 14½-degree Pressure Angle

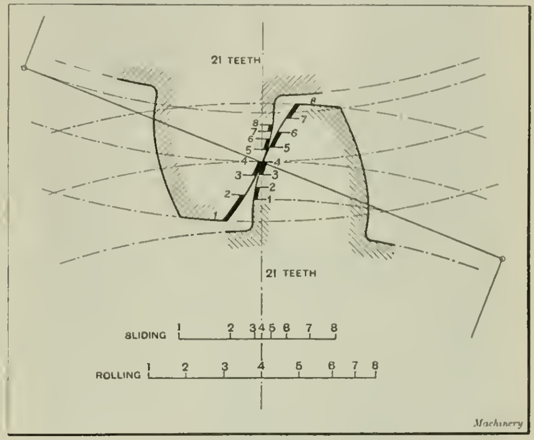

Fig. 4. Profiles of Teeth of Two Gears of the Same Ratio as those in Fig. 3, but with a Pressure Angle of 21 Degrees 44 Minutes

Another interesting gear ratio is 21 to 21; Figs. 3 and 4 show the teeth for gears of this ratio and pressure angles of 14½ degrees and 21 degrees 44 minutes, respectively. By following the same procedure as in Figs. 1 and 2, the comparison has again been made between sliding and rolling contact. The useless radial portions of the tooth flanks are again evident, and a comparison of the distances between points 1 to 2 on each is striking. The improvement following the adoption of a pressure angle and tooth proportions better suited to the gear ratio is evident as regards tooth shape, active profile, and proportion of rolling to sliding contact. As a further illustration, Fig. 5 shows the teeth for gears having a 5 to 50 ratio and a pressure angle and tooth proportions chosen to obtain the most satisfactory pair possible. While these teeth are kinematically correct, of ample strength, and have good wearing qualities, they represent an extreme case and are not to be recommended except where necessary to meet some unusual condition.

Principles of the Maag Gear System

One of the main arguments advanced in the early days of the involute gear was that a pressure angle of 14½ degrees meant a considerable increase in the force tending to separate the bearings of mating gears, and no doubt this fear was at the root of the failure to take full advantage of the properties of the involute for gear teeth. In the system

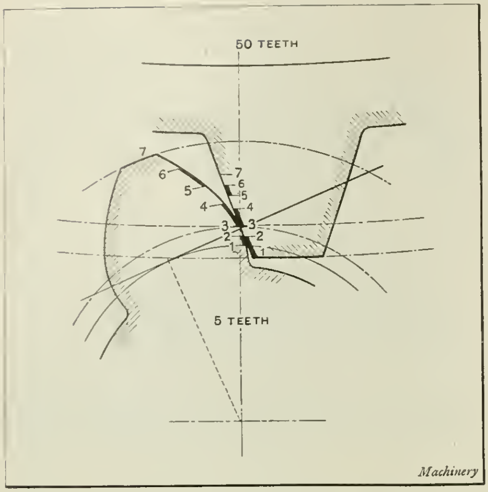

Fig. 5. Teeth of Gears of a 50 to 5 Ratio, with Pressure Angle and Proportions chosen to obtain the Most Satisfactory Combination

developed by Max Maag, Zurich, Switzerland, all standards for pitches, relations between addenda and dedenda and pressure angles are subsidiary, that is to say, each ratio is treated on its merits, and any pitches are therefore possible. Although the smallest number of teeth calls for pressure angles of 25 degrees if satisfactory teeth are to be obtained, this only means an increase of 6.6 per cent in the tooth pressure, while in less extreme cases where a pressure angle of, say, 20 degrees meets the requirements, the increase in the tooth pressure is only 2.7 per cent.

The increases in tooth pressure are, of course, inversely proportional to the cosines of the pressure angles. As far as the bearing load is concerned, it is claimed that although, for a pressure angle of 20 degrees, the pressure component in line with the two centers is increased 32 per cent, the increase being proportional to the sine of the angle, this involves no extra pressure on the bearings, since the same resultant pressure has to be sustained in any case. Any pair of components giving this resultant pressure will have the same effect, the only difference being one of direction. The increased tooth pressure amounting to 6.6 per cent for a 25-degree pressure angle is, therefore, the only increase of load on the bearings, while the advantage of really efficient gears having a small number of teeth may be considered to outweigh fully any disadvantage on this score. The independence of the center distance between gears having involute teeth overcomes the seeming complexity of a large number of arbitrary pressure angles. Neither need there be any clinging to well-defined pitches, and a designer can fix his center distances and pitches strictly as called for by any conditions that arise in the designing stage.

Using Standard 14½-degree Rack Cutters

If a pair of gears of a definite ratio is required and the best pressure angle and tooth addenda and dedenda have been decided upon, ignoring any standard proportions to get an efficient tooth, it is possible, within well-defined limits, by taking advantage of the properties of the involute, to cut these gears with a standard 14½-degree rack cutter. It is clear that one imaginary circle on the gear blank will be equal in circumference to the number of teeth cut multiplied by the pitch of the cutter. This imaginary circle will be the normal pitch circle for that particular rack, and no matter what depth the teeth are cut into the blank, this pitch circle will remain the same.

If this gear is mated with another produced by the same cutter, they will work correctly together at a pressure angle of 14½ degrees, if the center distance equals the sum of the halves of the pitch circle diameters. The pressure angle will vary, but the velocity ratio will be correct and uniform with any other center distance at which the teeth will mesh. This may have the effect of producing backlash if the teeth have been cut to the standard depth, but if the degree to which the gears are to be separated is known, the cutter can be fed to a lesser depth in one or both gears just sufficiently to prevent backlash, and the gears will have different pitch circles and a new pressure angle.

Working backward, the position relative to the teeth at which the pitch point is to occur can thus be determined, and also the outside diameters and the radii of the base circles. The position along the profile where the 14½-degree rack tooth flank will be tangent can be calculated, this point giving the radius of the normal pitch circle for cutting with the 14½-degree rack cutter. In this or any other rack system of gear cutting, it is possible, in general practice, to use only a stepped series of pitches. The teeth of the gears must be such that the involutes cut the pitch circle for a pressure angle of 14½ degrees, at points, the distances between which correspond to a circumferential pitch equal to the linear pitch of the rack cutter available.

There can be no doubt that the involute without corrections or under-cut of any kind is the right line of development for gears. Under the Maag system, in the case of pinions having small numbers of teeth, the so-called pressure angle and the fixed position of the pitch circle relative to the teeth, are abandoned. However, a 15-degree pressure angle is maintained for gears with a large number of teeth, the angle being increased and the blank diameters varied as required to obtain the most satisfactory teeth that can be obtained for gears with a smaller number of teeth.

The Maag Gear Generating Machine

A Maag gear generating machine for cutting gears up to 40 inches in diameter is illustrated in Fig. 7. A rack type tool cuts on the down stroke, being backed by a spring-tempered plate, which enables the tool to be used even when thin from repeated grindings. The faces of the rack-cutting teeth are ground concave to give a small amount of top rake to the cutting edges. The tool-holder is pivoted horizontally

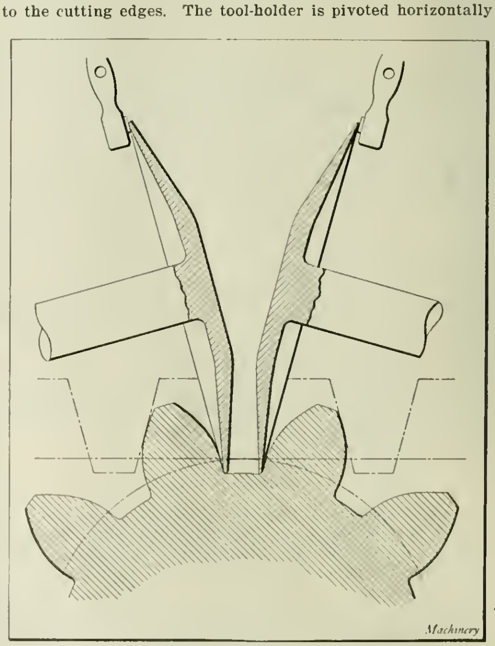

Fig. 6. Operating Principle of the Maag Gear-grinding Machine

in the ram, the tool being depressed positively at the end of each downward stroke, to provide clearance on the upward stroke. The blank remains stationary during the cutting stroke, and the indexing movement takes place during the return stroke. The cutter-head can be swiveled to cut helical gears, the setting being determined by means of a vernier scale which indicates readings to within 1 minute. The ram is driven by a slotted link giving a quick return. The stroke can be adjusted by a handwheel from the rear, and this can be done while the machine is running. The ram is counterbalanced, and the connecting-rod driving the ram is in two parts which are connected by a cast-iron sleeve that acts as a safety device, breaking if overloading occurs. The drive is controlled by a cam clutch which is connected with a brake, so that the movement of the tool can be controlled and stopped at any position.

In the generating movement given to the gear blank, the rotary motion is obtained through a worm, and the transverse motion through a feed-screw. The blank is set at the required position relative to the cutter, which always cuts at the full tooth depth, the generating cut being preceded by gashing. The setting is read on a scale and vernier. Fig. 8 shows a rear view of the machine. Several sizes of the machine are made, including those for the large gears used in turbo-reductions. In this country the Niles-Bement-Pond Co. is building a machine for cutting spur, helical, or herringbone gears up to 40 inches in diameter.

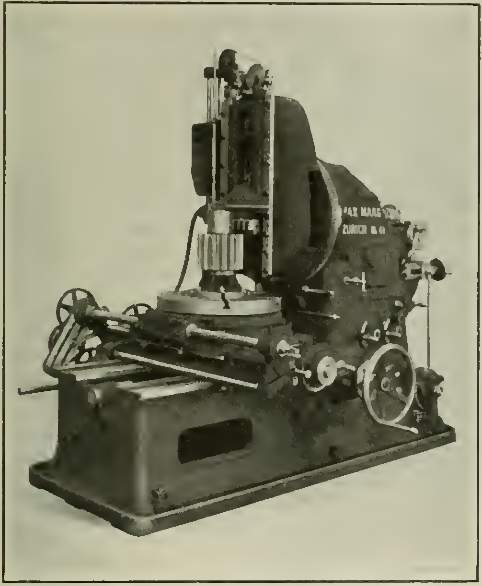

Fig. 7. Maag Gear Generating Machine provided with a Rack Cutter that cuts on the Down Stroke

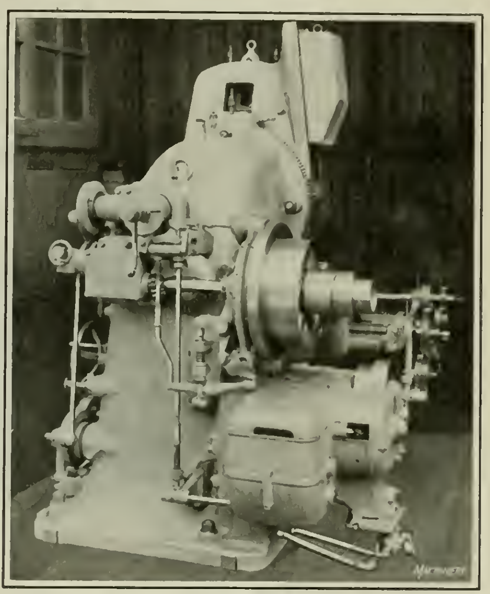

Fig. 8. Rear View of the Maag Gear Generating Machine illustrated in Fig. 7

Operating Principle of Maag Gear Grinding Machine

The distortion which occurs in hardening has a decided effect upon the efficient working of gears. It is useless to pay considerable attention to the cutting of accurate tooth profiles concentrically arranged around a center if the tooth conditions are upset in the subsequent hardening. The distortion produced in hardening Maag gears is corrected by grinding on a specially developed machine, the principle of which is shown diagrammatically in Fig. 6.

The problem in developing this machine was to secure a movement of grinding wheel faces in true planes parallel to the gear axis, the planes to include the profile of the rack tooth flank. The flat face of a grinding wheel has disadvantages, since the plane surface is quickly destroyed. This difficulty was overcome by the use of saucer-shaped wheels of which only the edges lie in the plane referred to. Generation is effected by feeding the gear tooth space under a pair of such wheels, the gear at the same time being rolled alternately in each direction an amount sufficient to generate to the full extent the involute required for the teeth profiles. The wheel edges are generally set 15 degrees from the vertical. When the teeth are small, both wheels cannot occupy the same tooth space, and so in such cases one wheel operates on the corresponding flank in the next space or the next space but one.

As the wheel wears, which is likely to take place quickly owing to the small area in contact, especially if soft wheels are used, the planes come nearer together and the teeth would become thicker as the work proceeded, if a remarkably effective compensating device were not provided. Near the upper edge of each wheel is a pivoted arm carrying a flat ground diamond. Every six seconds or so the diamonds are allowed to advance to the edges of the rotating grinding wheels. If the edge is still in the predetermined plane, the diamond touches the wheel and the lever is held up at this point. However, if the wheel has worn slightly, the diamond must advance further to touch the edge, and in so doing an electrical contact is made, and the wheels are fed outward 0.001 millimeter (four hundred-thousandths inch). It is claimed that the wheel edges are kept to the required plane within this degree of accuracy.

Construction of Maag Gear Grinding Machine

Fig. 9 shows a Maag grinding machine for gears up to 16 inches in diameter. The grinding wheel spindles are seen at *A*, each being driven by an independent motor which, through a light belt and worm-gearing, drives continuously a camshaft that rotates and permits the advance of the diamond as explained. A quick adjustment is provided for use when setting new grinding wheels. The continued adjustment of the grinding planes enables quick-cutting soft wheels to be employed. The spindles, with their ball bearings, are self-contained in sleeves that enable them to be changed easily. The spindle slide motion and compensating mechanism is a self-contained unit that can be swiveled to give the equivalent of a rack of any pressure angle. The units are carried on horizontal slides independently adjustable for setting the width of the ground tooth space, and the depth of tooth is set by the handwheel at the top of the machine, vernier scales showing the position accurately in each case. It is also possible to adjust vertically to enable different sizes of wheels to be used together. A diamond dressing attachment *C* enables both wheels to be dressed accurately as to height when the vertical scale reads zero.

The work carriage has a dead center at its inner end, and an automatic dividing head at its outer end. In addition to the movement for one passage from end to end of each tooth space under the grinding wheels, the carriage has to make several short cross traverses to supply the rolling movement to the work for generating the involute profiles. The bottom slide, with the work, is fed under the grinding wheels by a screw, the travel being adjustable according to the width of the work. The upper or rolling slide also has a variable stroke, and is driven by a slotted crank disk arranged horizontally at the far side of the machine.

The dividing spindle, which also carries the work, is mounted on the upper slide carrying the division plate, while the locking pawl that engages with the plate is carried by the aluminum circular housing *D*, which is mounted on a sleeve or outer spindle surrounding the dividing spindle. On the outer end of this sleeve are mounted four segmental blocks of equal diameter. Nine sets of these blocks are provided, corresponding to nine convenient pitch diameters. Four steel ribbons wrap around the circumferential parts of the segments, two passing to one side of the machine and two to the other, the free ends being secured at points *E*. The securing blocks are carried in a frame *F*, and can be partially rotated to adjust the ribbons by means of the heads *H*. The frame can be raised or lowered on vertical slides so as to bring the ribbons in a horizontal position for various segmental block sizes.

If the wheel being ground has an imaginary pitch diameter corresponding exactly to the segmental ribbon blocks in use, the work-slide is reciprocated during the traverses under the grinding wheels and the ribbon frame carrying blocks *E* remains fixed. A to-and-fro rolling motion along the pitch circle is thus given to the work. If the nominal pitch circle of the gear is not equivalent to that of an available set of segmental blocks, the ribbon carriage is also given a reciprocating movement that compensates exactly for the difference in pitch diameter, and this is originated by the cross-slide. The movement is transmitted by the slotted bar *J*, which rocks on a vertical axis that can be altered to vary the ratio of the two arms of the rocking bar.

The travel forward of the work during each short rolling motion is dependent on the finish required, 1/32 inch being suitable for a medium sized tooth when finish-grinding. Grinding takes place during both the in and the out travel of the main slide, and indexing occurs when the wheels are clear at either end. A pinion on which the teeth were ground on a Maag grinding machine is shown in the heading illustration. The hatched effect given to the teeth by the grinding wheels is very noticeable. When an indexing is to occur, the feed of the main slide is stopped and the position maintained by a solenoid lock. The gear-box, from which the slides are driven, is seen at the extreme outer end of the bed. The main driving motor is placed behind the gear-box, which it drives through worm-gearing. Four speeds are provided for the rolling slide, and four for the feed-slide.

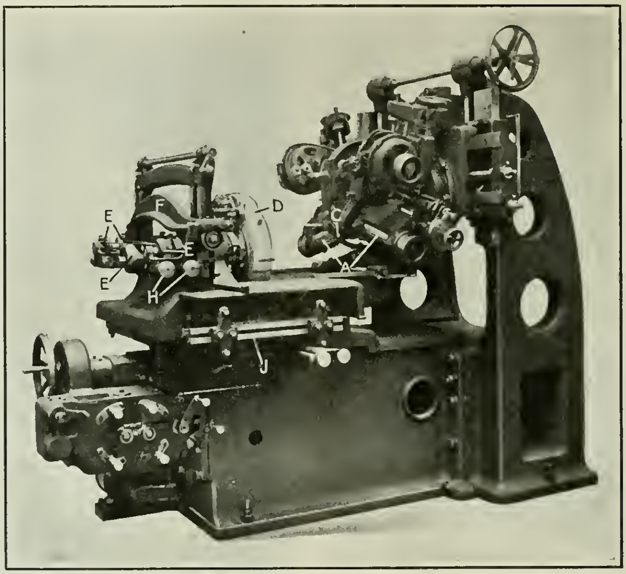

Fig. 9. Grinding Machine with Two Wheels used for grinding Profiles of Maag Gears

Applications of Maag Gears

Hardened and ground gears produced on Maag machines and designed without regard to standard pressure angles are in fairly extensive use. This is especially the case in Switzerland, where the state railways use them for motor drives on 2000- and 2500-horsepower electric locomotives. They are used almost exclusively on street-car motor drives in that country. In turbine reductions there are several instances in which double helical gearing has been superseded by straight-cut Maag gears, the pinions being hardened and ground. It is claimed that since the grinding operation produces a true tooth form and concentricity, the pinion acts as a master to the softer teeth on the gear, which are thus burnished and any irregularities corrected. In several turbine installations the gears run silently at the high peripheral speed of 13,400 feet per minute with no other lubrication than that supplied by leakage from bearings. The Niles-Bement-Pond Co. has the exclusive American rights to the manufacture of Maag gears. The Pond Works, Plainfield, N. J., have cut gears up to 80 inches in diameter, while the Pratt & Whitney Co., Hartford, Conn., has cut and ground gears up to 16 inches in diameter.

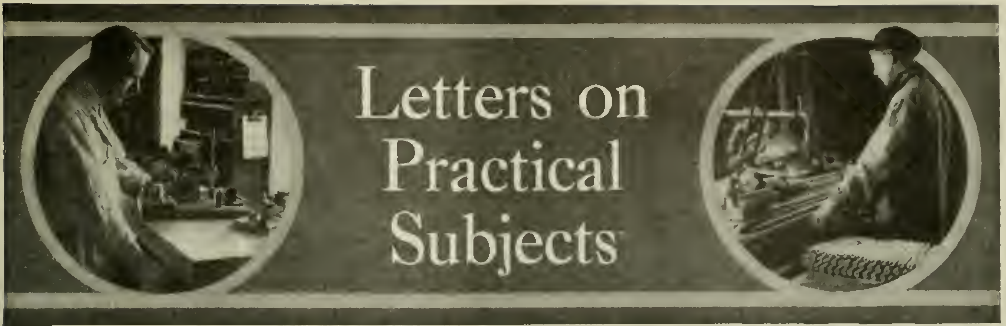
INDUSTRIAL CONDITIONS IN SWEDEN

The difficulties at the present time experienced by the Swedish industries were first felt in the metal and machine industries as early as 1919, but the depression did not become particularly acute until the last months of 1920. Out of the 120 blast furnaces in Sweden, only 42 were active in December, 1920, and the production of iron and steel was lower than for a great many years past. During the latter part of 1920, Germany offered severe competition, quoting prices in the Swedish markets lower than the bare cost of labor and materials in Sweden. Wages in Sweden are now three times as high as before the war, and the labor efficiency less, so that the actual labor cost per unit of production is four times as high.

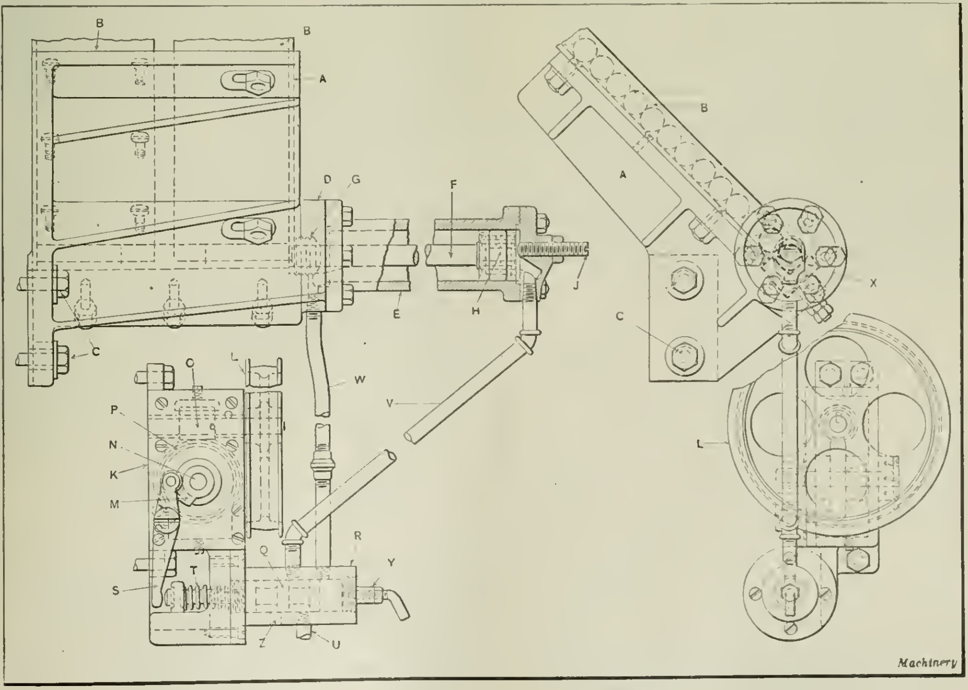


PNEUMATIC FEEDING ATTACHMENT FOR CENTERLESS GRINDER

The accompanying illustration shows a feeding attachment which has been successfully applied to a centerless grinder of the Detroit Tool Co.'s manufacture. This device is designed to handle rolls and pins of various diameters and lengths, the range of adjustment making it particularly well adapted for use in grinding parts employed in automobile construction, such as engine wrist-pins, valve rollers, etc. In designing this attachment, the writer was handicapped by lack of space around the grinder. This necessitated the use of a compact fixture, the stroke of which could be controlled without cumbersome and expensive mechanisms. Reference to the illustration will show that the feeder is operated by air, and is so designed that it can be easily controlled by an inexperienced operator. The advantages of a pneumatic device of this nature are: The ease with which the length of stroke can be adjusted; the adjustable slow feeding feature; and the rapid return movement of the feeding plunger.

It will be noted that the cast-iron slide *A* is provided with elongated bolt holes to permit the adjustment of the sheet-metal sides *B* to accommodate rollers or pins of different lengths. The slide can be made as long as desired and adapted for holding any length of work within the capacity of the feeding mechanism. The chute is bolted to the grinding block of the machine by means of bolts *C*. A flange *D*, cast integral with the chute, carries a bronze cylinder *E* fitted with a piston-rod *F*, a suitable packing-box *G*, and a properly packed piston *H*. The length of the stroke is adjusted by the headless set-screw *J*.

A small gear-box *K* is bolted to the side of the grinder. The pulley *L* of this gear-box is driven by a belt from the lineshaft or a countershaft. A cam *M* keyed to the worm-wheel shaft *N*, which is driven by worm *O* and worm-wheel *P*, actuates the plunger valve *Q* in the bronze cylinder *R* through the medium of lever *S* and spring *T*. The speed of the gear-box pulley *L* controls the number of strokes per minute of the feeding rod *F*. The point at which the air supply pipe *U* enters the cylinder *R* must be carefully located, that is, it must be correctly positioned with respect



Air-operated Feeding Attachment for Centerless Grinding Machine to the bored holes which lead through pipes W and V to and from cylinder E. In the illustration the plunger valve Q is shown in such a position that the air will travel up pipe V and enter cylinder E at its outer end. The air entering at this end of the cylinder, forces the piston H inward against the resistance of the air in the opposite end of the cylinder. The air thus forced down the vertical pipe W enters the outer end of cylinder R where it escapes through a small needle valve at Y.

A moderately fast or a very slow stroke of the feed-rod can be obtained by adjusting valve Y. When the valve is so adjusted as to permit the air to escape slowly from the inner end of cylinder E, the feed-rod F will move forward slowly, while if the valve is opened to permit the air to escape more rapidly, the feed will be faster. The return of piston H is accomplished when the valve Q, actuated by cam M, simultaneously opens exhaust port Z and the inlet port of pipe W. With the valve in the latter position, the air is quickly exhausted from one end of the cylinder through pipe V and opening Z while the air from the feed-pipe W, acting on the inner side of piston H, forces the latter quickly toward the outer end of the cylinder until it reaches the position shown in the illustration. When plunger F reaches the end of its outward stroke, a roll or pin, as the case may be, drops down by gravity into the feeding position, when it is carried forward into contact with the grinding wheel by the slow-feed stroke. The operation of the device is therefore automatic and continues as long as the feed-slide is supplied with work. The V-shaped block X is so designed that it is possible to adjust it in order to bring work of different diameters into the proper feeding position.

Rochester, N. Y. A. H. Schwab

SELF-ADJUSTING LATHE DOG

In a large factory devoted to the manufacture of textile machinery considerable difficulty was experienced in turning cast-iron drums for carding machines. These drums consist of a cast-iron cylinder of the shape shown in Fig. 1. and are about 5 feet long and 4 feet in diameter. At each end is a central hub supported by a set of six arms or spokes. When assembled in the carding machines and in operation, these drums maintain a relatively high surface speed. As no heavy loads are applied to them, it is desirable that they be of light weight construction.

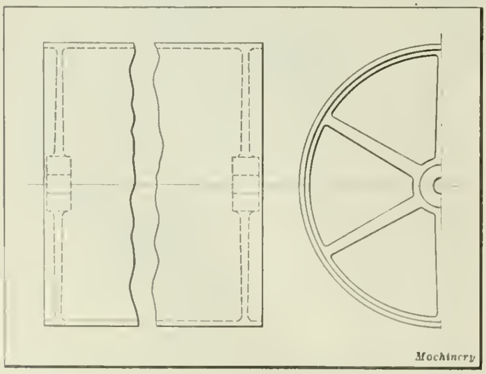


Fig. 1. Cast-iron Drum used in Textile Machine

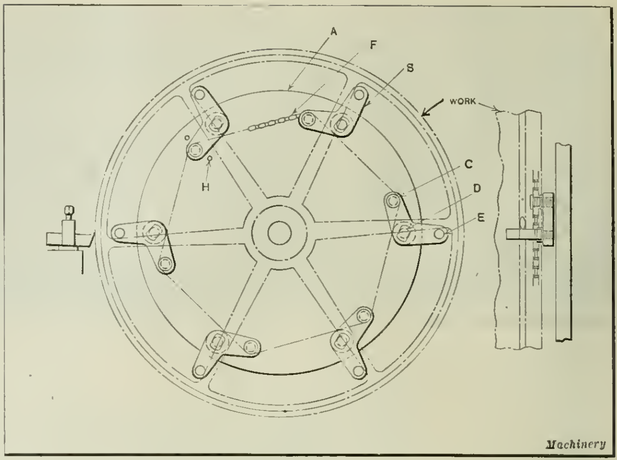

Fig. 2. System of Multiple Dogs for Lathe used in turning Drum shown in Fig. 1

While lightness is an advantage so far as the functioning of the drums in the carding machine is concerned it proved a drawback from the manufacturing point of view. When properly centered in the lathe, the outer surface is turned down to finish, and on account of the large dimensions a considerable amount of stock must be removed to give a clean surface all over. It often happens that some portions of the middle part of the rough casting will run out 3/8 inch or more, and it is a slow job to finish even the best castings.

A light cut and slow feed must be applied; otherwise the spoke in contact with the lathe dog will break off, thus ruining the drum. As it was impossible to have more than one fixed driving point, a system of self-adjusting multiple driving dogs was tried out which proved very satisfactory. The construction of this device is shown in Fig. 2. In this illustration A represents the lathe faceplate and B the main part of one of the six driving dogs. These dogs are made of cast iron of suitable dimensions and of approximately the form shown in the illustration. They swivel on a stud D fastened to the faceplate.

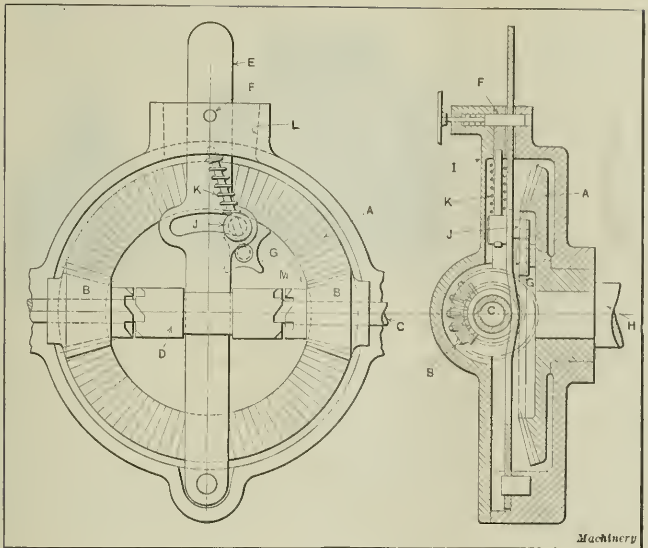
At E is shown one of the driving studs which make contact with the arms or spokes of the drum. There are also six studs C which are provided with flanges and which carry an endless block chain F. The six dogs are fastened at the proper distance and spaced 60 degrees apart. The chain is of suitable length and allows each driving pin to exert the same power on each spoke. Twelve pins H, only two of which are shown, are driven into the faceplate to prevent undue movement of the parts when idle.

With the drum in place and the lathe started, each of the six dogs will drive its respective spoke with an equal driving force. By this method of driving, a deeper cut and a higher feed are used, and the breakage is reduced to practically nothing, which results in a greater output.

New York City C. G. Youngquist

A RECIPROCATING MECHANICAL MOVEMENT

The type of mechanical device described and illustrated in this article is used for producing the reciprocating motion of a washing machine. The device is compact, and has but few parts to require attention. The working parts are contained in an enclosed case, which may be cast from any suitable material and which is provided with a cover I, attached to the case in any convenient manner. The working parts consist of a bevel gear A with which two bevel



Mechanism for producing a Reversal of Rotary Motion

pinions *B* mesh. These are a running fit on the shaft *C*. and should be provided with phosphor-bronze bushings and backed with a substantial flange or end thrust bearings. The construction shown in the illustration, however, does not show these features.

The purpose of the mechanism is to reverse the rotation of shaft *H* to which the bevel gear *A* is attached. This is accomplished by means of a sliding jaw clutch *D*, which operates on a sliding key carried on shaft *C*. The sliding member of this clutch is necked at the center, the width of the neck being such as to accommodate the width of the operating lever *E*, which bears against it from beneath. The operating lever fulcrums on an ordinary steel pin, and this movement slides the clutch *D* sufficiently to alternately engage and disengage the clutch teeth which are an integral part of each pinion *B*. These alternations of movement are accomplished by star-wheel *G*, which is made of casehardened machine steel. The star-wheel operates on a stud which screws into the body of the bevel gear. It is important that the star-wheel be securely attached to the gear, because if it becomes loose the operation of the mechanism will fail. The operating lever *E* is held in a neutral position by a spring plunger *F*, which extends through the cover of the case and is operated by a knob. There is a hardened steel stud *J* which operates in a circular slot in the operating lever and is held in contact with the end of this slot by the tension exerted by spring *K*. This spring is carried by a long pin, the opposite end of which is pivotally fastened to the gear *A*.

In order to more thoroughly understand the operation of the mechanism, the method by which the reversal of rotation is accomplished will be described. Assuming that the motor which drives the shaft *C* is in operation, the stop-pin *F* is pulled out and given a quarter turn to lock it in its raised position until the mechanism is again brought into a neutral position. The stop-pin releases the clutch-operating lever *E* which, owing to the tension exerted by spring *K*, is forced to the right until it is brought up against surface *L*. This engages the right-hand bevel pinion clutch and drives the gear in the direction indicated by the arrow. Each revolution of the bevel gear brings one point of the star-wheel *G* into contact with stud *J*, resulting in rotating the star-wheel a quarter turn with each revolution of the bevel gear. On the fifth revolution of the gear, the long arm of the star-wheel becomes wedged against surface *M* of the bevel gear, so that as the gear continues to revolve, the stud *J* will be swung over to the opposite side of the slot in which it operates, thus disengaging the right-hand clutch and engaging the clutch which operates the left-hand pinion. This results in reversing the motion of the machine during another five revolutions of the gear, at which time the transfer movement again occurs, and this sequence of mechanical movements continues until the machine is placed, manually, in a neutral position by again engaging the spring-pin *F*. It is important to remember that the number of revolutions before reversing the direction of rotation is governed entirely by the number of arms on star-wheel *G*, there being one more revolution required to reverse the shaft *H* than there are arms on the star-wheel. The length of the odd point of the star-wheel must be such as to just bind against surface *M*.

Cleveland, Ohio C. F. George

MILLING AND GRINDING HELICAL OR SPIRAL CAMS

The face or helical cam shown in the accompanying illustration at *A* is required to have a fairly accurate helix face, with a rise or pitch of ½ inch in 350 degrees. This cam is made from an iron casting about 6 inches in diameter. In milling the face, the blank was mounted on the arbor of the indexing head of a universal milling machine, as shown. A 1½-inch end-mill *B* mounted in the main spindle was used to mill the helical surface. By tilting the head the amount of rise or lead of the spiral, or helix, can be changed considerably from what it would be if the dividing head spindle were parallel with the surface of the milling machine table. If the lead obtained with the spindle of the dividing head set parallel with the surface of the milling machine table were 1 inch, the lead would be approximately 11/16 inch with the spindle of the dividing head set at an angle of 45 degrees as shown in the illustration. With the head set vertically, the lead would be zero, as the cutter would simply pass over the work.

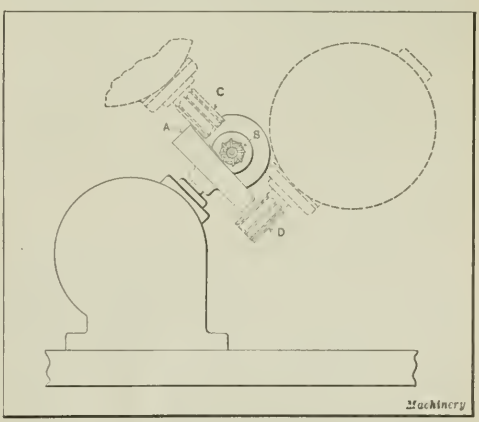


Diagram indicating Positions of Cutters for milling Helical and Spiral Cams

The helix generated by setting the head at an angle of 45 degrees was not strictly accurate, but it was sufficiently so in this case to meet the requirements. When greater accuracy is required, a vertical milling attachment can be used with the milling cutter set as indicated by the dotted lines at *C* for milling the face cam, and as at *D* for a plate or spiral cam. In setting up the milling machine for milling cams of the kind described, the machine is first geared to cut a spiral which is nearest the desired pitch or lead that can be attained with the available gearing. The dividing head is then set at the angle required to give exactly the desired result. The writer knows of no better way of setting the dividing head to the required angle than the trial method. By this method the high and low points are located, and an indicator is attached to the spindle in place of the milling cutter. The head is adjusted until the indicator registers zero at both points. The milling operation can then be performed with the assurance that the required lead or rise in the cam surface will be obtained. If it is desired to grind hardened steel cams, a portable electric grinder can, of course, be mounted on the milling machine spindle in place of the milling cutter.

Providence, R. I. JOHN T. SLOCOMB

USING A PUNCH PRESS FOR MILLING MACHINE WORK

The illustration Fig. 1 shows a tube connection used on an air-testing device. This part is made from a hard brass composition. The view at the left shows the condition of the work as it comes from the automatic machine. To finish

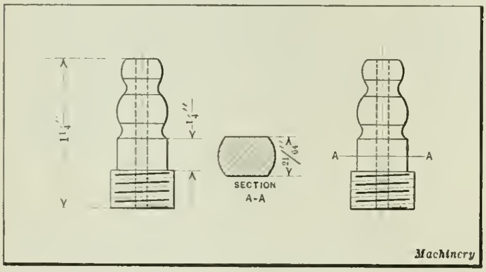

Fig. 1. Tube Connection requiring Machined Flats at Section A–A

the work, it is necessary to machine two flats on the shank as illustrated by the right-hand view and also by the section *A–A*. At first sight this looks like a milling machine job, but the only manner in which the flats could be milled with the milling machines available was to locate the work in a horizontal position using a side milling cutter, and then turn the piece 180 degrees and machine the other face; or else to place the piece in a vertical position and use an end-mill, which would also necessitate indexing the work after taking a cut on one side. Even the use of a special fixture to hold a number of the parts would not greatly facilitate production, as time would be required to place the work in the fixture and turn or index each piece in order to machine both flats.

This problem was solved by equipping a punch press for the job, the tools employed being shown in Fig. 2. The piece is placed in the die with its threaded end resting against stop-pin *A*, being located in the threads in the die which are cut to the same diameter and pitch as those on the work. The other end rests in the concave surface *B*, which has a radius equal to that of the larger spherical section of the part. The die is held rigidly in the bolster of the punch press. The punch *D* is made with two cutting edges. The space between the cutting surfaces is the width of the flattened portion of the part, or 21/64 inch.

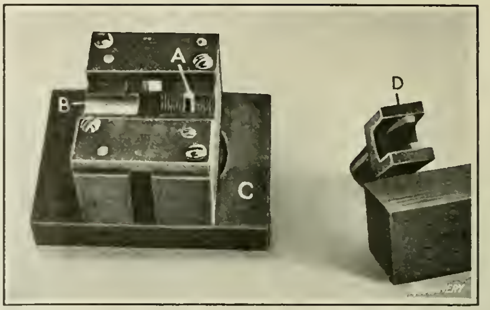

Fig. 2. Punch and Work-holding Block for machining Flats on Part shown in Fig. 1

In operation, the punch is held in the press by means of the shank, which fits the ram, and as it is forced down the two cutting edges shear away the material of the part to the correct width. The work is thus not only machined to the correct size, but owing to the knife-like cutting action of the punch it also has a smooth finish, and the production is far in advance of anything that could be expected from the use of a milling machine for this particular job.

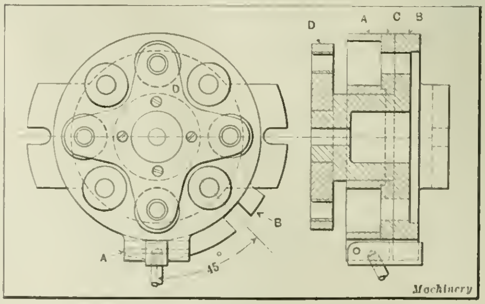
BERT TOWLER

CONTINUOUS DRILL JIG

The accompanying illustration shows the design of a continuous drill jig for use in drilling four cast-iron pinions at one time. This jig was made to be used with a four-spindle multiple drilling head, but can, of course, be employed with any multiple drilling head having spindles adjustable to the holes or bushings in plate *D*. The work-holding plate *A*, having eight equally spaced pockets, is indexed 45 degrees back and forth around the central part of jig body *B*. The latch attached to plate *A*, acting as a handle, is dropped into either slot on the projecting lug on the side of body *B*. Plate *C* is fastened to work-holding plate *A* and prevents the work from dropping through. Parts *A* and *C* can be made in one piece, if desired.

The bushing plate *D* is secured to the body of the jig in such a position that the drills are in line with one set of holes when the latch is in either slot. The pinions are prevented from turning by means of one or two teeth inserted in each pocket. It is advisable to provide feet on the jig in order to facilitate cleaning out the chips and also to give the drills sufficient room to pass through. When operating the jig, it is simply necessary to remove the four finished pinions and replace them with new ones while the four others are being drilled, then index the work-holding member *A* 45 degrees and repeat the unloading and loading of the jig.

Toronto, Canada J. J. LINTON



Continuous or Indexing Drill Jig for Use with Multiple-spindle Drilling Head

METHOD OF LOCATING TOOL WHEN CUTTING MULTIPLE THREADS

The following method of cutting multiple threads has been used successfully by the writer. First set the change-gears of the lathe to cut the required number of single threads per inch, or to give the correct lead. Then set the compound rest to the required angle (30 degrees for U. S. form threads) so that the tool can be fed to the work in the direction indicated by arrow *D* in the accompanying illustration. When one thread groove has been cut to depth, the tool is withdrawn a distance equal to dimension *A*, this distance being measured by the graduations on the dial of the compound rest feed-screw. The cross-slide is then employed to advance the tool in the direction indicated by arrow *E* until the point of the tool touches the work or has advanced a distance equal to dimension *C*.

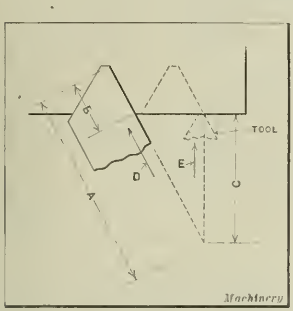


Diagram illustrating Method of setting Tool for cutting Multiple Threads

The formulas for obtaining the dimensions required in setting the tool for cutting multiple threads of U. S. form, as described, are as follows:

$A = B + \sec 60 \text{ degrees} \times P = B + 2P$

$B = \sec 30 \text{ degrees} \times 0.6495P = 1.1547 \times 0.6495P$

$C = \tan 60 \text{ degrees} \times P = 1.7321P$

$P = \dfrac{1}{\text{number of threads per inch}}$ = distance from center to center of thread.

For next thread proceed as before.

When using this method care should be taken to see that the compound rest is accurately set to the required angle and that the backlash in the feed-screw is taken up when using the graduated dial to set the tool. J. F. T.

[For information regarding the methods generally employed in cutting multiple threads see MACHINERY's book "Thread Cutting Methods." This book explains how the tool may be set when cutting multiple threads (1) by indexing or turning the piece being threaded a fractional part of a revolution; (2) by setting the compound slide parallel with the screw thread being cut, so that the slide can be used for adjusting the tool; (3) by disengaging the lock-nut from the lead-screw while the lathe spindle is stationary, moving the carriage the required distance; and (4) by engaging the lead-screw at the proper time (with the lathe in motion), as shown by graduations on the thread chasing dial or indicator.—EDITOR]

REDESIGNING JOURNAL-BOX TO FACILITATE REPAIR WORK

The handling of repair work in large manufacturing plants requires considerable ingenuity and executive ability. The designer, draftsman, or shop executive, who superintends this class of work, must be able to decide quickly what parts will be required to put any broken-down machine or equipment in operation, and he must also know how to get these parts in the quickest and cheapest way.

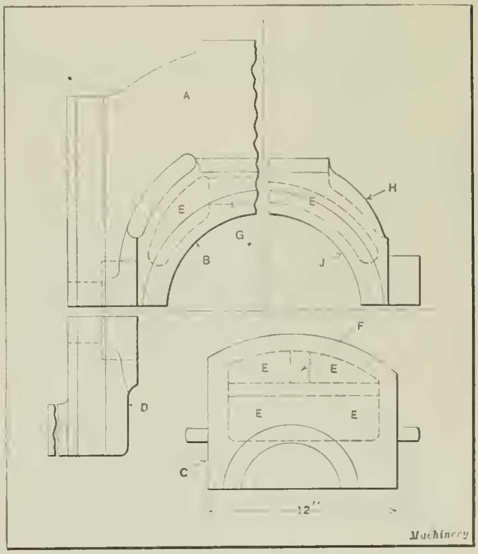
To accomplish this he will disregard all unimportant details of construction that may be incorporated in the original design, and have the repair parts made in the simplest possible manner consistent with the proper functioning of the part. The following instance serves to illustrate the importance of carefully considering the design of broken cast-iron parts when ordering new castings.

In the accompanying illustration is shown in broken sections, a water-cooled journal bearing of the saddle-trunnion type, incorporated in the design of a tilting rolling mill. The part shown at *A* is the upper trunnion slide, and the part shown at *D* is the lower trunnion slide. These slides, however, were not required to be replaced, but are merely shown to give a better idea of the relationship which the broken part bears to the complete assembly. The broken half view of the part shown at *B* indicates the shape of the upper half of the journal box as originally made. This is the part that was required to be replaced. At *C* is a side elevation of part *B*, and at *J*, a broken end elevation of the journal box as it was made to meet the requirements of a hasty repair job.

It will be noticed that the outer diameter of part *B* is oval in shape, starting with a very flat circle at the hub and ending in a circle of short radius at the "saddle." The cored water pocket *E* is made to conform to the shape of the outer surface, but where it comes next to the journal at *G* it is made flat.

This design calls for a pattern entirely shaped by hand. The middle portion of the journal box which has the greatest pressure against the neck of the roll, is solid, except for the narrow passage, and therefore derives but little benefit from the circulating water. From the illustration it is evident that the core-box for this part requires considerable labor, and that it is a somewhat difficult job for the core-maker unless he has special equipment for this class of work.

Now let the redesigned part as shown at *J* be considered. It might be mentioned here that a drawing showing every detail of the broken casting was given to the writer with instructions to have a pattern made for the part as soon as possible. After carefully studying the design, the writer



Original and Redesigned Journal-box Bearings for Rolling Mill

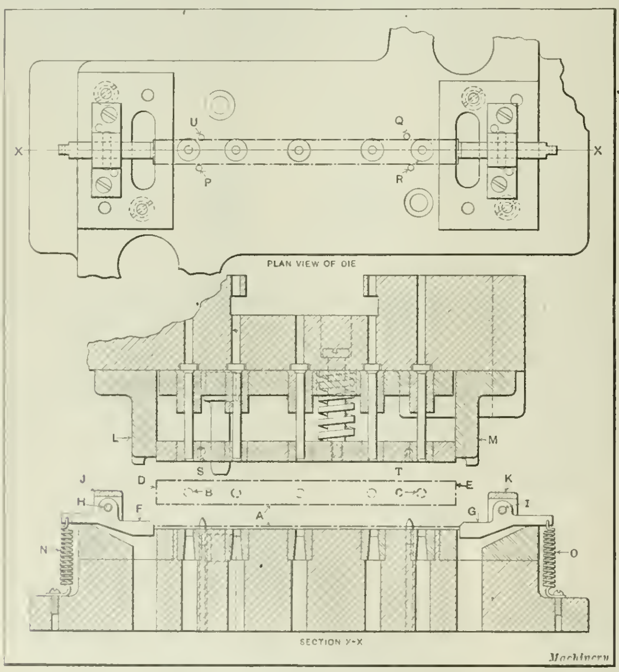
realized that considerable labor would be required to make the pattern according to the drawing. However, it was found that the design could be simplified without affecting in any way the proper functioning of the part. Referring to *J* it will be noted that the circles indicating the most important surfaces in the redesigned box are struck from a common center. It will also be noted that the design provides an unobstructed water-cooling chamber. The middle portion is reinforced with ribs of the shape indicated at *H*. By redesigning the part as shown, it was possible to employ the band saw in cutting and shaping practically all the pieces required in building up the pattern. Thus the pattern was made in half the time that would have been required had it been made according to the original design. The casting, as redesigned, with its large water-cooled chamber, was machined and substituted for the box shown at *B*. After a thorough trial it was found to be much more satisfactory than the one with which the machine was originally equipped.

Kenosha, Wis. M. E. Duggan

DISAPPEARING NESTS FOR SHAVING PUNCHES

When shaving a sheet-metal punching, the work is generally located by pilot-pins or by nest plates. As the former method is preferable, holes are occasionally punched merely to permit the use of pilot-pins in subsequent operations. When pilot-pins cannot be used, and the ends or sides to be shaved must also serve as locating surfaces, the disappearing nests described in the following may be used to advantage.

In the illustration, the work or punching *A* (a plan and side view of which are shown by heavy dot-and-dash lines) is required to have holes *B* and *C* accurately located from the ends *D* and *E* to within 0.0005 inch. Therefore, the ends were shaved and the holes pierced at the same stroke of the press. The work is located endwise by the disappearing or swinging nests *F* and *G*, which are pivoted on pins *H* and *I* to brackets *J* and *K*, respectively. Before shaving



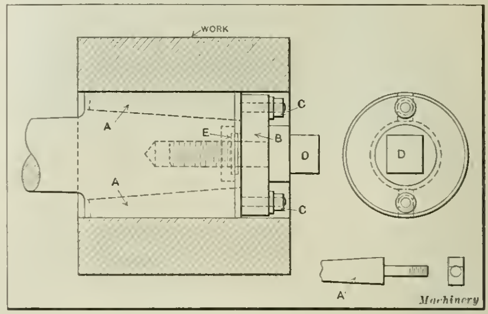
Shaving Punch equipped with Disappearing Nests

punches *L* and *M* come in contact with the ends of the work, they first hit swinging nests *F* and *G*, thus depressing the latter and bringing them out of contact with the work. On the upward or return stroke, springs *N* and *O* bring the nests back to their normal positions. The work is located sidewise by pilot-pins *U*, *P*, *Q*, and *R*. Holes *S* and *T* provide clearance for the pilot-pins that are shown at *U* and *Q*.

B. Spector

FRICTION ARBOR

The special arbor here shown has several advantages over the ordinary expansion arbors generally used to hold work of the kind indicated in the illustration. The chief advantage is that it will not work out of true after being in use



Friction Arbor for Work requiring Facing and Threading Operations

for a considerable length of time, as is frequently the case with arbors having spring collets. The operation performed on the work in this particular instance consists of facing both ends and threading the outside. It is, of course, necessary, in using an arbor of this kind, to have the hole in the work finished close to size.

After the chuck is turned and finished to a good fit in the work, two taper slots are cut to take the taper keys *A*. Two holes are drilled through collar *B* as indicated, to take the shanks of keys *A*. The holes through collar *B* are slightly larger in diameter than the key shanks to allow a slight rise or fall of the keys as they slide in the tapered slots. Nuts *C* are screwed on the end of the key shanks. Screw *D* is drilled to receive a pin *E*, and the tops of keys *A* are rounded to the same radius as the body of the arbor which fits the work. When the work is slipped in position, the tightening of screw *D* against collar *B* forces the wedges out against the work. When screw *D* is loosened for the purpose of removing the work, pin *E* comes in contact with collar *B* so that the wedges are withdrawn, thus releasing the work.

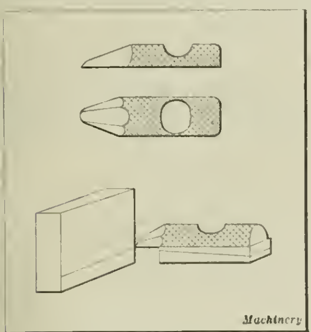
BUREAU OF INFORMATION AT WASHINGTON

On the initiative of President Harding a Bureau of Information has been established on the ground floor of the Post Office Department Building, Pennsylvania Ave. and 12th St., the purpose of which is to give as full information as possible concerning all governmental departments to those who go to Washington to transact business with any department or bureau of the Government. The Information Bureau will be able to advise the visitor as to the exact location of any particular department and the means of reaching it. Manufacturers and others having business to transact with the Government Departments in Washington are invited to make use of this facility. There is need for such an information bureau, as it is often a difficult matter to locate the department or official to be seen among the many government offices in Washington.

SHOP AND DRAFTING-ROOM KINKS

SCRIBE FOR LAY-OUT WORK

A marker or scribe for use in laying out lines a predetermined distance from the edge of angle-plates, die-blanks, etc., is shown in the accompanying illustration. This marker is made by knurling a piece of round carbon steel and then machining and filing the knurled piece to the shape shown by the two upper views in the illustration. The notch filed in the top of the knurled portion serves as a "finger-grip." After being hardened, the marker is, of course, ground flat on the bottom and to a sharp point at the end. It can be used with standard size blocks, or with adjustable parallels as indicated in the lower view.

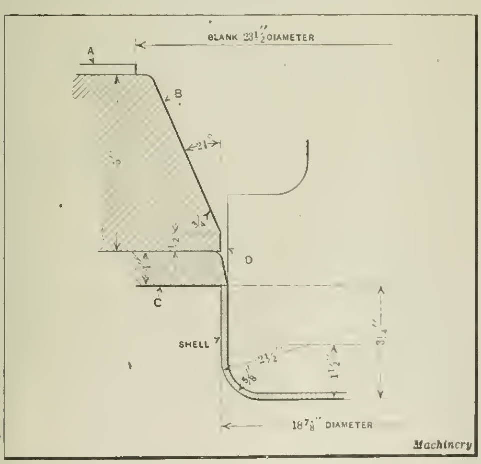


Scribe for Lay-out Work

Brooklyn, N. Y. HOWARD HOUSE

DRAWING DIE KINK

The accompanying illustration shows how a slight change in drawing die design enabled a shell to be drawn having a large radius at the bottom, which formerly had caused trouble. The die is of the push-through type, and the blank, which was 23½ inches in diameter, was located in the gage



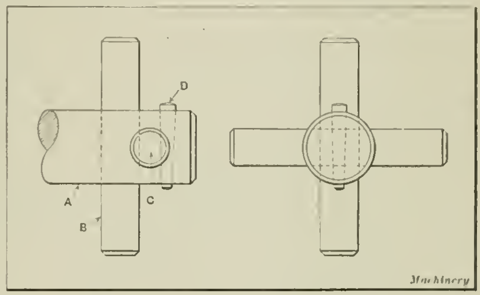
Tapered Drawing Ring for drawing a Part with a Large Radius

ring *A*. The drawing ring is shown at *B*, the stripper at *C*, and the punch at *D*. All the parts are standard construction, except the drawing ring, which is made with a 24-degree angle. By making the drawing ring with this angle, the shell was successfully drawn to the diameter and radius indicated. The stock is 5/32-inch sheet steel, and the operation was performed on a No. 78½ Bliss press.

Cleveland, Ohio D. C. OVIATT

SECURING TWO RODS AT RIGHT ANGLES

In the accompanying illustration is shown a method devised by the writer for rigidly securing two rods at right angles to each other, when the rods pass through a shaft. Shaft *A* is first drilled to take rod *B*. After rod *B* has been inserted and properly located, another hole is drilled at right angles to the first, to receive rod *C*. The distance between the centers of the two holes is made less than the diameter of the stock used for the rods, so that the drill will cut into rod *B* slightly, when drilling the second hole. Rod *C* is then inserted and properly located, after which another hole is drilled and reamed to receive taper pin *D*, as shown. When



Method of securing Two Rods at Right Angles

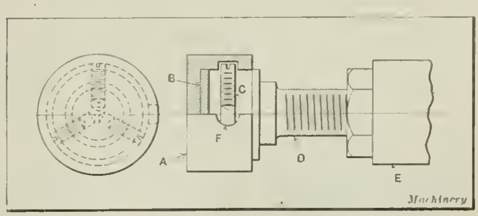
pin *D* is driven into place, it locks rod *C* securely, and rod *C*, in turn, locks rod *B*.

Baltimore, Md. HENRY R. BOWMAN

REVOLVING STOP FOR SCREW MACHINE

The revolving stop shown in the accompanying illustration was designed for use in an automatic screw machine or other machines such as turret lathes, where the stock to be machined is chucked while the spindle is revolving. The writer has found that a better quality of work will be produced when this stop is employed in place of the stationary type of stop generally used. In addition, it also reduces the time required to keep the machine adjusted, since it does not become scored or loaded with metal, as is frequently the case with the stationary type. The stop consists simply of a hardened and drawn steel cap *A*, a bronze bearing washer *B*, three evenly spaced set-screws *C*, and a shank *D* which is adjustable in holder *E*. It will be noticed that an annular groove is cut inside cap *A* into which the heads of screws *C* project. These screws are inserted through a hole *F*, drilled through cap *A*, and prevent the cap from slipping off the end of part *D*.

Akron, Ohio BERKLEY E. WIGGLESWORTH



Revolving Stop for Screw Machine

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

PROBLEM INVOLVING THE USE OF TRIGONOMETRY

R. T. R.—In the accompanying illustration, $a = 1\frac{1}{4}$ inches, $h = 4$ inches, and angle $A = 12$ degrees. Please show how to find distance x and angle B.

ANSWERED BY L. D. CASTOR, ELIZABETHPORT, N. J.

In April MACHINERY, page 792, under the title "Problem Involving Algebra and Trigonometry," a solution involving considerable algebra was given to this problem. The writer

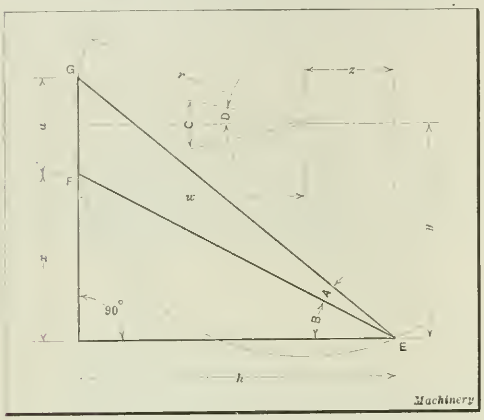


Diagram used in Trigonometric Solution

believes that the solution here presented is much simpler than the one referred to. Draw an arc through points E, F, and G, as shown, with r as a radius. According to a well-known theorem of geometry, which is given on page 250 of MACHINERY'S HANDBOOK, if an angle at the circumference of a circle, between two chords, is subtended by the same arc as the angle at the center, between two radii, then the angle at the circumference is equal to one-half the angle at the center. This being true, angle C is twice the magnitude of angle A, and angle D = angle $A = 12$ degrees. It will now be readily observed that

$$r = \frac{a}{2 \sin D} = \frac{1.25}{2 \times 0.20791} = 3.0061$$

$$w = \frac{a}{2} \cot D = 0.625 \times 4.7046 = 2.9404$$

and

$$z = h - w = 4 - 2.9404 = 1.0596$$

Now

$$y = \sqrt{r^2 - z^2} = \sqrt{7.9138505} = 2.8131$$

and

$$x = y - \frac{a}{2} = 2.8131 - 0.625 = 2.1881 \text{ inches}$$

Finally,

$$\text{Tan } B = \frac{x}{h} = \frac{2.1881}{4} = 0.54703$$

and

$$B = 28 \text{ degrees } 40 \text{ minutes } 47 \text{ seconds}$$

A similar solution was submitted by C. N. Pickworth, Manchester, England.

CALCULATING DIAMETER OF ROLL FOR ROLLER CLUTCH

W. A. Z.—In the accompanying diagram are shown the conditions encountered in the design of a roller clutch. From the dimensions given, please explain the method of finding the diameter of the roll.

ANSWERED BY W. W. JOHNSON, CLEVELAND, OHIO

A.—Referring to the diagram, the diameter of the roll can be found in the following manner: Since, by construction, $MK = KL$, angle KHM = angle $KHL = \frac{1}{2}$ (90 degrees $- x$)

Let $\frac{1}{2}$ (90 degrees $- x$) $= y$; then,

$$KL = r \tan y$$

and

$$LA = HN = b - KL; \; HN = b - r \tan y$$

$$HO = \sqrt{(HN)^2 + (NO)^2}$$

But

$$HO = R - r$$

Therefore

$$\sqrt{(b - r \tan y)^2 + (a + r)^2} = R - r$$

Squaring both sides of the preceding equation,

$$(b - r \tan y)^2 + (a + r)^2 = (R - r)^2$$

Expanding, combining, and arranging terms with reference to r, we get the quadratic equation

$$r^2 \tan^2 y + 2r\,[(R + a) - b \tan y] - (R^2 - a^2 - b^2) = 0$$

Solving this equation for r,

$$r = \frac{-[(R + a) - b \tan y]}{\tan^2 y} \pm \frac{\sqrt{(R + a)^2 - (R + a) \tan y\,[2b - (R - a) \tan y]}}{\tan^2 y}$$

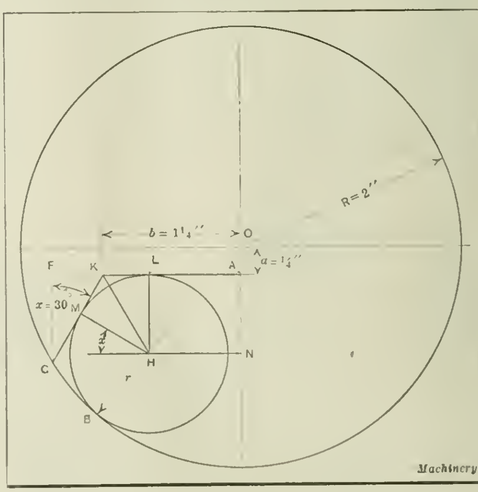

Diagram for finding Diameter of Roll for Roller Clutch

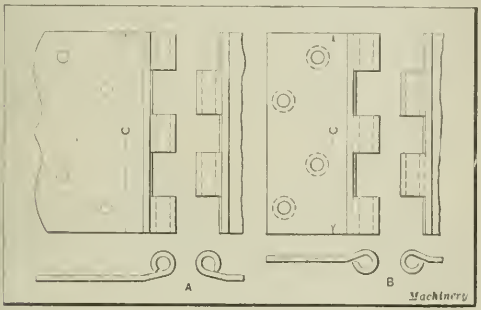
Now, $y = \frac{1}{2}$ (90 deg. $- x$) $= 30$ degrees. Tan 30 deg. $= 1/3\sqrt{3}$ and $\tan^2 30$ deg. $= 1/3$. Inserting these values of $\tan y$ and $\tan^2 y$ and those given in the diagram, in the foregoing equation, and taking the plus value of the quantity under the radical sign, we find that

$$r = \frac{\sqrt{3.12740 - 1.52831}}{0.33333}$$
$$= 3(1.76844 - 1.52831)$$
$$= 3 \times 0.24013 = 0.7204 \text{ inch}$$

The diameter of the roll, then, is equal to $2r$ or 1.4408 inches.

MANUFACTURE OF HINGE BUTTS

C. L.—Can any reader of MACHINERY give information as to the methods in use in some shop for manufacturing hinge butts of the two styles illustrated at *A* and *B*, in



Types of Hinge Butts of which Information is desired concerning Manufacturing Methods

various sizes of which *C* ranges from 1 to 4 inches? It is desirable that only tools actually used in producing such parts be described and that production figures be given.

DETERMINING ALTITUDE OF AN ACUTE-ANGLED TRIANGLE

A. A. G.—Will you please show how to find the distances x and y from the dimensions given in the illustration?

ANSWERED BY W. W. JOHNSON, CLEVELAND, OHIO

A.—Referring to the illustration, we have

$$y^2 = R^2 - x^2 \quad (1)$$

$$y^2 = r^2 - [(R + r - c) - x]^2 \quad (2)$$

From Equations (1) and (2) by comparison,

$$x = \frac{R^2 + (R + r - c)^2 - r^2}{2(R + r - c)} \quad (3)$$

Substituting this value for x in Equation (1), we get

$$y^2 = \frac{[2R(R + r - c)]^2 - [R^2 + (R + r - c)^2 - r^2]^2}{4(R + r - c)^2}$$

Then,

$$y = \frac{\sqrt{[2R(R + r - c)]^2 - [R^2 + (R + r - c)^2 - r^2]^2}}{2(R + r - c)}$$

Factoring and reducing the terms under the radical sign in this equation,

$$y = \frac{\sqrt{([(R + r - c) + R]^2 - r^2)\,(r^2 - [(R + r - c) - R]^2)}}{2(R + r - c)} \quad (4)$$

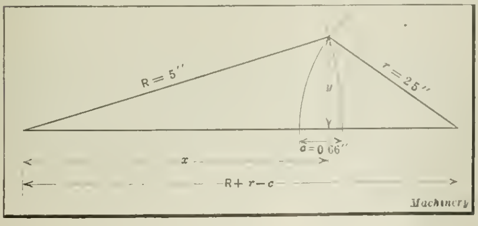


Diagram for calculating Distances x and y

Substituting numerical values for the known quantities in Equations (3) and (4), we find that

$$x = \frac{65.5356}{13.68} = 4.7906 \text{ inches}$$

and

$$y = \frac{\sqrt{133.9356 \times 2.8644}}{13.68} = 1.4318 \text{ inches}$$

TANGENCY PROBLEM

L. M. S.—Referring to the accompanying illustration will you please show how to find angle y without involving the use of higher mathematics? Let it be assumed that in this problem a equals 5.5 inches; b, 3 inches; and R, 1.625 inches.

ANSWERED BY J. F. THORNTON, CINCINNATI, OHIO

The following method of solving the problem stated requires only an elementary knowledge of trigonometry and the use of a table of trigonometrical functions. According to trigonometry,

$$\text{Tan } x = \frac{b}{(a - R)}$$

and

$$t = \sec x \times (a - R),$$

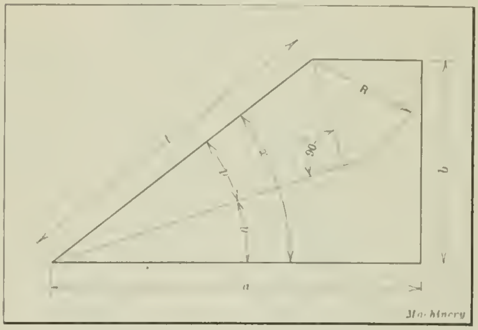
also

$$\text{Sin } p = \sin (x - y) = \frac{R}{t}$$

and

$$y = x - p$$

Substituting the known values and solving,



Conditions of Tangency Problem

$$\text{Tan } x = \frac{3}{3.875} = 0.77419 = \tan 37 \text{ degrees } 44 \text{ minutes}$$

and

$$t = 1.2644 \times 3.875 = 4.89955$$

Also

$$\text{Sin } (x - y) = \frac{1.625}{4.89955} = 0.33166 = \sin 19 \text{ deg. } 22 \text{ min.}$$

Therefore,

y = 37 deg. 44 min. — 19 deg. 22 min. = 18 deg. 22 min.

* * *

A machine tool dealer in Germany, writing on the prices of machine tools in that country, states that standard machines of first-class quality, such as lathes, milling machines, grinding machines, upright and radial drilling machines, planers, etc., cost about 10 to 11.5 marks (11 to 13 cents present exchange) per pound, net weight. First-class American machine tools in the German market, with ocean freight and import duty into Germany added, cost about 30 marks (34.5 cents) per pound. Machine tools of the cheaper class of German make cost only from 7 to 9 marks (8 to 10 cents) per pound.

Demand for Machine Tools in India

By GEORGE CECIL

THERE was a time when European employers of native labor in India did not encourage the use of imported tools; and the obstinate native mechanic also, for many years, fought shy of modern tools and methods, anything in the way of a time-saving device being objectionable to him. The longer he worked, the greater his profit, so he thought; consequently, he allowed his task to drag on. Finally, employers and mechanics alike more or less fell into line with the new order of things, and today machine tools have been adopted in the mill repair shops; indeed, many of them are particularly well equipped.

India being preeminently conservative, this result was not achieved without a severe struggle. The native argued that his father, grandfather, and great-grandfather had used tools of Indian manufacture, and nothing would, at first, induce him to desert those to which he had been accustomed from his youth. But by degrees contractors and other employers of labor came to the conclusion that "time is money." Today, though the old-fashioned users of native tools refuse to bend their knees to progress, they are, fortunately, in a minority. As to the European concerns, both large and small, they expend money freely in acquiring suitable tools, a certain pride being taken in the shops.

General Industrial Conditions

Of late, India has, for an Eastern country where progress seldom is encouraged, been unusually active industrially. Some of the railway companies, for example, have constructed their own locomotives with good results. For many years past, most companies have made their own cars, India being rich in suitable lumber. The shops are well equipped, and skilled European foremen, brought from England, are in charge. Under their fostering care the natives, who are employed by the thousand, often do very good work—they can, in fact, hardly be excelled. When, however, a supposed economy is effected by putting an incompetent and inexpensive half-caste native in charge, the quality of the output usually falls off. The semi-white man is naturally indolent; he seldom masters the use of the machinery entrusted to his care, and the men dislike working under him.

Some of the small native shops in which machine tools are used serve apparently as an outlet for mere rubbish in the way of tools and machines. Obsolete contrivances, instead of being "scrapped," are purchased for a trifle by the economical Indian mill or mine owner, and those who use them are but poorly acquainted with their operation. One finds an antiquated lathe in a repair shop, with a venerable native endeavoring to operate it. The lathe is coated with rust; so, too, is the mind of the operator.

Types of Machine Tools in Demand

A small percentage of the machine tools in local use are manufactured in India, but the number imported is by far the most important. Milling and drilling machines and woodworking machinery are in demand; light gap lathes (12-inch swing), heavier gap lathes (16-inch swing), screw machines, bolt- and nut-making machinery, shapers, and saws are needed. Woodworking machines are used in Calcutta, Bombay, Madras and elsewhere. The market, while not unlimited, is well worth the exporters' close attention. India has many capitalists, both native and European. With a little urging, they often are ready to launch out upon new enterprises.

Both Japan and Germany have made frantic efforts to capture the Indian market. The Japanese products, unfortunately, seldom are like the samples, or representations made. German manufacturers have not always kept their word, a failing which neither European nor native machinery users are inclined to tolerate. The Indian himself may not be a model of all the virtues; but he has a great admiration for the exporter whose honesty is unassailable; and it must be confessed that during many years' trading with India, Germany has scarcely earned a reputation for upright dealing.

Small Tools in Demand

The demand for small tools is considerable. The European tea and indigo planters provide themselves with tool-chests, for in many cases the exiled agriculturist is far from the haunts of the native mechanics. Missionaries are in the same position, and government officials who find themselves in isolated spots are forced to supervise, if not to undertake, domestic repairs. Well-stocked tool-boxes may be found in the large hardware establishments, but they seldom include everything that is required. A really complete box would need to be very large—a miniature shop. It should contain everything by means of which the possessor may perform temporary repairs of all kinds—both in wood and metal—and should include even a lavish supply of nails and screws. As to the nature of the tools used in India, they are the same as those required in other countries. The native, though haggling over prices, knows when he is getting value for his money.

Dealers in Machinery and Tools

In the three main cities, Calcutta, Bombay, and Madras, there are many reputable machinery and small tool dealers. They generally know their business; and they are as active as the enervating climate permits them to be. The consul at each town should be in a position to vouch for their standing and capabilities. Calcutta and Bombay support hardware establishments of repute, all of which deal largely in small tools. Both the machinery agents and the hardware men are in a position to know what is wanted, and they possess the necessary means of distribution. Their travellers constantly are on the move; they are in complete touch with requirements—both European and native. Consequently, the manufacturer who aspires to conquering the Indian field may safely leave his interests in their hands.

The large mercantile houses also are ready to undertake agencies for the sale of anything—"from a needle to an anchor." Jute firms, cotton firms, wine merchants, even tailors—all are willing to pose as agents for lathes and drilling machines, hammers and nails. These people are, of course, worse than useless as agents or representatives.

A number of automobile manufacturers in France have recently formed a combination known as L'Union Commerciale des Marques Francaises, capitalized at 1,500,000 francs. The object of this organization is to develop foreign markets by securing capable agents throughout the world for automobiles; it is stated that the organization will also handle machinery in general. The office of L'Union Commerciale des Marques Francaises is at 2 rue du Bois de Boulogne, Paris.

STRADDLE-MILLING FIXTURE FOR CONNECTING-RODS

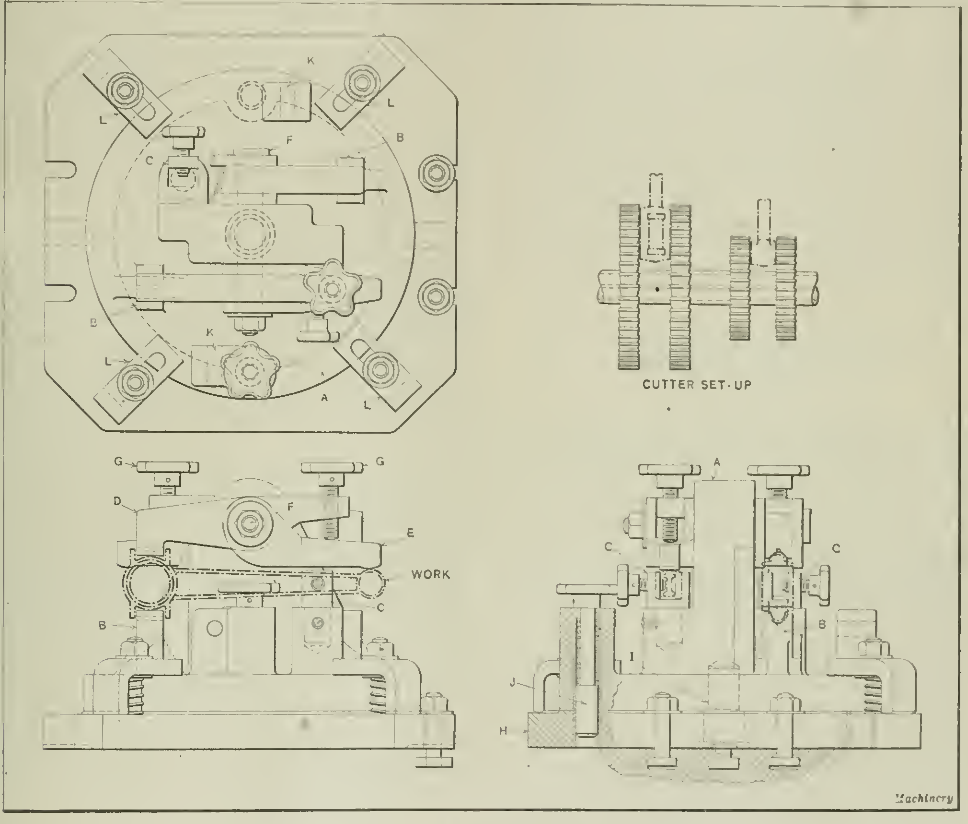
By CLARENCE M. SCHLEH

In machining the faces of crankpin and wrist-pin bearings of automobile connecting-rods it is essential that these surfaces be finished correctly in relation to each other, and also that they be held as closely as possible in alignment with the web and bolt bosses of the forging. Connecting-rods are made as light as possible, and so the bolt holes usually have only from ⅛ to 3/16 inch thickness of wall. Therefore, if the bearing faces should be milled off, say 1/16 inch, in relation to the center line of the rod, through some faulty method of setting up the work, and the holes are drilled and reamed by means of jigs, the holes would be located 1/16 inch off the center of the bolt bosses, as the rods are located in the jig for drilling and reaming, from the milled bearing surfaces. One way of accurately machining the bearing faces is by using a fixture such as shown in the accompanying illustration, which is designed for straddle-milling. Its construction and operation are simple.

The fixture is used on a Milwaukee horizontal-spindle milling machine with a double over-arm construction. The bearings on the connecting-rod for which the fixture was designed are of two different lengths. If they were of the same length it would have been a simple matter to make a fixture in which one or more rods could be secured, mill one end of the rods first, then lower the table to permit the cutters to clear the fixture, traverse the latter past the cutters, again raise the table, and finally mill the opposite end of the rods. In the present case this procedure was impossible, because the distance between the cutters on the arbor would have to be altered to suit the two bearings, and so there were but two alternative methods of machining. Either the work must have to be reset for milling the second end or else a fixture must be provided which would permit the milling of opposite ends of two rods at one time, and then could be indexed for milling the other two ends. The fixture developed was based on the second of these principles.

The two connecting-rods are mounted on the fixture as indicated by the heavy dot-and-dash lines, a large end of one rod being placed beside a small end of the other rod. The larger end of each rod is located by having the bolt boss on the lower side rest in the V-groove of a lug *B* cast integral with the rotary body *A*, while the upper bolt boss is held in a V-groove in clamp *D*. Lugs *B* are narrower than the connecting-rod bearing which they support, for a sufficient distance beneath the work to permit the cutters to finish the bearing faces without interference with the fixture. The I-section close to the small end of each rod is supported in the slot of a steel block *C*, which has a shank that is a pressed fit in a hole in the body, and is held by means of a small headless set-screw. The I-section of the rod is forced against the inside wall of the slot by means of an adjusting screw. This locating arrangement permits both bosses on the large end of each rod and the web to be brought approximately in line with the cutters.

After a connecting-rod has been located as described, it is secured in place by means of clamps *D* and *E*, the former bearing on the large end as already mentioned, and the latter on the small end. There are, of course, two sets of



Indexing Fixture used in straddle-milling the Bearing Faces of Automobile Connecting-rods clamps, all four fulcruming on pin *F*. Each set of clamps is brought to bear on the corresponding connecting-rod by adjusting a screw *G*, which is contained in a threaded hole in clamp *D* and bears on clamp *E*, thus affording a quick-acting device. Body *A* may be rotated on base *H*, being pivoted on the vertical pin *I*, and there are two bushings located 180 degrees apart to accommodate spring plunger *J*. When the plunger has been placed in either of these bushings, body *A* is clamped to base *H* by means of clamps *L*. Then the work is fed past the cutters mounted on the arbor as shown in the upper right-hand corner of the illustration until the ends nearest the cutters have been machined.

The table is next withdrawn, clamps *L* loosened and swung sidewise, plunger *J* lifted and body *A* revolved by means of a round bar inserted in either one of the holes *K*, until the plunger, as it rides on the finished surface of the base, springs into the bushing opposite the one in which it was placed during the first step. After clamps *L* have been retightened, the opposite ends of the work are fed past the cutters, and when the machining of these ends is completed, the table is again withdrawn and two new rods are mounted in the fixture. Base *H* is held in the correct alignment on the table by two keys attached by means of screws in slots on the under side of the base, these keys fitting the center T-slot of the table. The base is attached to the table by means of four bolts. It is preferable for a machine to be equipped with two of these fixtures, as then, while the work in either of the fixtures is being fed past the cutters, the other fixture may be indexed or reloaded with unfinished forgings. Thus an almost continuous milling operation will be obtained.

HYDRAULIC ACCUMULATORS AND PIPING SYSTEMS

By A. SEARLES

To the writer's knowledge, there is no class of factory equipment that requires more painstaking care in the design, installation, and operation than that included in hydraulic systems, on account of the severe service to which such equipment is subjected as well as the danger involved by storing up an enormous amount of energy, the release of which, due to the failure of some part to function properly, might cause serious damage. This is especially true of systems having an accumulator of large capacity, where the stored energy amounts to millions of foot-pounds, including floating ballast weighing several hundred thousand pounds.

To begin with, a consideration of the accumulator may be of interest. There are two types of accumulators in common use, namely, those having a stationary ram with the ballast attached to the floating cylinder, and those having a ram attached to, and movable with, the ballast weight. The former arrangement is the more common, although open to some rather serious objections as to accessibility for repairs to the parts most usually in need of attention, such as the ram, which may in time become so badly scored by the packing and foreign material that excessive leakage and consequent loss of power make it imperative that it be removed and refinished. If a cast-steel ram proves defective and leaky from sponginess, for instance, a total dismantling of the accumulator is necessary in case the ram is of the stationary type. This is no small task, involving as it does the removal of the cylinder, and ballast, the latter often weighing several hundred thousand pounds and consisting of such material as iron ore or steel punchings, the removal of which requires considerable manual labor. The movable ram, on the other hand, may be detached from the ballast tank and lifted clear without disturbing the other parts. This type also permits easy access to the gland bushing of the cylinder, which must be replaced on account of the reduction of the ram diameter if the latter is refinished. An accumulator of this design also has the advantage that the outside of the cylinder may be inspected for leaks without difficulty; while the ballast of the previously mentioned design hinders or prevents such an inspection.

Construction of Accumulators

The materials from which accumulators are constructed should be given careful consideration. For moderately high pressures of 1600 pounds or less, cast iron is satisfactory for both cylinder and ram, as the castings can generally be relied on to be free from blow-holes and such defects as result in leaks. Cast iron of a proper grade, namely, gray iron, also seems to lubricate easily, probably due to the graphitic content; at any rate, under reasonable conditions the ram soon takes on a glossy surface, thus promoting the best operating conditions. For higher pressures, the cylinder is usually made of cast steel, and while the same material is commonly used for the ram, it is not to be recommended, as a steel casting of such proportions is frequently honeycombed, and although it may withstand a pressure test, subsequent and continued operation may eventually force the water through, and open serious leaks in the spongy spots. Considering that such a condition may not be entirely corrected by plugging or electric welding, it is much more satisfactory to equip the accumulator with a forged steel ram in the first place. Although the first cost may be slightly greater, the additional insurance against leakage would seem to be justified.

Accumulator gland packing requires careful attention in that it must be fitted and compressed to avoid leakage, as all leaks represent a considerable loss of power since, for instance, a loss of 14.3 pounds of water per minute from a system operating under a pressure of 1000 pounds per square inch represents one horsepower and a proportionate power loss at other pressures. Soft metallic packings seem to give good results for accumulators, without wearing the ram unduly as is often the case where hemp and other hard fabric packings are used. A means of lubricating the ram is found advantageous when water is used as the fluid medium in the system. Lubrication may be accomplished satisfactorily by attaching a ring or swab of absorbent fabric to the outside of the gland and encircling the ram; this ring is kept saturated with oil which works off on the ram through contact with the ring.

To prevent such awkward and dangerous occurrences as the over-traveling of the accumulator due to the failure of the by-pass valve or pump regulator, which would result in pumping the moving element of the accumulator up to such a point that the ram emerges from the cylinder with the probability of a serious wreck from the falling of the moving element, manufacturers provide release holes in the ram which become uncovered or exposed when for any reason the accumulator over-travels. These holes are drilled radially in relation to the axis of the ram and enter the central hole in the ram, thus forming a vent to the whole system; they must be sufficiently large to relieve the system as fast as the pumps can deliver.

Design and Installation of Piping Systems

Hydraulic piping systems must be carefully designed and installed so as to avoid as far as possible any danger to life and property. A case is known where a large accumulator was wrecked, because the piping was of such capacity as to permit the accumulator to drop at an excessive speed. This may be avoided by so proportioning the piping as to prevent an excessive rate of flow, or by properly regulating the operating valve opening to the presses, but better still by installing a suitable check valve at the accumulator connection. This valve has a hole which regulates or throttles the flow from the accumulator, but opens, if necessary, to permit the pumps to deliver at a higher speed. This arrangement has the added advantage of safely regulating the lowering of the accumulator in case of failure in the system, such as a split pipe, joint gasket blow-out, or other causes tending to release the water at an undue rate. The piping of a hydraulic system must be rigidly restrained at short turns to avoid the danger of breaks due to the jarring and springing resulting from the sudden changes in speed of water flow due to the sudden opening and closing of operating valves. For this reason it is desirable to install piping with long bends of pipe, where possible, in place of short-radius fittings. Even when this is done, if the runs of pipe are of such length as to involve a large capacity of water, representing considerable force at high rates of flow, additional protection of the pipe from shock must be provided by the installation of shock valves.

Location of Pipes

Where possible, it is best to install high-pressure pipe in trenches below the floor level, as overhead installations increase the danger to operators from leaks due to splits in the pipe and failure of joints. It is also a better location for the restraining devices at the pipe elbows. An overhead system may transmit disagreeable if not dangerous vibrations to the building. Flanged pipe joints, which are commonly used, should be guarded by a metal ring as a matter of safety to operators in the event of a leak.

Oil and water are the liquid mediums used in hydraulic systems. Oil has the advantage of lubricating the moving parts throughout the system and maintains an excellent condition of such parts as accumulator rams, pump pistons, and press rams, but has the disadvantage of higher cost, while water is a fair substitute, if treated with a good emulsifying lubricant, such as used for cutting compounds.

Some systems give trouble from considerable heating of the fluid medium due to the small storage capacity, which does not present sufficient radiating surface to carry off the heat generated by the friction of the fluid flowing through small passages in the system, such as partially closed operating valves, or from by-passing when the pump regulator has cut the pump off the line. This is often destructive to packings, and it may be found necessary to discharge the liquid into a cooling apparatus before returning it to the storage reservoir.

Advantages and Disadvantages of Direct System

Generally a system which pumps directly to the presses without an accumulator is more economical from the standpoint of power, as many operations require full pressure for only a short portion of the stroke of the press. However, this arrangement has certain disadvantages. If the operation is such as to limit the stroke definitely at a certain point, the pressure will increase enormously, and probably cause damage to the equipment, although relief valves may be installed to safeguard against this condition. Again, unless the system is quite free from leaks, the pulsations of the pump strokes may be so amplified as to show in the product, especially extruded material. In order to effect a saving of power, a double-pressure system is frequently employed, which involves a double-pressure pump or two pumps —one for low and the other for high pressure. This further complicates the piping and valves, and may even require two accumulators. The low-pressure pump operates during the early portion of the stroke and when insufficient to continue its operation, is discontinued and the high-pressure pump applied. The direct system necessitates the use of individual pumps for each press, while the system including an accumulator may serve more than one press.

Operating valves may be considered as necessary evils, as they require the most constant and careful attention to insure against leaks; consequently the first consideration in their design is accessibility for repairs—they should be so constructed as to obviate the necessity of removal from the line for repairs and repacking. For pressures up to 1600 pounds per square inch, some forms of balanced piston valves give satisfaction, but pressures of 4000 to 5000 pounds require a poppet type of valve which may need frequent refacing of the seats due to wire drawing.

MAKING BLANKING DIES

By J. F. THORNTON

Antiquated methods and devices, many of which cause undue strain on the workmen's eyes, are still employed to a considerable extent in making blanking dies. The use of such methods and devices should be discouraged, and it is the purpose of this article to explain a method that should have a wider application in diemaking, and come into more general use among diemakers to replace the older, inaccurate, and time-wasting methods. Endeavoring to "split a scribed line with a file," that is, relying only on one's ability to determine by sight when the metal has been filed away until the center of the scribed line has been reached, is a practice that should be discontinued, as the method here described and illustrated will, in almost every case, give more accurate results and permit the work to be done in much less time.

An outline of the opening in a simple piercing and cutting-off die is shown in the upper left-hand corner of Fig. 1. The making of a die of this kind is facilitated by the use of hardened disks as guides for the diemaker's file, the posi-

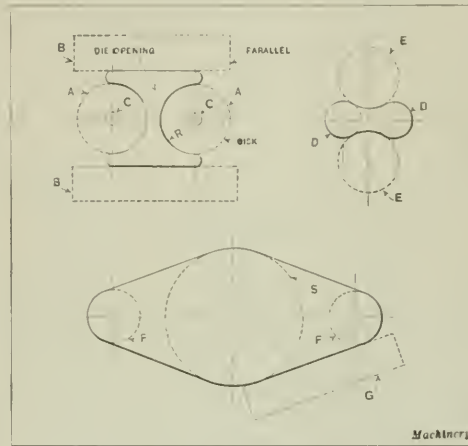

Fig. 1. Use of Hardened Disks and Parallels to guide File when filing Die Opening

tion of these disks being indicated by the dotted circles *A*. Hardened parallels, the positions of which are indicated by the dotted lines *B*, are also used as guides when filing the straight portions of the die-opening. The disks should ordinarily be made from stock 1/8 or 3/16 inch in thickness. As the profile of the punch used with this die is exactly the same as the profile of the work, the radius *R* of the die should be slightly smaller than the radius of the work. The metal to be punched in this case is steel, so 1/40 the thickness of the stock should be subtracted from the radius of the work in order to obtain the correct radius *R* for the die. For work requiring ordinary accuracy, or for work having limits of plus or minus 0.002 inch, the disks may be turned and bored on a lathe, and then hardened. When extreme accuracy is required, they should be hardened and ground all over and located by the use of gage-blocks or a height gage. The disks employed in making dies can be used over and over, so that it is not usually necessary to charge up the cost of making them to any one job. A set of parallels and disks consisting of four 2-inch and four 4-inch parallels, and a few disks of the more commonly used sizes will cover a surprisingly large range of work, and should be included in every toolmaker's kit. Disks which are not of a standard size should be stamped with the tool or die number on which they are used, to facilitate identification.

Since the forms or outlines of practically all dies consist of combinations of true geometric figures, it is evident that there are but few cases in which disks and parallels cannot be used to advantage. The disks and parallels, or "masters," as they are sometimes called, are intended to be used as guides for the workman's file, and thus prevent the opening in the die from being filed beyond the limiting profile line. It is true that a file in the hands of a careless workman will be quickly dulled by continually striking the hard edges of the disks, but the number of unskilled workmen to be found in tool-rooms is, or should be, very small.

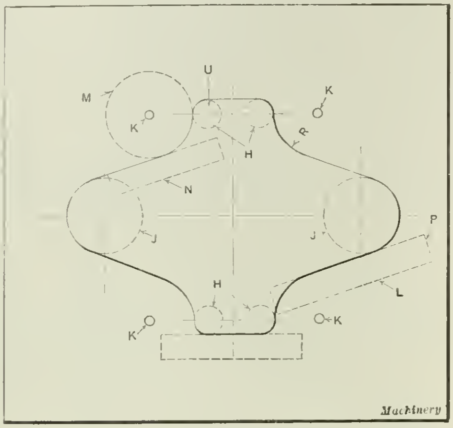

Fig. 2. Method of drilling Small Holes in Die to facilitate Location of Disks

Regarding the setting of the disks *A*, the two piercing holes *C* should first be laid out, drilled, and reamed. The disks in this case should have central holes of the same diameter as the piercing holes in the die. This permits the disks to be located by pushing small plug gages through the holes in the disks and into the die. The disks may be clamped or soldered in place, great care being taken, if they are soldered, to see that the heat does not change their position. Parallels *B* are then located in their proper relation to the disks, after which the core of the die is removed by drilling or sawing. The locating or attaching of the "masters" before removing the core will prevent drilling or sawing into the metal beyond the outline of the die profile.

In making a die having a profile such as indicated in the view at the upper right-hand corner of Fig. 1, it is evident that holes *D* should be laid out and bored first, after which plugs placed in these holes may be used in locating hardened disks in the positions indicated by the dotted circles *E*. After the disks have been attached to the die, the plugs are removed from holes *D* and the die opening filed to shape.

The method of using disks and parallels in making a die having an opening or profile such as indicated in the lower view in Fig. 1, is evident, and should require but little explanation. The positions and relative sizes of the disks required in making this die are indicated by the dotted circles *F* and *S*, while the position of one of the parallels is indicated by the dotted lines at *G*.

The contour or outline of the die shown in Fig. 2 is such that all the disks or "masters" required cannot be placed on or attached to the die at one time. After the four holes *H* and the two holes *J* have been bored, four small holes *K* should be drilled in the die, if this is permissible. The drilling of these small holes will facilitate the placing of parallels such as indicated by the dotted lines at *L*. After the sides of the die opening determined by these parallels have been finished, the parallels are removed, and disks having the correct radius *R* are attached to the die, being located by holes *K*.

The position of one of the disks located in this manner is indicated by the dotted circle at *M*. If it is not permissible to drill holes *K* in the die, the disks may be located against parallels clamped to the die. The correct position of a parallel used for this purpose is indicated by the dotted lines at *N*. With a parallel in this position, the disk can be properly located by bringing its edge into contact with both the parallel and a plug inserted in hole *H*. After attaching the disk to the die, the plug and parallel are removed, and the profile of the die filed to shape in the manner previously described.

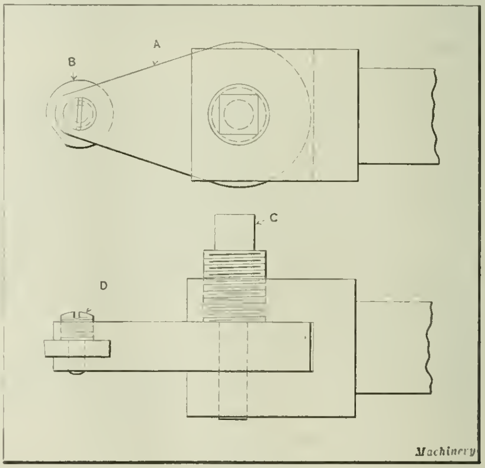
The "masters" are exceptionally useful when making shaving and burnishing dies having perpendicular walls or no clearance angle. For dies of this kind disks should be placed both on the face and on the back of the die blank. Care must, of course, be taken to see that the face of the die is parallel with the back of the die, and a height gage or other accurate gaging methods must be employed in setting the "masters." It is the writer's belief that using disks as described, instead of attempting to file to scribed lines will reduce the cost of diemaking as much as 60 per cent.

* * *

CHAMFERING TOOL

By HARRY MOORE

In cutting either internal or external threads on a hand-screw machine, it is necessary to chamfer the end of the work before bringing the threading die or tap into operation. The tool shown in the accompanying illustratiou was designed to perform the required chamfering operations, and it proved more satisfactory than the hand tool commonly employed for this purpose. In addition to performing chamfering operations, it is also used for cutting rings in faces of fittings which are required to be water-tight.



Adjustable Chamfering Tool

Referring to the construction of the tool, piece *A*, which holds cutter *B*, is drilled to receive the special holding screw *C*. The front end of part *A* is slotted and tapped for the screw *D*, which holds cutter *B* in place. All parts are made of machine steel except cutter *B*, which in this case is made of tool steel. In setting the tool, arm *A* is swung and cutter *B* adjusted to give the required chamfer. When properly set, screws *C* and *D* are tightened to hold the cutter in position. The advantage of using a cutter of circular form is that as the position of arm *A* is altered, the cutting face of the tool can be swung around to produce a 45-degree chamfer. The circular cutter can also be ground many times before it is necessary to replace it.

ASSEMBLING DEVICE FOR PULLEYS, HANDWHEELS AND GEARS

A motor-driven draw-bench is used by the Hopedale Mfg. Co., Milford, Mass., for forcing such parts as handwheels, pulleys, and gears on the ends of shafts which have previously been lined up in their machine bearings. This device is used primarily in connection with the erecting of cotton looms, the crankshafts of which extend beyond the sides of the frame and carry pulleys and similar parts which are regularly assembled after the crankshafts have been fitted in their bearings. Although this device was especially constructed, the principle involved is of general application where assembling methods of a like nature are encountered.

The device consists of a four-legged iron table on which is mounted a reversing motor which drives a train of reducing gears, compactly mounted on the top of the table. The table top is not more than 2½ feet square, and when not in use the entire device takes up very little space. The final gear in the reducing train is fitted to a hollow threaded arbor so that as the gear revolves it advances on this arbor. On opposite sides of the table top there are cast two slotted lugs, the slots being about 2 feet apart, the position of which is indicated in the diagrammatic sketch which accompanies this article. Two long reach-rods, yoked together as shown at *A*, are used when drawing the parts to be assembled on the projecting end of the crankshaft. The nuts for the threaded end of the two long rods form a bearing against the vertical surface of the lugs on the table, while the bar which joins the two rods rests against one arm of the crankshaft. The threaded arbor previously mentioned has a hole extending through it which is of sufficient diameter to receive the projecting end of the crankshaft, so that as the hub of the gear advances into contact with the handwheel, gear or pulley, as the case may be, the part will be forced on the shaft. The pressure exerted against the end of the part to be assembled has a tendency to force the table

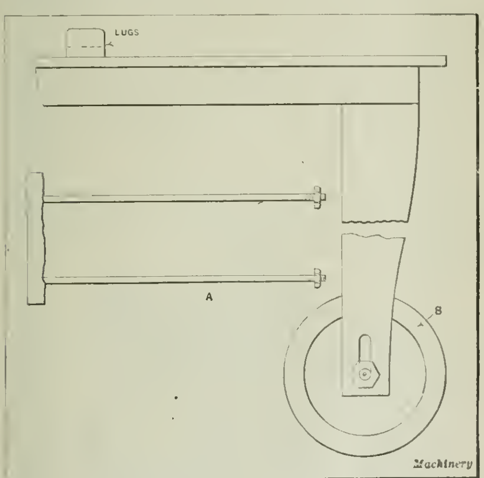


Diagram illustrating Features of the Assembling Device

away from the side of the loom, but this is prevented by the brace consisting of the two rods and yokes as previously mentioned.

Obviously, there must be some means of adjusting the height of the table so as to bring the center of the threaded arbor into alignment with the center line of the crankshafts of different sizes of looms. This is accomplished by a very simple means. A circular sheave is attached to each leg in a fixed position by means of a bolt passing through an elongated slot. The sheave can then be secured so as to bring the level of the table to the required height, and for the purpose of locomotion a steel rim *B* revolves on the fixed sheave as a center. This arrangement also permits variations in floor levels to be quickly compensated for. By having a reversible motor it is a simple matter to strip such parts as handwheels, etc., from the crankshaft.

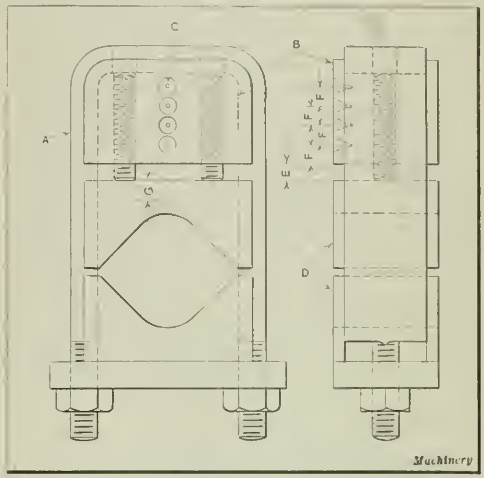
ADJUSTABLE OFFSET DEVICE FOR CRANKSHAFTS

By D. R. GALLAGHER

Automobile repair shops generally keep on hand a quantity of offset fixtures for use in mounting crankshafts between the centers of machines when desiring to turn or grind the crankpins, it being necessary to have a number of fixtures



Adjustable Offset Fixture used in re-turning or regrinding Crankpins

on account of the difference in dimensions existing between crankshafts of various makes and sizes of cars. Although the diameter of the end bearings may be the same on a number of crankshafts, the length of throw is likely to be different. The accompanying illustration shows an offset fixture which is adjustable for the diameter of the end bearings and for the length of throw. It consists essentially of a bent strap *A*, which is finished on all sides, a block *B* provided with four centers *C*, and two sliding V-blocks *D*. One of these devices is placed on each of the end bearings of the crankshaft, blocks *D* being slid apart enough to admit the bearings. The crankpins to be machined must, of course, be in alignment with one of the centers in block *B*. That center which is nearest to the center of the crankpin when the fixture has been placed on the crankshaft is selected as the one to be used in mounting the crankshaft on the machine. The axes of the crankpins are then brought accurately in line with the center to be used, through the adjusting screws in block *B* which control the distance between this block and the upper one of blocks *D*. Blocks *D* should be kept parallel, and feelers used to insure that distance *E* on both offset fixtures is identical. Each offset fixture is finally tightened on the crankshaft by means of the nuts on strap *A*. After a little practice a workman can make necessary adjustments quickly.

Strap *A* may be made from a forging, and block *B* from machine steel and pack-hardened or from a non-shrinking tool steel. The distance *F* between the various centers should be located accurately in each pair of offset fixtures. V-blocks *D* should also be made from steel, hardened and ground to a sliding fit. Dimension *G* must be the same in each fixture of a pair to obtain accurate results. This dimension may be determined by plug or ball measurement.

The Metal-working Industries

THERE has been but little change in conditions in the metal-working industries during the last month. The conditions in the industries throughout the country are practically the same as in the New England district, where the Federal Reserve Bank of Boston made a complete survey covering the month of July. This survey shows that in New England these industries as a whole are operating at approximately one-third capacity, but there is great variation as regards different plants; a few shops work full time, while some are entirely closed down. Activity is greatest in plants making tools, supplies, and hardware for the building trades, and some business is reported from drop-forging plants. A manufacturer of pumps reports the last six months as the best in the history of his business, this line having suffered relatively little from the depression.

While cancellations are now but few, as there are but few old orders on the books that would be subject to cancellation, manufacturers are frequently asked to suspend shipments of machines or other products. A Connecticut manufacturer says: "We have on our books a large volume of business which has been manufactured and is now being held in our shipping rooms, as our customers have held up the orders."

The price situation in the iron and steel industry has been one of the chief problems confronting manufacturers in the metal-working field, and one firm states that it is impossible "to look for improvements until steel prices are sufficiently stabilized so that customers feel reasonably assured that the bottom has been reached, at least temporarily."

The Iron and Steel Industry

There is still comparatively little activity in the iron and steel industry, pig iron production being estimated at 30 per cent of normal, and steel ingot production at slightly over 25 per cent of normal. The only mills reporting improved business are those engaged in sheet metal rolling, several mills having been reopened; but there is evidence of better demand for pig iron and inquiries and orders for steel are increasing, although much of this business is done at the expense of price cuts. A gradual if slow increase in the buying of railway and building materials is reported, and the pig iron market shows a tendency toward becoming more active, due, doubtless, to the low prices now being quoted for this raw material, various grades being sold at base points at from $18 to $20 a ton. The corresponding grades a year ago were quoted at $46 and $46.50 a ton. Prices of finished steel average 2.36 cents a pound, compared with 3.94 cents a pound a year ago. The average price for ten years previous to the war for the same grades of finished steel was 1.68 cents a pound.

The Automobile Industry

So far, seventy-two automobile manufacturers have announced reductions in the prices of their cars. Some of the prices announced are back to the 1918 level. While there has been some revival in sales in consequence of these price cuts, the reductions have not affected the market to the extent expected by the manufacturers. The public appears to be expecting still further reductions, losing sight of the fact that present conditions, taxes, increased overhead due to decreased production, are factors to be reckoned with in making a selling price that will not mean a loss to the manufacturer. Measured in percentages, the reductions range from 5 to 35 per cent; the average reduction announced by forty-five companies is 15 per cent.

The National Automobile Chamber of Commerce reports that production of passenger cars and motor trucks during the second quarter of the year was 87 per cent of the production figures for the corresponding period of 1920, which is a figure that will surprise a great many, and shows that the automobile business surpasses most other industries during this period of depression. Partly, this record is due to the high average maintained by the Ford factories, whose production schedule for August called for 117,800 cars and trucks from all the plants owned by the corporation. This is the highest production for any one month on record. The Buick, Hupp, White, Chandler, Jordan, and Dodge plants also report increased production, while the Willys-Overland reduced its August schedule and is laying off men. The Akron tire industry is reported operating practically on the 1918 level, which is considered normal.

Machine Tool Exports

The exports of machine tools during June, 1921, the last figures published by the Bureau of Foreign and Domestic Commerce, amounted to $460,000 as compared with $2,370,000 in June, 1920. Perhaps the most noticeable falling off in machine tool exports is to England, the June exports this year amounting to only about $28,000. It was $560,000 for June a year ago. Belgium took $60,000 worth of machine tools in June, 1920, and only $2,000 during the same month this year. The exports to Canada show a very decided falling off, amounting to over $44,000 in June, as against $101,000 in April, this year, and $410,000 in June, 1920. Mexico remains a good customer, taking nearly $50,000 worth of machine tools in June, France following closely with a similar amount. Japan heads the list with nearly $75,000, and China more than $25,000 worth. In May there was an unusually large shipment of machine tools to the Dutch East Indies, amounting to nearly $60,000.

Compared with 1913, the value of the exports of metal-working machinery (statistics prior to 1918 include machine tools under that general heading) in May, 1921, was at the rate of 110 per cent of the average monthly shipments of metal-working machinery in 1913; 145 per cent of the average shipments in 1912; 182 per cent of the average shipments in 1911; and 295 per cent of the average shipments in 1910. This indicates that present exports are low only when compared with the unusually large volume during and immediately after the war.

Labor Conditions

The announcement has been made that the Erie Railroad has leased its shop at Marion, Ohio, to a private company which can operate it without being bound by the labor union rules governing the railroad shops. This may prove to be the only way in which efficiency can be attained in locomotive repair shops, for it is only too well known that irrespective of the wages paid, these rules have increased costs. Union wages will be maintained in the shops operated by the private company, but the work and methods will be in accordance with the best manufacturing practice and free from rules which reduce efficiency without in any way benefiting the worker.

The building of small homes is brisk in many sections of the country, and wherever new wage arrangements have been made with the labor unions, increased activity is also noticeable in the construction of office and factory buildings. Employment in fourteen major industries reported upon by the Federal Reserve Bank in the New York district indicates improved employment conditions in nine industries, stationary conditions in two, and decreased employment in three industries—the iron and steel, car building and repairing, and paper-making.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application.

Garrison Gear Grinding Machine

An automatic machine for generating and grinding the involute profiles of spur gear teeth has been placed on the market by the Garrison Gear Grinder Co., of Dayton, Ohio. Gears which have previously had their holes hardened and ground and been roughed out on a gear-cutting machine leaving a grinding allowance of from 0.008 to 0.012 inch on the tooth thicknesses, are mounted on the work-spindle of the gear grinding machine and have the teeth generated and ground to the correct form and size. This operation takes about the same time required for taking a finishing cut on a gear-cutting machine. The grinding wheel is dressed on both sides to the pressure angle of the teeth and to the correct thickness. It is traversed back and forth through the gear tooth spaces by means of a ram.

The gears being ground are indexed one tooth after each stroke and fed toward the wheel slightly after each revolution of the latter, thereby accomplishing the generation of an involute. The gears are rotated slightly each time the table is fed over, through a hardened and ground master gear on the outer end of the spindle and a master rack.

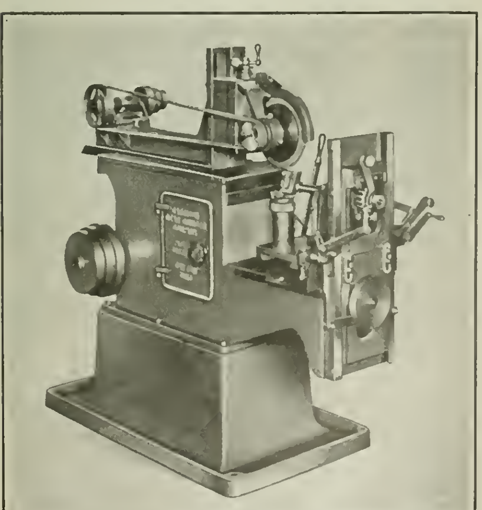


Fig. 1. Automatic Gear Grinding Machine developed by the Garrison Gear Grinder Co.

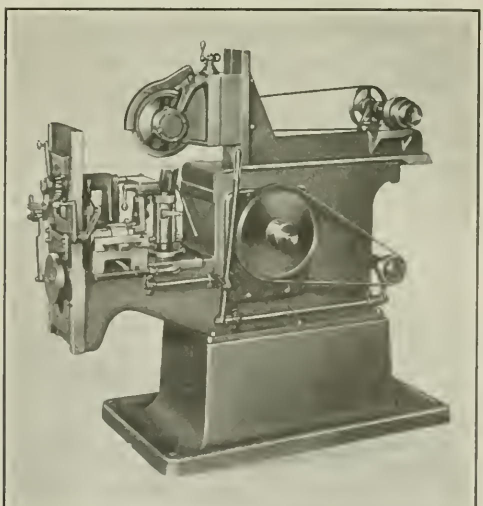

Fig. 2. View of Right-hand Side of Garrison Gear Grinding Machine

By this arrangement a new tooth surface is presented to a new surface on the grinding wheel after each revolution of the wheel. This prolongs the accuracy of the wheel by distributing the wear over a comparatively large area. As the master rack is meshed with the master gear at all times when the grinding wheel is in contact with the work, an accurate spacing of the teeth is insured. Any given tooth is not touched a second time by the grinding wheel until the gear has been indexed through a complete revolution; in this way, the generation of heat in the gears being ground is avoided.

The machine is so designed that after being adjusted for grinding a gear of given dimensions, an unskilled operator can run several of them on gears having as few as twelve teeth, and more machines in proportion to the number of teeth. No adjustment of the grinding wheel is necessary subsequent to dressing, and so, after the dresser is once set for truing a wheel to grind a certain size gear, the wheel may be dressed repeatedly without any change in the size of the gear teeth. The wheel is fed downward for the dressing step, diamonds being used for this operation. All feeds and the stopping of the machine at the completion of an operation, are automatic. It is not necessary to stop the grinding wheel in order to load or unload the machine as the work-table can be moved over to eliminate interference. The machine is suitable for grinding gears of from 2 to 9 inches in pitch diameter and any number having a combined width of 3 inches or less. It is adapted for grinding wheels of from 6 to 10 inches in diameter. The machine complete with a countershaft weighs approximately 1500 pounds.

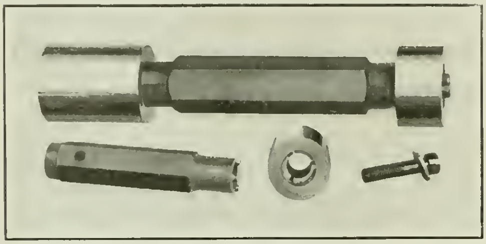

Fig. 1. Assembled and Disassembled Plain Plug Gage made by the Pratt & Whitney Co.

PRATT & WHITNEY GAGES

A new line of palin and thread plug and templet gages has just been placed on the market by the Pratt & Whitney Co., Hartford, Conn. The plain plug gages are made of an alloy steel and are machine-lapped by a modification of the Hoke process which results in a finely finished surface entirely free from circular grooves. The gages are of uniform size from end to end to such a degree that no errors are shown by measuring machines, fluid gages, or amplifying gages. The ends are reversible and their sizes are marked on them instead of on the handle. The "Go" ends are held to a small plus limit from the marked size to allow for wear, while the "Not Go" ends are held to a still smaller minus limit as they are subject to little wear. All blanks are well seasoned before lapping.

The handles are made of hexagonal stock and the plugs are secured to them by a novel method. Three prongs, whose sloping sides form an included angle of 90 degrees, are provided on each end of the handle; these prongs engage three grooves machined in the gage ends, the sides of the grooves forming included angles of 75 degrees. The wedge-like prongs are forced into the grooves by means of a single screw inserted through the plug. In this way, the gage ends are so secured that they can neither rock nor shake and so destroy the sensitiveness of the "feel." The head of the screw used in attaching the "Go" end to the handle is below the surface of the plug end, while the head of the screw on the "Not Go" end projects slightly. This design insures that the gage will always be in an upright position with the heavier end down. All sizes of handles are made in either the single- or double-end design. A hole is provided through the handle to permit of hanging the gage on a nail when desired, and if the gage becomes fast in work being inspected, a file tang or some other suitable object may be inserted in the hole and used to free the gage. These gages are now made in various sizes ranging from 5/16 to 2 inches in nominal diameter, but smaller and larger sizes are made.

The various styles of thread gages shown in Fig. 3 are made from the same alloy steel blanks as the plugs of the gages just described. The "Go" and "Not Go" ends are made interchangeable with the plugs and either length can be used according to a customer's preference. Short gages are particularly recommended for threads of fine pitch. The gages are secured to the handles in the same manner as the plug ends, so that the same rigidity is obtained and the sensitiveness of touch is not lost. The gages shown at *A* and *B* are single- and double-ended, respectively. That shown at *C* is a protected master gage, so called because it is impossible to screw it into a hole and thus impair its accuracy. It is used as a standard for checking thread plug gages by means of a measuring machine, micrometer, etc. The gage shown at *D* is used for setting thread gage templets, the threaded end being a duplicate of the thread in the templet, while the plain end is used for checking the root diameter.

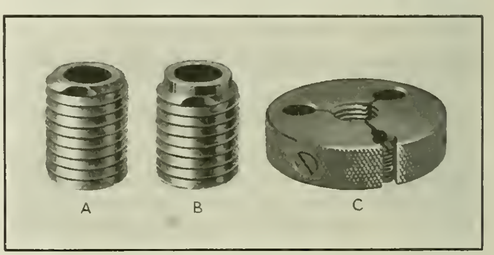

Fig. 2. (A) and (B). Gage End Details showing Chip Groove and Pilot. (C) Adjustable Thread Templet Gage

The gage shown at *E* is a non-reversible thread plug gage. This style is used for sizes ½ inch in diameter and smaller and for larger sizes where the reversible feature is not desired. The surfaces of the handle and thread plug in contact are tapered and so the parts cannot work loose after being driven together. Where the limits specified on the work are very large, extreme accuracy is not required of the gages, and so working gages made to tolerances recommended by the National Screw Thread Commission are made in different forms and sizes for such work. These gages have the same appearance and wearing qualities as master gages, but are not lapped, being ground to size instead, with an allowance of about 0.0005 inch for wear.

A feature of the plug thread gages is the groove provided for carrying dirt and chips ahead of the gage when the latter is being entered into a hole. This groove may be seen at the top of the thread plug shown at *A*, Fig. 2. It avoids the wedging of dirt or chips between the threads of the gage and those of the work. A modification of this style is shown at *B*, in which the first convolution of the thread is removed to form a pilot of the root diameter. This pilot is of assistance in entering the gage in running work or when the gage is held in a reversing speed lathe and the work fed to it while running.

A thread templet gage of the familiar round type, but having an improved adjustment, is shown at *C*, Fig. 2. The adjusting screw is short and tapered and is placed parallel to the axis of the gage. One full turn of this screw changes the effective diameter of the gage about 0.001 inch, and adjustments finer than 0.0001 inch can be made. The first thread of the templet is chamfered to the angle of the thread

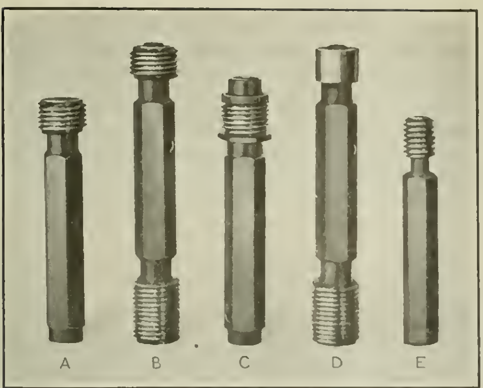

Fig. 3. Various Styles of Thread Plug Gages, with Reversible Ends on All but One

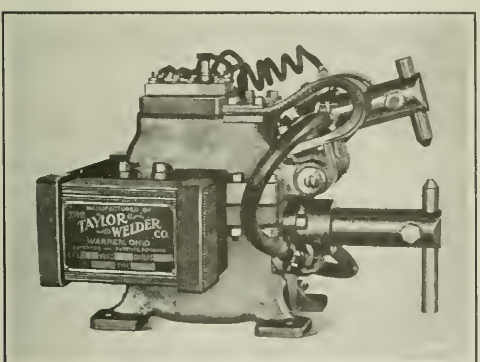
for ease in starting. The chip groove of the thread plug gage can be furnished on the templet gage but this is not usually necessary because a male thread can be more readily cleaned than the threads of a tapped hole, and moreover, the slots in the templet provide chip space.

TAYLOR BENCH SPOT WELDER

The type S-4-B bench spot welder now being built by the Taylor Welder Co., 12 Atlantic St., Warren, Ohio, is shown in the accompanying illustration. This machine is recommended for spot-welding sheet metal of light gage, cross-wire welding, welding contact points of platinum or tungsten to steel, and brazing and soldering small parts of electrical instruments, optical goods, etc. A special feature of this machine is the cast-copper frame which acts as a secondary. The lower horn may be set at three different heights on the

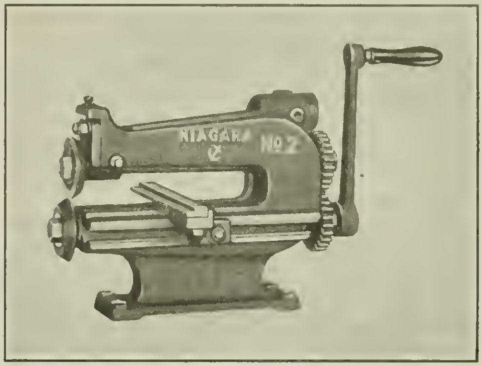


Bench Type Spot Welder built by the Taylor Welder Co.

frame to suit the work, by the provision of different sets of holes. A long electrode is provided on this horn to suit the various settings. Cooling of the machine is accomplished by the circulation of water in the upper and lower horns. The horns are made of cold-drawn copper and are $1\frac{3}{4}$ inches in diameter. The greatest movement of the upper electrode is 1 inch and when this electrode is lowered the minimum distance between the horns is 3 inches and the maximum, 5 inches. The machine is operated through a foot-pedal. One set of solid points is furnished with each machine and the weight of the latter is approximately 150 pounds. The machine is equipped with a 3-kilowatt transformer and a 4-step regulator for adjusting the current. The switch is of the automatic single-pole type.

NIAGARA ROTARY SHEAR GAGE

The Niagara Machine & Tool Works, Buffalo, N. Y., recently obtained a patent on a slitting gage that is being applied to rotary sheet metal shears. The accompanying illustration shows a hand slitter equipped with the gage. The gage consists essentially of a bar extending transversely through the gap of the machine and against which one edge of a sheet bears so that it is cut to the required width. The bottom of the transverse bar rests upon the frame of the machine and is connected at the ends to sliding blocks. These blocks may be clamped in any predetermined longitudinal position along the machine so that the distance from the rotary knives to the gaging bar may be altered to suit a job. They are clamped on machined surfaces of the frame by means of T-bolts. The only member of the gage subject to wear is the transverse bar, and this can be readily replaced, as it is located on the sliding blocks by means of

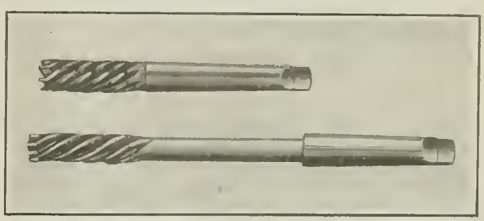


No. 2 Slitter equipped with Gage patented by the Niagara Machine & Tool Works

dowels and attached by bolts. The gage can be removed from the shear when it interferes with such operations as circle or ring cutting.

GAMMONS-HOLMAN END-MILL AND CHUCKING REAMER

The Gammons-Holman Co., Manchester, Conn., has introduced on the market the new types of end-mills and chucking reamers shown in the accompanying illustration. The end of the cutting portion of both tools is made in the usual way while the body is provided with helical cutting edges, the "hand" of the helix being opposite to that of the tool. That is, the chucking reamer and right-hand end-mill have left-hand helical cutting edges while the left-hand end-mill has right-hand helical cutting edges. It is stated that the helical body counteracts the tendency of the straight-fluted end to chatter, with the result that the reamer produces a true smooth hole and the end-mill leaves the surface it mills so smooth that further finishing is unnecessary. There is no chatter of the tools in use.



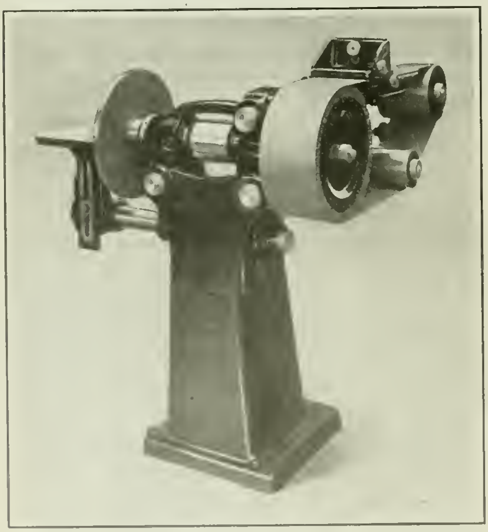
End-mills and Chucking Reamers placed on the Market by the Gammons-Holman Co.

GRINDING AND POLISHING MACHINE

A combination machine designed to handle the work of a disk grinder, a polishing wheel, and a belt-surfacing machine and which, in addition, can be converted into a double-spindle buffing machine or into a light snagging grinder has been developed by the Production Machine Co., Greenfield, Mass., and is known as the "Type R." This machine is adapted for a wide range of work, and the construction is such that three operators may work simultaneously without interfering with one another. The base and head are cast integral, so as to supply the necessary rigid support for the spindle and its bearings.

The spindle is equipped with Timken roller bearings, and these are packed in grease and sealed from dust. On one end of the spindle is mounted a double-faced disk grinding wheel, and on the other end, a patented leather cushion wheel over which an abrasive belt runs. This wheel, together with the belt, is used for a variety of polishing operations. The belt is 6 inches wide, endless, and kept under the proper tension by means of a swinging idler pulley. A table is furnished for use in surfacing operations, and this is equipped with an adjustable rest that facilitates the handling of articles having straight or angular edges. This rest is so hinged that it may be quickly swung over the back of the machine when it is necessary to change the abrasive belt. The idler arm is arranged with a latch, so that the idler may be lifted off the belt and held in a raised position while the latter is being changed.

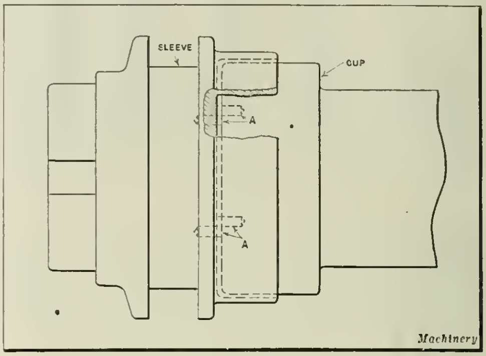
The double-faced disk wheel is reversible. A table is provided for supporting work being ground on this wheel, the table having a rocking seat which enables the supporting of angular work. The table has a vertical adjustment and a circular adjustment on the holding post. The machine is equipped with four holding posts, two in the front and one on each side, and these posts adapt the machine for the application of a variety of fixtures. Some of the principal dimensions of the machine are as follows: Diameter of disk wheel, 15 inches; dimensions of disk-wheel table surface, 9¾ by 8 inches; leather cushion wheel, 14 inches in diameter and 6 inches wide; and surfacing table, 14 by 6½ inches. The spindle speed is 1300 revolutions per minute, and the surface speed of the abrasive belt, 4760 feet per minute.



Combination Grinding and Polishing Machine developed by the Production Machine Co.

JOHNSON FRICTION CLUTCH

The design of the friction clutch manufactured by the Carlyle Johnson Machine Co., Manchester, Conn., has been modified to incorporate a positive locking feature. The load can only be started under friction, but when the clutch is completely engaged it becomes positively locked and so the driven member is rotated constantly at the speed of the driver without any possibility of slippage, due to variations in the load or to other causes. The clutch is operated by an outside shifter sleeve, which carries a sliding wedge between two toggle levers that expand a friction ring and cause the latter to grip the opposing surface of a cup member. On the faces of the cup and shifter sleeve are six pairs of opposing pins *A* spaced equidistantly around a circle. When the clutch is disengaged, both frictional surfaces and the opposing pins are out of engagement. However, as the shifter sleeve is thrown in, the frictional surfaces begin to take the load and practically carry it at full speed before the opposing pins come into contact with one another. Then, the full throw of the clutch having been accomplished, the pins are in engagement so that the clutch drives as a positively locked unit.



Friction Clutch with Positive Locking Feature, manufactured by the Carlyle Johnson Machine Co.

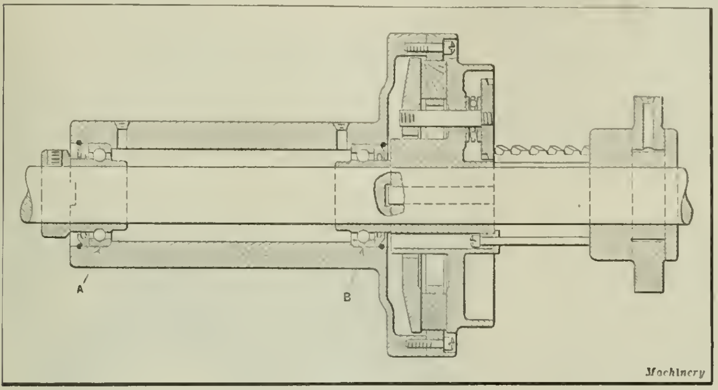
THERMIT-WELDING MOLDING MATERIAL

A new grade of molding material for thermit-welding has recently been brought out by the Metal & Thermit Corporation, 120 Broadway, New York City. It is stated that this material prevents blow-holes, stands up well under the preheating flame, and is extremely porous to the gases generated in the mold so that a sound weld with a clean exterior results. The mixture is composed of three parts clean sharp silica sand to one part of Welsh mountain plastic clay. The sand must pass through a screen of 0.03 inch square mesh, and 40 per cent must be retained on a screen having 0.012 inch square openings. In using the material, the sand and clay are thoroughly mixed together with 1/40 part "Glutrin" compound and sufficient water to bring the mixture to the proper consistency.

HILLIARD CLUTCHES AND COUPLINGS

The line of sleeve clutches made by the Hilliard Clutch & Machinery Co., Elmira, N. Y., is now being equipped with Fafnir ball bearings as shown at *A* and *B*, in order that the clutches may be satisfactorily used for high speeds up to 2000 revolutions per minute. The bearings are of the annular type and are fitted with caps provided with felt washers that exclude dust and retain the lubricant. The use of the ball bearings insures that the sleeve member will be kept in the proper alignment with the member keyed to the shaft, and that the frictional surfaces will always be in the proper plane with each other.

The friction cut-off couplings made by the same concern, for directly connecting centrifugal pumps, generators, and blowers to gasoline or electric motors are now furnished with a Fafnir ball bearing for the pilot. The driving member of the coupling is very similar to that of the clutch illustrated. Provision of the ball bearing in the coupling insures the proper alignment between the driving and driven shafts and satisfactory lubrication. Both the cut-off couplings and the friction clutches are made for shafts of various diameters from 1 3/16 to 3 15/16 inches.



Ball Bearing Modification to the Sleeve Clutch made by the Hillierd Clutch & Machinery Co.

GENERAL ELECTRIC CONTROL FOR DIRECT-CURRENT MOTORS

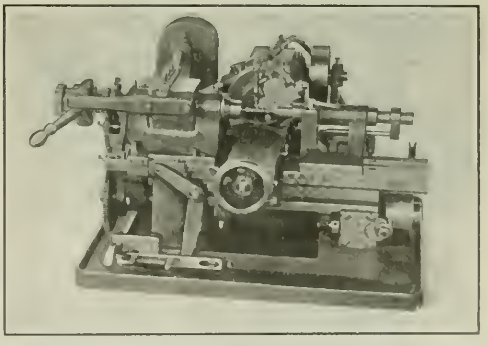
A type of control for direct-current motors of either reversing or non-reversing applications, which is a combination of time and current limit, allows high torque when necessary and minimizes current peaks on light loads, has been designed by the General Electric Co., Schenectady, N. Y. This control system is known as the "voltage drop," being so named from the fact that the relays controlling the accelerating contactors are operated by the voltage drop across the starting resistor of the motor. A current limit system of some sort is considered best for motors subjected to frequent starting and stopping and which are required to operate under varying conditions of torque. Such conditions include applications where the motor is required at infrequent intervals to accelerate loads as high as twice normal, and should be protected from such high current peaks the remainder of the time. This system uses an improved form of shunt contactor and is applied to standardized panels for the control of various types of motors.

WALTHAM AUTOMATIC THREAD MILLING MACHINE

The Waltham Machine Works, Newton St., Waltham, Mass., are now manufacturing an automatic thread milling machine which is intended for manufacturing purposes and is so designed that it may be equipped for a large variety of work. After the work has been placed in position either on centers or in a chucking device, the machine is started by raising a lever at the left end. The feeding of the cutter into the work to the required depth, the milling of the thread, the withdrawal of the cutter after the required length has been milled, the returning of the cutter to the starting point, and the stopping of the machine are wholly automatic. These automatic features enable a number of machines to be handled on some kinds of work by one operator. With multiple threads the operation is continuous until all threads have been milled, so that for a triple thread the cutter would engage the work for its entire length, three times before the machine would stop.

The length of a thread cut by the machine corresponds to the amount of rise on the cam that controls the work-slide, and its pitch is governed by the relation between the gearing from the work-head to the camshaft, and the lead of the cam. The indexing for multiple threads is obtained by a fractional proportion in the gearing and as the work-head revolves continuously there is no backlash to cause inaccurate spacing. The maximum travel of the work-slide is 2 inches, and threads of this length or shorter may be milled. Adjustments enable the milling to be done either close to the work-spindle or in any position not more than 6 inches distant. The approximate locating of the cutter-slide relative to the work-head is obtained by moving the support of the cutter-slide along tongued ways, while the exact location is obtained by adjusting the work-slide cam-shoe attached to a slide at the front of the machine. An angular adjustment of 45 degrees each side of the horizontal is provided for the cutter-head. A special high-speed cutter-head is provided for brass work.

A single belt drives the entire mechanism with the exception of the oil-pump. This is separately driven and pumps oil from a reservoir in the base upon which the machine is mounted. The work-spindle is made of hardened steel; it has a spring collet and is equipped with a lever-closing attachment. The mechanism for automatically stopping the machine can be adjusted to function at the end of one cam revolution or after any predetermined number of revolutions necessary for the cutting of multiple threads. The machine can be modified for cutting helical gears. It may be installed either on a bench or a cabinet base.



Automatic Thread Milling Machine developed by the Waltham Machine Works

DUPLEX CUTTING-END TOOL BITS

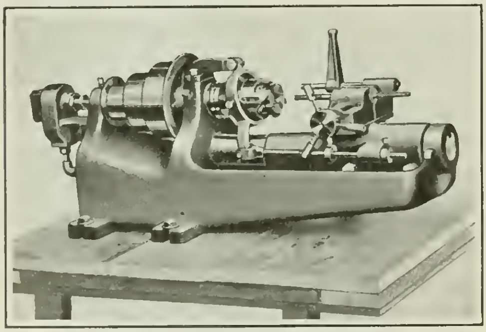
A line of tool bits of various sizes and shapes and having cutting edges ground on both ends, has been introduced by the New England Tool & Machine Co., Inc., 51 Taylor St., Springfield, Mass. A few styles are shown in the accompanying illustration. These bits are intended for being held

Tool Bits made by the New England Tool & Machine Co., Inc.

in tool-holders taking square stock, are cut from annealed bars of high-speed steel, and are hardened and ground. Their size permits them to be checked out from tool-cribs the same as drills and other tools, so as to reduce their loss. The line includes bits of the following styles: Right- and left-hand diamond point, right- and left-hand side, round nose, U. S. standard thread of all pitches, V-thread and cut-off. The sizes listed are from 3/16 to ½ inch square.

GEOMETRIC BENCH THREADING MACHINE

A bench threading machine equipped with a Geometric rotary die-head for the cutting of fine-pitch threads of from 1/16 to 5/16 inch in diameter is here illustrated. This machine has just been introduced by the Geometric Tool Co., New Haven, Conn. The bed consists of a single casting and has a spindle mounted in bronze bearings. This spindle is driven through a three-step cone pulley and carries the rotary die-head at its inner end. The die-head is operated by a yoke lever and trip-rod. Adjustable stops conveniently arranged on the trip-rod govern the opening and closing of the die-head. It is opened with a forward movement of the carriage and closed with a backward movement.



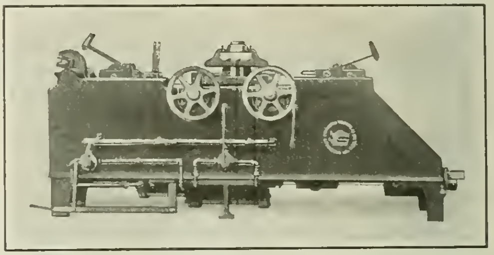
Small Bench Threading Machine recently brought out by the Geometric Tool Co.

The carriage is equipped with a two-jaw chuck operated by a handwheel, but collets, expanding arbors, or special holders can be furnished when the work requires such accessories. An adjustable swinging stop on the side of the chuck enables the accurate setting of work for the cutting of a thread to a predetermined length. The carriage is mounted on a round bar on which it is guided by a large bronze key that engages a keyway on the bar. An adjustment is provided for maintaining the proper fit of the carriage on its support. This construction facilitates the removal of chips from the bed of the machine. Oil from the reservoir in the bed is forced through the spindle and against the work by a geared pump having a direct drive from the spindle. The cone pulley furnishes proper spindle speeds for the rated capacity of the machine.

Different sets of chasers are required to cover the threading range of the machine and these may be readily removed from their slots after the die-head has been tripped and the stop plunger pulled out. Identification numbers are placed on the chasers and on their corresponding slots to insure the correct assembly of the chasers. This machine is arranged for bolting to a bench, or it may be mounted on a separate pedestal for floor use. Some of the specifications are as follows: Maximum length of thread which can be cut at one setting, 3¼ inches; with resettings, 18 inches; bench space required, 9½ by 29 inches; floor space required when mounted on pedestal, 16 by 29 inches; weight without pedestal, 90 pounds; and with pedestal, 175 pounds.

COVINGTON HOSE DISMANTLING AND ASSEMBLING MACHINE

A new development of the Covington Machine Co., Inc., Covington, Va., intended for use in railroad shops, is a machine for dismantling and assembling air-brake, signal and steam hose. It is claimed that with this machine no damage can be done to fittings and that a much better assembling job is accomplished than when the operation is performed by hand. On a test, one man dismantled one hundred pieces of air-hose in an hour and assembled twenty-five ready for service in another hour. The changing of the tools used in one operation for those of another averages less than two minutes. Air and signal hose are handled by the same tools except the nipple puller, and the latter can be put in place within ten seconds.

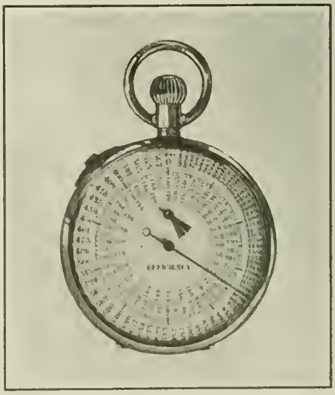


Railroad Shop Machine developed by the Covington Machine Co., Inc.

SILBERBERG TIME-STUDY WATCH

A time-study watch designed for the timing of from one to ten operations, up to and including five minutes' duration, has been developed by the Mortimer J. Silberberg Co., 122 S. Michigan Ave., Chicago, Ill. This instrument has three circles of numbers on the face of the dial, those of the outer circle being red, the middle circle, black, and the inner circle, blue. The large hand makes a total revolution in 100 seconds and the small hand near the center moves over red, black, and blue sectors to show which circle of numbers the large hand is indicating.

All figures on the dial denote production per hour based on the timing of ten operations at one



Duration Time-study Watch brought out by the Mortimer J. Silberberg Co.

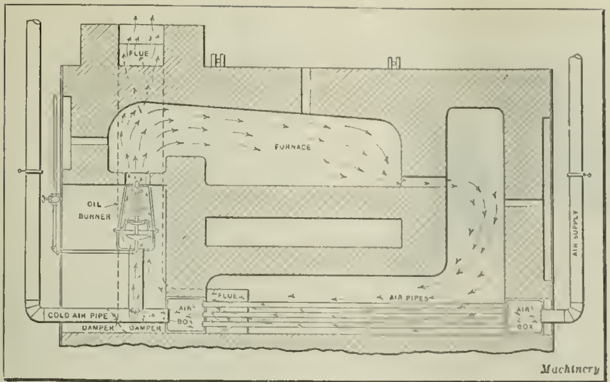
time. For instance, if one operation requires twenty seconds, the figure under the large hand in the red circle of numbers is 1800, but as this figure is based on ten operations being performed at one time, it is necessary to divide the number by 10 in order to find the total number of operations per hour. The result would be 180.

If the duration of an operation is 130 seconds, the large hand will have made a total revolution plus a partial revolution to the 30-second graduation. In the meantime, the small hand near the center of the dial will have passed through the first sector and indicate the second or black sector, thus denoting that the number of operations per hour should be read in the black circle of numbers. The figure in that circle of numbers beneath the large hand when the latter indicates the 30-second mark, will be 277, this again being for ten operations.

The instrument has a feature which permits an operator to start and stop the watch without returning the large hand to the zero graduation. When an operation is entirely completed, all hands are returned to the starting point by pressing down the crown of the watch. The dial is divided into half-seconds.

PITTSBURG OIL-BURNING APPARATUS

In some cities it is common practice to shut off the supply of natural gas to industrial consumers in the event of a shortage, in order that domestic users may have a sufficient supply. To meet such a contingency the Pittsburg Saw & Mfg. Co., 32nd and Smallman Sts., Pittsburg, Pa., is placing on the market the A.G.S. oil-burning apparatus which has industrial and domestic applications. The burner is of the gasification type. In the metal-working field it is especially suitable for forging furnaces and core-ovens. A forging furnace installation is shown diagrammatically in the accompanying illustration. The furnace is 4 feet wide, 8 feet long, and 5 feet high. Air may be supplied to the burner by a small fan or blower, and arrangements have been made in the furnace for the exchange of heat between outgoing hot gases and incoming fresh air. The imparting of heat to the incoming air contributes materially to the efficient use of the fuel and makes possible the attainment of high temperatures in the heating chamber.



Forging Furnace Installation of Oil-burner developed by the Pittsburg Saw & Mfg. Co.

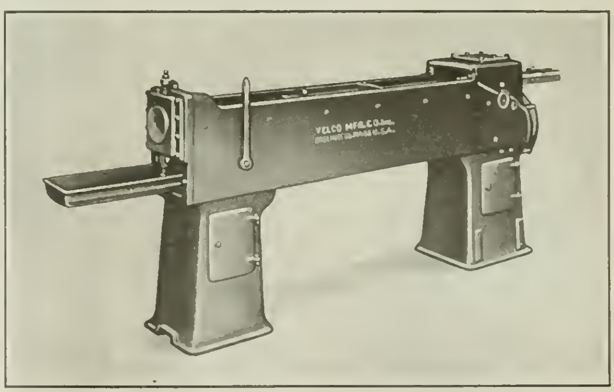
At no time has the temperature of the flue gases at a point six inches above the furnace been in excess of 650 degrees F., while temperatures of from 2600 to 2800 degrees F. have been maintained in the heating chamber. The consumption of oil in heating the furnace varies from 5 to 6 gallons per hour, and the time required is from 1 to 1½ hours. After the furnace has been raised to the desired temperature, the oil consumption necessary to maintain the temperature varies from 2½ to 3 gallons per hour. The oil used with this furnace must be free flowing at 32 degrees F., must have a flash point higher than 150 degrees F., must have less than 5 per cent residue at 700 degrees F., and must have a viscosity less than 100 Saybolt at 100 degrees F. Kerosene, mineral seal, mineral seal substitute and distillate, etc., can be used in connection with the burner. It is stated that the oil is consumed without producing smoke or odorous vapors. The installation of the burner is easy and its operation simple.

VELCO NO. 4 HIGH-SPEED BROACHING MACHINE

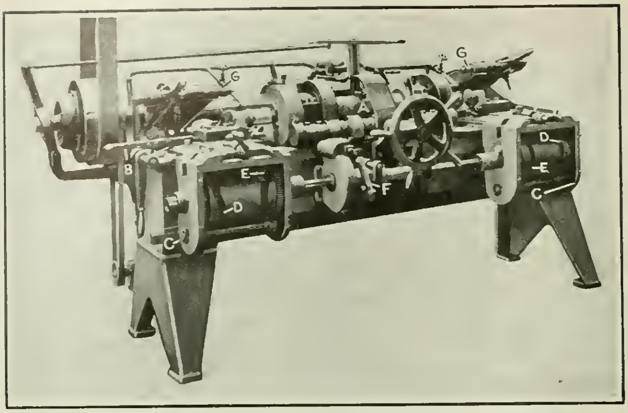
A heavy-duty high-speed broaching machine having several novel features has been developed by the Velco Mfg. Co., Inc., Greenfield, Mass. This machine has a cutting stroke speed of 15 feet per minute and a return stroke speed of 55 feet per minute. The broach holder is attached to a solid steel head and this is supported throughout its travel by bronze gibbed bearings sliding on steel ways. Power is applied to a rack that meshes with a pinion cut integral with a heavy shaft. The broach is attached to this rack so that the pull comes directly on the pitch line of the rack teeth. All vertical adjustments are made at the faceplate.

Stub gear teeth are provided on the rack and driving pinion. The teeth of the rack are on the under side, and the sides of the rack are guarded to protect the operator from injury. All other moving parts are completely enclosed. The rack is held in proper mesh with the pinion by means of rollers placed at the sides of the pinion and guide bars fastened to the sides of the rack, thus making a rolling contact on the pitch line. The pinion-shaft is driven through a phosphor-bronze worm-wheel and a hardened steel worm which runs in oil. The worm-shaft is provided with ball thrust and radial bearings.

The rapid return stroke is accomplished by means of an internal gear cut on the worm-wheel. This internal gear drives the return gear shaft, the return motion being applied through the driving pinion. The driving clutch is not operated during the cutting stroke and so acts as a positive coupling. All parts are protected from shock due to the operation of a positive clutch under load.



No. 4 Heavy-duty High-speed Broaching Machine built by the Velco Mfg. Co., Inc.



Semi-automatic Automobile Axle-shaft Turning Machine made by the T. C. M. Mfg. Co.

In operating the machine, the belt is first shifted on the loose pulley to relieve the load from the clutches. A further movement of the shifting lever causes a friction brake to be applied to the driving pulley and withdraws the positive clutch. A still further movement of this same lever engages the reverse clutch and then shifts the driving belt on the tight pulley, thus reversing the machine. Automatic stops are provided and these are quickly adjustable and positive in action. Non-removable emergency stops protect the mechanism in the event that an operator neglects to set the automatic stops. A single lever conveniently placed regulates every motion of the machine, and the direction in which this operating lever is moved corresponds to the direction in which the rack will travel.

Coolant is supplied to the broach by a gear-driven pump of large capacity. A pan which telescopes into the bed catches chips and returns the fluid to the reservoir. The bed is of box section and is supported at the front and back ends by cabinet bases. A three-point suspension is a feature of this assembly. The front cabinet has storage space for small equipment. The maximum pulling effort of this machine requires 15 horsepower, but ordinary broaching operations may be accomplished with a 10-horsepower motor. The machine is furnished for either belt or motor drive, there being no difference in the construction for the two driving methods.

T. C. M. AXLE-SHAFT TURNING MACHINE

The accompanying illustration shows the front view of a semi-automatic machine built by the T. C. M. Mfg. Co., Hunterdon and First Sts., Harrison, N. J., for machining rear-axle shafts of the full-floating type for automobiles and trucks. These shafts are made from nickel or chrome-nickel steel forgings, and are heat-treated and straightened before any finishing is done. The machine squares the ends of the forgings to length, turns down each end to the correct diameter, bevels one end, turns and bevels a small projection on the other end, and finally centers each end. The centers are necessary for supporting the work in succeeding operations in which the ends are finish-ground and splines are hobbed.

A forging to be machined is placed in the hollow spindle *A* with both ends projecting. Two chucks hold the forging close to the portions to be turned, and the forging is located in these chucks by means of a positioning stop *B*, which is brought up by operating the lever at the left end of the machine. When not in use, this stop is lowered out of the way as shown. The two chucks are operated together through the large handwheel at the front of the machine and a differential which enables the chucks to be brought equally tight on each shaft end, irrespective of any variations in the diameters of the surfaces gripped.

The machine is provided with four slides *C*, two at the front and two at the rear, and each of these slides is provided with a cross-slide. The slides at the front carry the tools for turning the ends, while those at the rear are equipped with tools for facing the ends to length, cutting the small projection on one end and beveling both ends. The front slides make two movements across the work during each cycle of the machine, and the rear slides, three. The tools are advanced into the work before each traverse is made. The slide movements are obtained through cams *D*, which are provided at the front and rear of the bed, and which engage cam rollers set in the bed. The cross-slide movements are controlled by cams *E*. The variations in the diameter of the work are compensated for by screw adjustments.

When a forging has been clamped in position, the cam-operating shafts are started by operating trip-lever *F*. Then the four tools simultaneously move over the work, and when the cycle is completed, the tools stop clear of the surfaces which they have finished. The operator then swings down the drilling spindles *G* and drills the centers while the shaft continues to revolve. The finished shaft is ejected from the machine by an extension of the positioning bar *B*, which pushes the shaft sufficiently out of the chucks to permit the operator to lift it out. A gear-box at the rear of the machine provides three spindle speeds and three feeds to suit shafts of various diameters.

The hollow spindle is telescopic and the position of slides *C* at one end of the machine may be altered, so as to accommodate shafts of various lengths from 36 to 48 inches. The diameters may vary from 1¾ to 2¾ inches. To enable quick adjustments to suit different lengths of shafts, the adjustable slides and the corresponding drilling spindle and spindle bearing are connected by bars to a bracket which can be moved along the bed by rotating a screw at the right-hand end. Therefore, by loosening the clamping bolts and turning this screw, all the required length changes are made simultaneously. A pump supplies coolant to the cutters and these may be either of the circular-formed or solid-rectangular types. The machine is driven through a single belt and a clutch pulley. The time required for machining an axle-shaft averages from four to ten minutes, according to the diameter of the portions turned and the quality of the forging.

"DUMORE" PORTABLE AND BENCH DRILLS

A small portable electric drill, known as the Model 1-BD, having a capacity for drilling holes up to ¼ inch in steel and ⅜ inch in wood is shown in Fig. 1, while a similar drill, model 2-BD, of the same capacity, but mounted on a stand for bench use, is shown in Fig. 2. These drills are

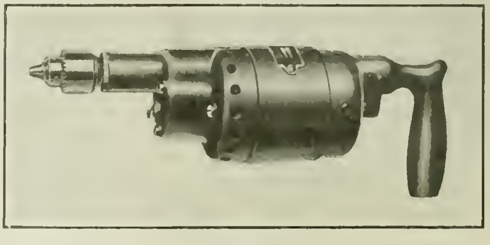


Fig. 1. Model 1-BD "Dumore" Portable Drill made by the Wisconsin Electric Co.

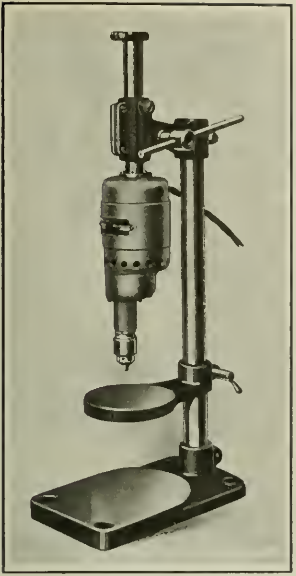

Fig. 2. Model 2-BD "Dumore" Drill

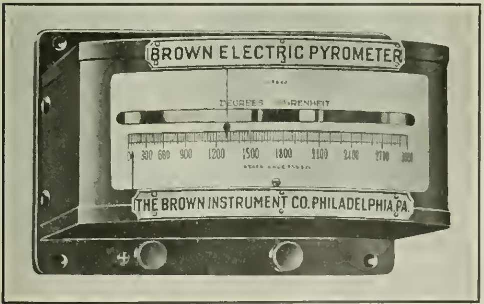
manufactured by the Wisconsin Electric Co., 2539 Sixteenth St., Racine, Wis. The drills are equipped with motors which operate on either direct or alternating current. The drill spindle is driven through helical gears made from steel and heat-treated. The surfaces on which these gears are mounted are ground to size.

The drill spindle is offset 31/32 inch from the center of the housing and runs in two self-aligning annular ball bearings. The column of the bench drill is nickel-plated and the over-all height of the machine is 20½ inches. The feed is 3¼ inches and is obtained through a rack and pinion. The table is adjustable for height and may be swung to the rear when desiring to drill work resting on the base. Both drills are furnished complete with ten feet of cord, a plug, a switch and a No. 1 Jacobs chuck. The net weight of the bench drill is 21 pounds, and that of the portable drill, 5 pounds.

BROWN COLD-JUNCTION COMPENSATED PYROMETER

It is well known that the millivoltage developed by the thermo-couple of thermo-electric pyrometers is dependent upon the difference in the temperatures of the hot and cold ends of the thermo-couple, and in order to secure accurate measurement of temperatures the cold end should be maintained at a constant temperature or else the pyrometer should compensate for the changes of temperature at this junction. On the pyrometer illustrated, which has been developed and patented by the Brown Instrument Co., 4512 Wayne Ave., Philadelphia, Pa., such a compensation is automatically obtained. The pointer of the instrument can be set to zero in the usual manner.

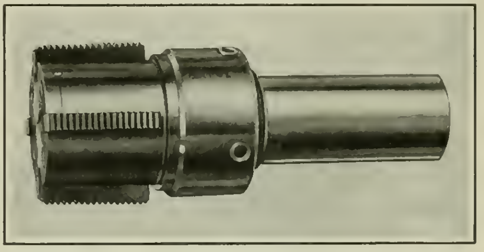


Improved Thermo-electric Pyrometer patented by the Brown Instrument Co.

It is common practice to use extension or compensating leads to transfer the cold junction from the binding posts of the thermo-couple to a distant point where a constant temperature can be maintained. With this pyrometer, however, the extension or compensating leads are brought to the meter as the changes in the temperature at the end of the leads also take place in the meter and can be compensated for. In using the pyrometer, the pointer is set by the zero adjuster to correspond with the index on the scale. If the values of a thermo-couple are based on a cold junction of 75 degrees F., the index will indicate that temperature, provided the atmosphere surrounding the instrument is of that temperature. If the instrument pointer does not correspond with this index, it is set accordingly. When the temperature of the atmosphere surrounding the instrument rises to 90 degrees F., the index automatically shifts to 90 degrees F. and the instrument pointer also moves to that graduation. Any number of thermo-couples with their extension or compensating leads can be brought to one instrument. Recording instruments can also be equipped with this automatic compensation.

GEOMETRIC ADJUSTABLE TAP

The accompanying illustration shows an adjustable tap which has been placed on the market by the Geometric Tool Co., New Haven, Conn. This tap does not have a collapsing device, as it is intended for use on machines that are not provided with a means of closing collapsible taps. The chasers are easily removed for regrinding, and as they are adjustable, the correct size of the tap can always be maintained. Each size of tap accommodates chasers for a range of diameters, and when the chasers become worn, they can be renewed at a small cost, as compared with the cost of a new tap.



Adjustable Tap made in Various Sizes by the Geometric Tool Co.

THIBERT SELF-LOCKING NUT

The new type of self-locking nut shown in the accompanying illustration is made in all sizes from ¼ to 1 inch, and with either S. A. E. or U. S. form threads. This nut has been introduced recently by the Industrial Lock Nut Co., 306 Main St., Worcester, Mass. The locking member consists of a circular wire spring, one end of which projects outward and the other, inward. The outer face of the nut is counterbored and recessed to receive this spring, and the latter is forced to turn with the nut due to the outwardly projecting end engaging a groove cut on the nut face. The other spring end engages the thread of the bolt or part on which the nut is screwed, and although it does not interfere with screwing the nut in place, it prevents the nut from being loosened by vibration.

Thibert Self-locking Nut sold by the Industrial Lock Nut Co.

PRATT & WHITNEY SCREW PLATE SETS

The Pratt & Whitney Co., Hartford, Conn., is now marketing screw plate sets made up from their regular line of products, for cutting either U. S. standard, S. A. E. or Whitworth threads. These sets are sold in various combinations to suit the requirements of small shops, garages and toolrooms, and are packed in nicely finished and suitably marked cases. They may be furnished with either plug or taper taps, or both. The set here illustrated consists of eighteen taps, nine adjustable round split dies, one diestock, two tap wrenches, and a screwdriver for adjusting the dies.

One of the Screw Plate Sets now being sold by the Pratt & Whitney Co.

STOLP LOCK-SEAMING MACHINE

An automatic machine for bending and lock-seaming sheet metal parts from strips or coils of stock by a patented process is illustrated in Fig. 1, while Fig. 2 shows some of the sections which can be formed. This machine is a recent development of the Stolp Co., Inc., Geneva, N. Y. The machine is equipped with a self-feeding attachment. The stock, on being fed into the machine, is first pressed into a U-shape by a punch, after which a round mandrel enters the blank from the rear and pushes it endwise through lock-seaming dies. The mandrel is fastened to a crosshead connected to a chain. This chain runs continuously and carries the crosshead back and forth the entire length of the frame.

As the mandrel reaches the farthest back position, the U-shaped punch descends and presses the blank into a position in line with the mandrel. The mandrel enters the blank as the punch leaves it and carries the work forward as previously explained. The lock-seaming dies have no moving parts, but they are so constructed that the blank is closed and the lock-seam produced in one operation. The machine will lock-seam taper tubes within certain limits. Among the many parts which can be produced on this machine are tubes for automobile mufflers and radiators, blowers, and ventilators.

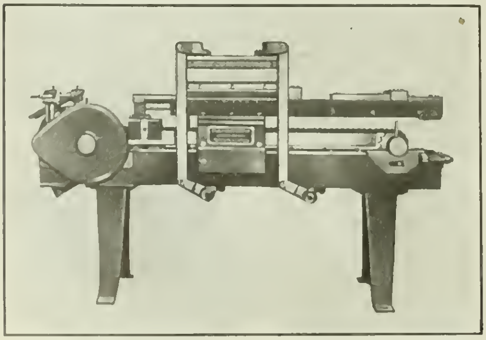


Fig. 1. Automatic Lock-seaming Machine patented by the Stolp Co., Inc.

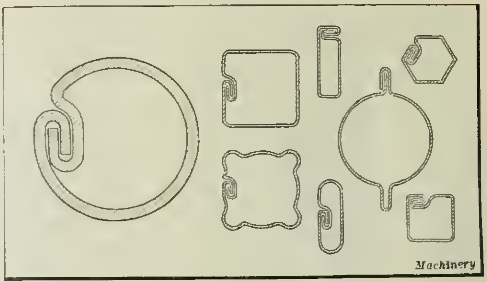

Fig. 2. Various Tube Sections formed on the Lock-seaming Machine

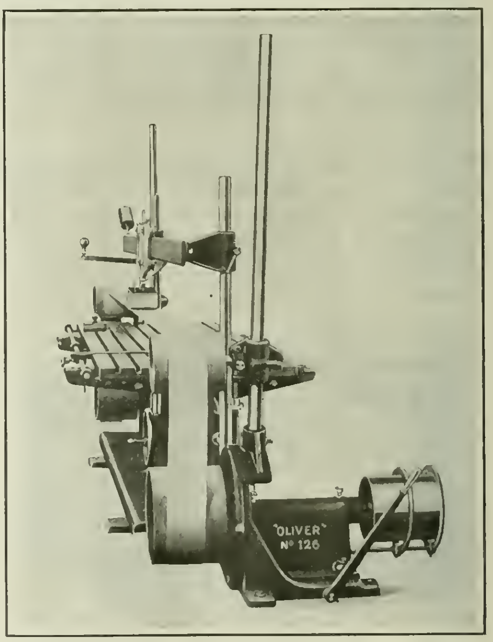
OLIVER UNIVERSAL BELT SANDER

A No. 126 universal belt sander has just been brought out by the Oliver Machinery Co., Grand Rapids, Mich., for the rapid sanding and polishing of line and edge moldings, patterns and various other parts made from wood. It may also be used in the polishing of metals. The abrasive side of the sand belt is in contact with the pulley faces. In addition to the safety features obtained by this arrangement, the breaking of sand from the belt is avoided and so the longevity of the belt is increased. The table rolls on ball bearings and is so easily moved that a slight push causes it to roll the full travel of 36 inches. This construction is covered by a patent. The table top consists of plain wooden strips, spaced one inch between each strip. The different gaps allow any dust which may accumulate to drop through



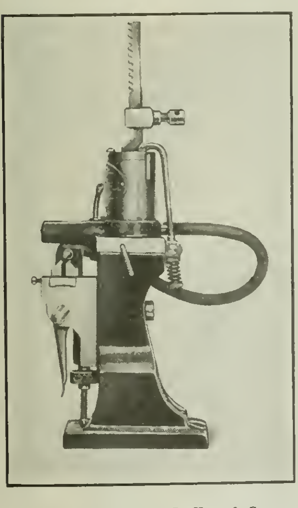
No. 126 Universal Belt Sander built by the Oliver Machinery Co.

the table, and thus serve to keep the top clean. The table is 36 inches wide by 96 inches long and is provided with an adjustable bar to hold the work.

Means are provided for taking up slack of the sand belt so that a suitable tension for the work in hand may be obtained. An idler is supplied for this belt and this idler is adjustable up and down to the height of the work. It can also be placed in a tilted position to prevent the belt from running to either side of centers. An attachment is furnished for the power stand arm for use in sanding edge work. This attachment has an adjustable table that can be tilted 45 degrees up or down and raised or lowered to suit conditions. Attachments are also supplied for sanding edge moldings and irregular shapes, and the machine may be arranged either with or without a sanding pad attachment. The machine may have a motor drive or it may be driven by belt from a roller-bearing countershaft. The machine will sand to a center of 72 inches, and will take work on the table up to 54 inches in height and on the floor plate, up to 72 inches in height. The table has a vertical adjustment of 14 inches, and sanding belts up to 10 inches in width may be used. The machine occupies a floor space 72 inches wide and any preferable length. The over-all height is about 80 inches, and the weight, approximately 1400 pounds.

CAULKINS AUTOMATIC DRILL JIG

An improved automatic drill jig designed especially for use with Avey and Leland-Gifford high-speed drilling machines, is shown in the accompanying illustration. This attachment has recently been brought out by E. L. Krag & Co., 50 W. Randolph St., Chicago, Ill. It is provided with a V-block to enable the drilling of holes for cotter-pins, etc., up to 3/16 inch in round, square, or hexagonal stock of various sizes up to 1 inch in diameter or across flats. More elaborate holders can be provided for indexing work to suit the drilling of two or more holes, or for cross- or end-drilling regular or irregular shaped pieces. The jig is operated through a foot-pedal, the work being clamped, drilled, and ejected by a forward movement of the pedal. The drilled work is removed by hand and a new piece inserted during the backward movement of the foot. By thus working the hands and one foot in unison, high rates of production are secured. All parts of the jig are accessible and readily adjusted for any size or length of stock within the capacity of the device. Lubricant is supplied to the point of the drill.



Drill Jig sold by E. L. Krag & Co.

NEW MACHINERY AND TOOLS NOTES

Sheet-heating Furnace: Electric Furnace Co., Alliance, Ohio. A portable resistance-type electric furnace used in the heating of sheet metal for forming automobile body parts and fenders. The hearth is 3 feet 4 inches wide and 6 feet 5 inches long. The furnace can heat 750 pounds of material per hour to a temperature of 1800 degrees F.

Tap-holder: Apex Machine Co., Dayton, Ohio. A friction-slip tap-holder which permits slippage within the holder itself in case a tap becomes wedged or strikes the bottom of a hole. It is thus particularly suitable for tapping blind holes. The holder is made in two sizes, one of which will hold taps up to and including 1/2 inch in diameter, while the other holds taps from 1/4 to 3/4 inch in diameter.

Drill Chuck: American Equipment Co., 5928 Second Boulevard, Detroit, Michigan. A slip-collet drill chuck which permits the rapid insertion or removal of the tool while the machine spindle is running. Drills, reamers, counterbores, and taps may be held in the collets. Two driving keys prevent crowding to one side and give a balanced drive in either direction so that the chuck is suitable for tapping operations.

Burning-in and Running-in Machine: Theodore W. Jansen Machine Co., 739 Twenty-first St., Des Moines, Ia. A burning-in, running-in and testing-out machine developed for use in the repairing of automobile engines. It will hold all types of engines without special blocking or fixtures. The work is mounted on the stand by securing it at each end to pivoted holders so that it can be rotated about its crank-shaft and held in any desired position.

Cylinder Reboring Tool: International Purchasing & Engineering Co., Inc., 506 McKerchey Bldg., Detroit, Mich. A device which was originally intended for driving by hand or by means of a drilling machine, but which has now been fitted with an individual motor drive. The original type was described in May MACHINERY. The motor is mounted as a part of the tool and drives through a friction clutch which enables slippage in the event that the cutter-head becomes wedged.

Cylinder Reamers: New Britain Tool & Mfg. Co., New Britain, Conn. A set of expansion reamers for machining the cylinders of gas engines. It is intended that they be used in pairs for roughing and finishing. The pilot of the roughing reamer is ground to fit the normal bore of the cylinder and the cutting blades remove about 0.030 inch of stock. The pilot of the finishing reamer fits the bore left by the roughing reamer and its blades remove about 0.005 inch of metal.

Tool Grinding Machine: Wheeler Co., Railroad, Pa. A tool grinding machine provided with ball bearings for the spindle, countershaft and loose pulley. The head can be used on a bench or mounted on a pedestal. The countershaft is mounted at the rear of the pedestal and is provided with a shifter operated by a foot-pedal at the front of the machine. The head is made in two sizes, one for wheels 10 inches in diameter and 1 1/2 inches thick, and the other for wheels from 12 to 14 inches in diameter and up to 2 inches in thickness.

Protractagraph: Turner Devices, Inc., 5 S. Newstead Ave., St. Louis, Mo. An instrument which is intended to take the place of such drafting tools as triangles, scales, and protractors, and which may be used with any parallel ruler attachment. It consists of a plate formed at its lower end into a semicircular protractor graduated in 1/2 degrees. Various scales and a transparent inking blade are easily attached to this plate. A knob on the axis of the device is used to revolve the scale. The instrument can be slid along the straightedge to place it in the desired positions on the drawing-board.

Surface Grinding Machine: William Osterhom, 2301 N. Knox Ave., Chicago, Ill. An automatic surface grinding machine intended for the grinding of surfaces up to 12 by 40 inches. The work is locked in a fixture which is mounted on a table pivoted about a swinging arm and moved past the surface of the abrasive wheel by means of a cam. Upon the completion of a cam cycle, the fixture is tilted 45 degrees away from the wheel to enable the operator to remove the work. The length of the swinging arm stroke may be varied from 2 to 24 inches. The feed of the wheel is automatically controlled by a cam.

Combination Lathe, Milling and Drilling Machine: Dalton Mfg. Co., Sound Beach, Conn. A combination machine especially designed for use in garages, etc. A single hollow spindle serves both the lathe and the milling equipment. The lathe and the milling equipment or the lathe and the drilling equipment may be used simultaneously. The lathe has a swing of 13 inches over the ways and by removing a section of the bed, a gap 6 1/2 inches wide is obtained which will permit the handling of work 18 1/2 inches in diameter. The milling table has a working surface of 24 by 7 1/2 inches and a longitudinal feed of 15 inches in either direction. The transverse movement is 6 1/4 inches.

SPOKE NIPPLE DRILLING AND TAPPING MACHINE

The machine described in this article was especially designed and constructed by the Langelier Mfg. Co., Arlington, Cranston, R. I., for drilling and tapping in large quantities, cold-rolled steel nipples such as are used on the wire spokes of automobile wheels. The machine is semi-automatic in operation, five nipples being inserted by hand at a time into a row of steel bushings in the drum *A*. Aside from the loading of the drum the machine is automatic. The drum is mounted on the main shaft which extends through to the rear of the machine and there carries a stop-cam *B*, Fig. 3, to which there is attached on the inner side, a gear driven by another gear on the index-shaft *C*. This gear is enclosed by a suitable guard. The drum revolves intermittently, as determined by the index mechanism, to bring the work into position for loading, drilling, tap-drilling, tapping and ejecting the nipples. The first drilling head *D*, Figs. 1 and 2, carries the drills for producing clearance holes three-quarters through the nipples; the second head *E*, the tap-drills for finishing the holes; and head *F*, the taps. The knock-out arm is shown at *G*.

Main Drive and Safety Device

The driving side of the machine is shown in Fig. 2. The machine is belt-driven, and the flanged pulley transmits motion to the driving shaft by means of a friction clutch which is operated by the shipper rod *H*. This clutch must be engaged by hand, but may be disengaged either by an automatic safety device, or a foot-lever connected to this device. This foot-lever is not shown in the illustrations. For hand operation, lever *I* is employed to turn a segment gear which engages rack teeth cut on the under side of the shipper rod. The safety device for automatically disengaging the clutch is illustrated in Figs. 1 and 2 and its purpose is to instantly stop the machine whenever a nipple is improperly seated in a bushing. In case any of the five nipples which are simultaneously loaded into a row of bushings should project sufficiently to strike the arm *J*, the safety device would immediately operate. This arm, by means of its lever connections, moves a latch carried in slide *K*, which releases finger *L* on the shipper rod, and, with the aid of coil spring *M*, disengages the friction clutch and engages a multiple disk brake.

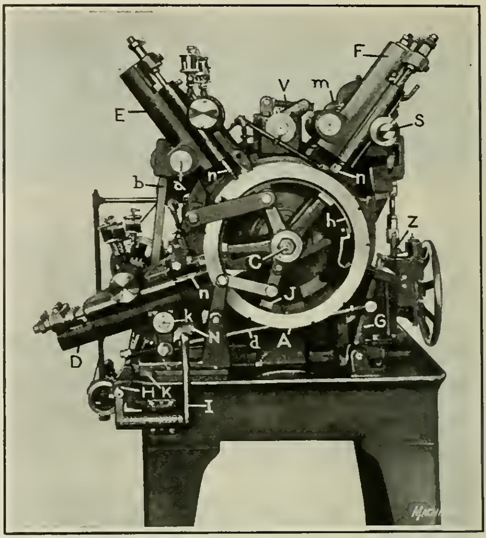


Fig. 1. Front View of Machine used for drilling and tapping Wire Wheel Spoke Nipples

Driving Mechanism for the Heads

The main shaft which carries the drum *A* and stop-cam *B* runs through a perforated cast-iron sleeve which is stationary and which provides the bearing for a large worm-wheel, on the hub of which the indexing- and feeding-cams are fixed. The driving shaft carries a bakelite gear *N*, Fig. 2, (also shown in Fig. 1) for driving the drilling head shaft *O* by means of a pinion, and the tap-drilling head shaft *P* by means of a belt. The driving shaft also carries a bevel pinion *Q* for driving a cross-shaft that extends through the machine at the rear, and at the opposite side (see Fig. 3) drives the tapping head *F* by means of suitable bevel gearing. This cross-shaft projects at *R* sufficiently to allow a handwheel to be assembled, this handwheel being the means provided for turning the rotative parts by hand, when so desired. Shafts *O* and *P*, Fig. 2, as well as a similar shaft *S* for the tapping head (see also Fig. 3) carry suitable spiral gears for driving the five spindles in their respective heads. It will be noticed also that shaft *O* has a flanged pulley belted to the pulley of the lubricant pump, and that this lubricant pump is piped direct to the three heads. This is more clearly shown in Fig. 1.

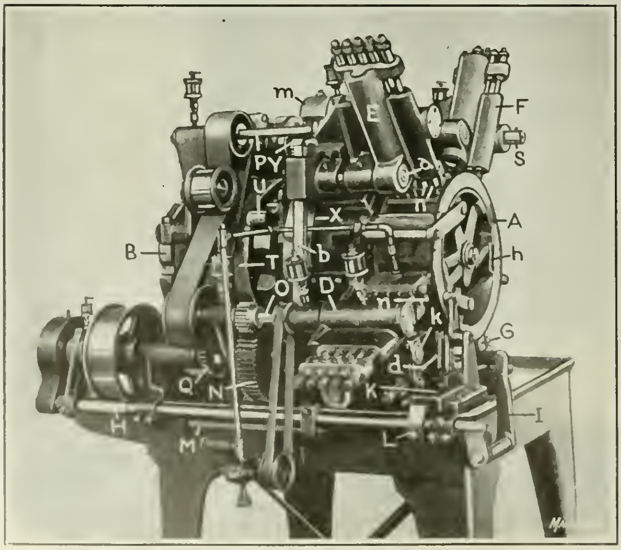

Fig. 2. Driving Side of the Machine shown in Fig. 1

Indexing and Feeding Arrangement

The cross-shaft *R*, Fig. 3, carries a worm located just back of and above shaft *C*, and this worm drives the aforementioned large worm-wheel mounted on the perforated cast-iron sleeve through which the main shaft of the machine operates. This worm-wheel with the index-cam *T* and the feed-cam *X*, Figs. 2 and 3, revolves as a unit on the stationary cast-iron sleeve. The index-cam carries a single gear tooth *U*, Fig. 2, on its side, so that as the cam is revolved a five-tooth index-pinion located directly beneath it on a short shaft will be intermittently revolved part of a revolution with each complete revolution of the index-cam. The short-index shaft carrying this five-tooth pinion extends to the rear of the machine, being the one previously mentioned and

indicated at C, Fig. 3. With every movement of the five-tooth pinion it is evident that the stop-cam B will be revolved, turning the drum A at the front of the machine, as required to index it from station to station during the operation of the three multiple heads. The notched stop-cam B is temporarily locked in position by a steel toe carried in slubber arm W, this steel toe engaging with inserted steel cradles in the stop-cam. The synchronization of the movement of this arm with the indexing movement is accomplished by a roll that runs in a cam groove in the side of the index-cam, the movement being assisted by coil spring V, Figs. 1 and 3, directly above the shaft which carries slubber arm W.

Located slightly to the front of the index-cam on the worm-wheel hub is the feed-cam X, Figs. 2 and 3. This feed-cam has two cam grooves, one for radially operating the short rack Y, Fig. 2, and the other for operating a rack on the opposite side of the machine, shown in Fig. 3 at Z. The first of these racks meshes with a double spur gear for the purpose of revolving the tap-drilling head feed-shaft a,

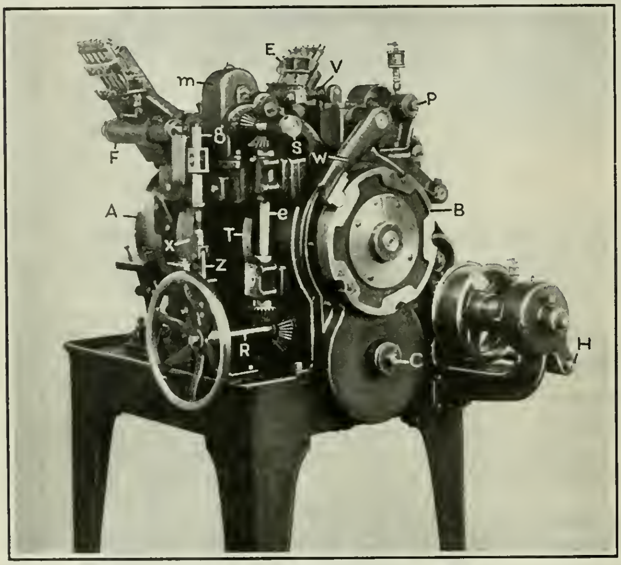

Fig. 3. View from the Rear showing Indexing Cam and Tapping Head Drive

Figs. 1 and 2 and for operating the vertical rack b. The teeth at the lower end of this rack mesh with a spur gear on the drilling head feed-shaft k, so that the feed movement for both heads D and E is controlled from one groove in the feed-cam. The spindle feed for the two heads is obtained by a spur gear and rack contained within each head. The drill-head feed-shaft k carries a finger at its front end so that as the feed is transmitted to the drill-head, the knock-out rod d will rock the arm G in which the knock-out pins are carried, and so dislodge the finished work from the bushings before the next index movement of the drum.

The other cam groove on the feed-cam controls the vertical movement of rack Z, Figs. 1 and 3, by means of which the reversal of the tapping-head shaft S is accomplished. The vertical bevel gear shaft c drives one end of this shaft, the other end being connected in gear-box n by a specially designed gear-and-segment reversing mechanism which is alternately shifted by post g as the rack Z moves up and down. The provision for changing the gearing of this reversing mechanism is the only means required for altering the feed of the taps, the mechanism being provided with change-gears so that it may be set up to furnish the correct speed to follow the lead of the tap that is employed.

Other Details of Construction

The feed-cam also carries a lug at its periphery for releasing the locking mechanism for drum A. This mechanism is located beneath the bed of the machine and consists of a lever hung at one end so that it can be pushed down by the cam lug, causing the opposite end of the lever to release a V-shaped detent from engagement with the drum. The drum A is provided with a hardened and ground steel spider h Figs. 1 and 2, which is held stationary by an arm so that as the drum revolves the ends of the nipples which project from the inside of the drill bushings will ride nicely over this spider and furnish the thrust backing for the drills and taps during the performance of the various operations. It will be seen that the spider is so fashioned that when the nipples are knocked out they will be prevented from dropping down to the lower part of the drum and thus will not interfere with the loading of the bushings. All the drilling and tapping spindles of this machine are provided with radial ball bearings as well as ball thrust bearings for the feed movement. The tools have straight shanks and are carried in split collets. They are driven by tangs ground on their shanks so that as the collets are pinched together by nuts m the tools will be securely chucked. The output of this machine is twenty drilled and tapped nipples per minute.

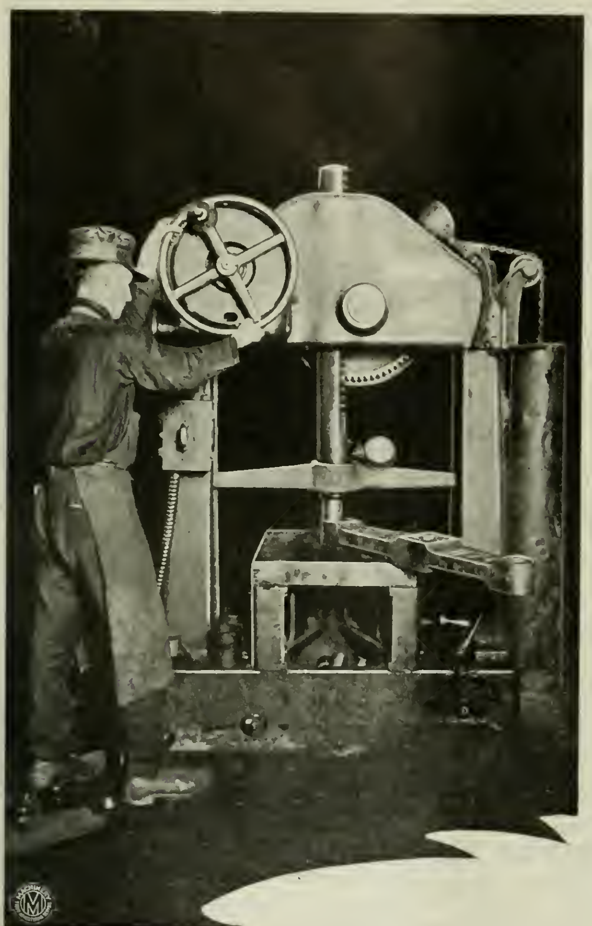
REVIEW OF INDUSTRIAL CONDITIONS

A general review of the main industries of the country shows the greatest activity in the textile field, especially in New England. The woolen and worsted mills are operating at the rate of from 75 to 100 per cent capacity, and the cotton mills at about 75 per cent capacity. An improvement is noted in the New England shoe factories, which have steadily gained until they were working up to 60 per cent of full capacity on July 1, with operations continually being expanded. Business in the retail field is from 10 to 20 per cent in physical volume of goods over the business done for the corresponding month last year, although, on account of reduced prices, the business in dollars and cents is slightly less than it was a year ago.

Improvements in railway traffic is indicated by the report of the American Railway Association, which shows that a gradual increase in the number of loaded freight cars. The reports for June, covering 144 railroads, also show that the net operating income of these roads amounted to over $48,000,000, as compared with a deficit of $10,600,000 on the same roads during the corresponding month last year. The total operating expenses in June, 1920, were $220,000,000, while in June, 1921, they were only $171,000,000, which accounts for the improvement in the net revenue. As the railroads are not yet operated to full capacity, it may be expected that when their operating revenue rises to a normal level, the net income will be further improved. The removal of the taxes on transportation provided for by the new revenue bill will doubtless help to stimulate traffic, particularly if the railroads themselves, in view of their improved financial condition, find themselves able to reduce the present high rates and fares.

* * *

Out of a total of 19,106 locomotives in good condition before the war, there are at present in Russia from 5500 to 7500 locomotives reported in working order. This represents a decrease of motive power of about 66 2/3 per cent. Of this number of locomotives, approximately 1000 are idle owing to lack of fuel.



A LUCAS

Power Forcing Press at Work in the D L & W's Scranton Shop

There are two of these simple and effective machines in this busy railroad shop—one a 30-ton press, the other with 50 tons capacity. The oldest has been in use for five years and both are giving excellent satisfaction.

The operation shown is forcing a bushing 4″ long by $2\frac{1}{2}$″ diameter into a locomotive hanger forging to be used in brake rigging, and is readily accomplished with 3 to 4 tons of pressure.

The sphere of the Lucas Power Forcing Press covers that big tract of "no man's land" where the hand or screw press is too small and the hydraulic too large to work to advantage.

Control and adjustments center in the wheel, which automatically applies power when the ram meets with the resistance of the work. Action is rapid and positive.

Power is obtained from a worm-wheel on the pulley shaft through a friction clutch and is transmitted to the ram by means of gearing controlled by the handwheel.

No valves to leak—no pipes to freeze—no packing to renew. "A good all-around tool" is the verdict on this machine wherever it is installed, whether for bending, straightening, forcing, marking, forming or broaching and new uses develop for it every day.

Illustrated Circular tells the whole story.

LUCAS MACHINE TOOL CO. NOW AND ALWAYS OF **CLEVELAND, OHIO, U.S.A.**

FOREIGN AGENTS: Alfred Herbert, Ltd., Coventry. Societe Anonyme Belge, Alfred Herbert Brussels. Aux Forges de Vulcain, Paris. Allied Machinery Co., Turin, Barcelona, Zurich. Benson Bros., Sydney, Melbourne. V. Lowener, Copenhagen, Christiania, Stockholm. R. S. Stokvis & Zonen, Rotterdam. Andrews & George Co., Tokyo.

PERSONALS

Frank A. Power, for the last fifteen years with the Garvin Machine Co., New York, has resigned as sales manager.

Lyman M. Waite, formerly of the National Acme Co., and recently with the Springfield Automatic Screw Machine Corporation of Fitchburg, Mass., has been appointed sales manager of the Garvin Machine Co., New York City.

Ralph C. Schwarz has taken over the northwestern New York territory for the distribution and sale of Stewart industrial furnaces and appliances, made by the Chicago Flexible Shaft Co., Chicago, Ill. Mr. Schwarz will be located at 921 Granite Bldg., Rochester, N. Y.

Herman Voges, Jr., has resigned as president of the Webster & Perks Tool Co., Springfield, Ohio, in order to take a much needed rest from business. He has been continuously connected with the Webster & Perks Tool Co. for nearly thirty years, and has served in practically all capacities with that company. He will remain as a director of the company.

Clarence H. Landsittel, for three years director of purchases for the Templar Motors Co., Cleveland, Ohio, and prior to that director of purchases for the Haynes Automobile Co., Kokomo, Ind., has become associated with the Climax Motor Devices of Chagrin Falls, Ohio, in the capacity of sales engineer. This company manufactures magneto and generator couplings.

Alexander Gabay, formerly tool and efficiency engineer for the Western States Machine Co., Salt Lake City, Utah, is now production manager and assistant superintendent with the Baird Lock Co., Chicago, Ill., manufacturer of locking devices and non-pickable cylinder locks. Mr. Gabay, before he came to the Western States Machine Co., was connected with the Cincinnati Milling Machine Co., Cincinnati.

Robert B. Moir has been appointed manager of the New York branch of the W. A. Jones Foundry & Machine Co., 4401-4451 W. Roosevelt Road, Chicago, Ill. Mr. Moir will assume his new duties immediately, making his headquarters at the present sales office and transmission warehouse of the company at 20 Murray St., New York City. Mr. Moir has been actively connected with the home office and factory of the company for a number of years, and is well qualified to assist in power transmission and general engineering problems.

Julius Klein, who was appointed by the President as Director of the Bureau of Foreign and Domestic Commerce, to fill the position made vacant some time ago by the resignation of R. S. MacElwee, has assumed his duties. Dr. Klein first came to the bureau in September, 1917, as chief of the Latin-American Division. He remained in that capacity until May, 1919, when he was made commercial attaché to the Department at Buenos Aires, Argentina. He resigned from his position in October, 1920. Dr. Klein has specialized in Latin-American economics and trade.

Walter H. Rastall has been appointed by Secretary Hoover chief of a new division in the Department of Commerce, which has been especially created to give attention to the foreign trade in industrial machinery; this is one of the new divisions provided for by Congress in making appropriations under the recent Export Industries Act. It is the plan of this division to cooperate with American manufacturers and exporters of factory machinery, and to take such steps as may be possible for a government department to assist manufacturers in solving their foreign trade problems. Mr. Rastall has had extensive experience, both in domestic and in foreign trade, and has spent nine years in the sale of machinery in Asia, from where he has recently returned after an investigation of the machinery markets in that part of the world. He is a graduate of Cornell University and a mechanical engineer.

Arthur H. Adams, for twenty years active in the manufacture of telephone and telegraph apparatus, is opening offices on October 1 for consulting work at 41 Park Row, New York City. Mr. Adams was for some years superintendent of the Bell Telephone Mfg. Co. of Antwerp, Belgium, during which time he was called upon to inspect in a consulting capacity a number of European plants; he has since done development and design work for the Western Electric Co., Inc.; and for the last three years has been successively factory superintendent and chief engineer of the North Electric Mfg. Co. of Galion, Ohio. He has developed and patented several special machines in these years, including rotary thread-rolling, coil-winding, braiding and telephone switching machinery, as well as printing telegraphs. He will specialize in the field of lighter mechanics, with special emphasis on the coordination of design with manufacturing equipment.

STATISTICS OF THE AUTOMOBILE INDUSTRY

In a pamphlet recently published by Leonard P. Ayres, vice-president of the Cleveland Trust Co., Cleveland, Ohio, some interesting statistics are given relating to the automobile industry and its future. Since the beginning of the automobile industry in America twenty-five years ago, the number of cars manufactured up to January, 1921, was 11,775,000, of which more than 700,000 were imported. About 9,000,000 cars are in use in the United States, 2,000,000 having been worn out or destroyed by accidents. The average length of life of an automobile is estimated at about six years. At the end of 1920 there was approximately one car to every twelve persons in the United States. If, instead of considering the entire population, the basis for comparison is the number of white, native born men above the age of 21, it will be found that there are 42 cars in the United States to every 100 men. The number varies in the different parts of the country from about 22 cars to 100 men in the South Central States to 60 cars per 100 men in the Pacific States.

COMING EVENTS

September 7-28—Shipping, Engineering and Machinery Exhibition, Olympia, London, W., England. General Manager, Frederic W. Bridges, 36-38 Whitefriars St., Fleet St., London, E.C.4.

September 12-17—Fall meeting of the American Institute of Mining and Metallurgical Engineers in Wilkesbarre, Pa. Secretary, Bradley Staughton, 29 W. 39th St., New York City.

September 14-18—Annual convention of the National Association of Cost Accountants in Cleveland, Ohio; headquarters, Hotel Cleveland. Secretary's address, 233 Woolworth Bldg., New York City.

September 19-24—Third annual convention and exhibition of the American Society for Steel Treating in Indianapolis, Ind. Secretary, W. H. Eisenman, 4600 Prospect Ave., Cleveland, Ohio.

September 28-October 8—New York Electrical Exposition at the 71st Regiment Armory, Park Ave. and 31th St., New York City. For information relating to exhibits, apply to Norman Maul, the Electrical Show Co., 130 E. 15th St., New York City, Room 828.

October 3-4—Regional meeting of the American Society of Mechanical Engineers in Cleveland, Ohio; headquarters, Hotel Winton.

October 5-8—Twelfth annual convention of the American Manufacturers' Export Association in New York City; headquarters, Waldorf-Astoria Hotel. Secretary, A. W. Willmann, 160 Broadway, New York City

October 5-7—Fall meeting of the Society of Industrial Engineers in Springfield, Mass.

October 17-22—Twenty-fourth annual convention of the American Mining Congress in the Coliseum, Chicago, Ill. In conjunction with the convention there will also be a national exposition of mines and mining equipment.

October 17-22—Twenty-seventh annual convention of the National Hardware Association of the United States in Atlantic City, N. J.; headquarters, Marlborough-Blenheim Hotel., Secretary, T. James Fernley, 120 High St., Boston, Mass.

October 17-22—National exposition of mines and mining equipment in Chicago, Ill., under the auspices of the American Mining Congress, Washington, D. C.

October 18-20—Annual convention of the National Machine Tool Builders' Association in New York City; headquarters, Hotel Astor. General Manager, Ernest F. DuBrul, 817 Provident Bank Bldg., Cincinnati, Ohio.

November 4-5—Regional meeting of the American Society of Mechanical Engineers in Kansas City, Mo.

December 1-3—Fall meeting of the Taylor Society in New York City. Secretary, Harlow S. Person, 29 W. 39th St., New York City.

May 8-11, 1922—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga. Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

SOCIETIES, SCHOOLS AND COLLEGES

Michigan College of Mines, Houghton, Mich. Year book for 1920-1921, containing calendar and announcement of courses for 1921-1922.

University of Nebraska, Lincoln, Neb. Fifty-first annual general catalogue, containing announcements for 1921-1922, an outline of the various courses offered, and general information.

NEW BOOKS AND PAMPHLETS

Wages in the United States and Foreign Countries. 103 pages, 6 by 9 inches. Published by the Government Printing Office, Washington, D. C.

This book, copies of which may be obtained free by addressing a request to the Ways and Means Committee, House of Representatives, Washington, D. C., has been prepared for the use of the Committee on Ways and Means of the House in connection with pending tariff legislation. It covers, mainly, wages paid in the United States, Germany, Japan, England, France, Belgium, and Italy. The sources of information are furnished in each case, so that the reader may judge for himself as to the authoritativeness of the figures presented. Often the figures quoted are given in the United States currency, which is somewhat unsatisfactory, because the rate of exchange upon which the conversion has been based is not stated. In many instances, however, the wages are given in foreign currency, which is far more satisfactory because the corresponding figure in United States currency can then easily be obtained by using the current rate of exchange. The book is somewhat misleading for present use, because in many cases it reports wages in the United States for that period of 1920 when they were at their high peak, and in the general resume of wages for ten selected industries in seven of the leading countries, no statement is made of the year when these wages

Made in three Grades—Black, Red, and Green Label

Tell us your particular requirements, or better still try out a small lot.

If your springs are made on the outside it will be to your advantage *to insist* they be made of "F & G" wire.

Special Circular No. 232 upon request.

Hammacher, Schlemmer & Co.

Hardware, Tools and Factory Supplies

New York Since 1848 4th Ave. & 13th st.

were paid. Hence it is difficult to determine the value of the figures given, particularly for the important work of tariff legislation. If Congress bases its work upon 1920 wages, or wages in July and August, 1920, as given in some instances, the figures will be from 15 to 25 per cent higher than present wage rates in most industries.

NEW CATALOGUES AND CIRCULARS

Bausch & Lomb Optical Co., Rochester, N. Y. Circular descriptive of the Bausch & Lomb stereoscopic eye-piece, for use with monocular microscopes.

Pawling & Harnischfeger Co., 38th and National Aves., Milwaukee, Wis. Pamphlet TX, illustrating and describing the new Skimmer scoop attachment for P & H Types 205 and 206 excavator cranes.

New Departure Mfg. Co., Bristol, Conn. Loose-leaf data sheets, 134, 135, and 136 FE, containing illustrations and descriptions of ball bearings in a hydraulic dynamometer, pneumatic grinder, and steam turbine.

Bell & Gossett Co., 609 W. 30th St., Chicago, Ill. Circular folder advertising "Caseite," a hardening material for use in the cyanide process. Also circular giving dimensions and weight of carbonizing boxes and cyanide pots.

Electric Controller & Mfg. Co., Cleveland, Ohio. Bulletin 1033-A containing data on direct- and alternating-current automatic pressure regulators. Bulletin 1042-C illustrating and describing E. C. & M. automatic compensators for alternating-current squirrel-cage motors.

Union Switch & Signal Co., Swissvale, Pa. Folder entitled "Drop-forgings" illustrating types of drop-forgings made by the company for trucks and tractors, including axles, crankshafts, camshafts, connecting-rods, steering knuckles, gear blanks and pinions, crank and gear-case covers, etc.

Electric Dynamic Co., Bayonne, N. J. Bulletin 300, showing pictures of the facilities of the company's factory for producing electrical machinery. The illustrations show electric motors in process of manufacture ranging in size from ½ to 1000 horsepower, both for alternating and direct current.

H. D. Smith & Co., Plantsville, Conn. Circular illustrating and describing the "Perfect Handle" tool kit, comprising three different sizes of screwdrivers, tire tool or pry bar, hammer, standard wrench, pipe wrench, monkey-wrench, regular punch, nail punch, cold chisel, and offset slip joint pliers.

Hart Roller Bearing Co., Orange, N. J. Pamphlet on "Increasing Production," containing a discussion of the application of roller bearings in machinery, and the possibility of increasing production through their use. The construction of Hart staggered roller bearings is illustrated and described.

Pierce, Butler & Pierce Mfg. Corporation, 437 E. 162nd St., New York City. Catalogue of Pierce packless valves, illustrating and describing valves for different purposes manufactured by the company, and also putting forth briefly some of the underlying facts that determine the serviceability of valves.

Goddard & Goddard Co., Detroit, Mich. Leaflet No. 1, entitled "Real Production Tools" illustrating and describing the "Go and Go" half side mill. The advantages claimed for the design and construction are clearly set forth, and the possible saving by the use of these cutters specifically pointed out.

Medart Patent Pulley Co., St. Louis, Mo., manufacturer of complete lineshafting equipment, including shafting, couplings, bearings, hangers, pulleys, friction clutches, belt tighteners, rope drives, gearing, sprockets, etc., is issuing a monthly publication known as "The Dart," containing matter relating to the personnel, methods, equipment, and products of the company.

Cutler-Hammer Mfg. Co., Milwaukee, Wis. Catalogue containing 40 pages, 8½ by 11 inches, descriptive of Cutler-Hammer elevator controllers and accessories. A discussion of the types of motors best suited to elevator work is presented, as well as an outline of the usual method of selecting motors of the right horsepower and starting torque to insure satisfactory performance.

Sterling Grinding Wheel Co., Tiffin, Ohio. Circular describing the application of "Sterbon" grinding wheels in foundry practice, and for cylindrical grinding, internal grinding, and surface and edge grinding. The circular also gives a grading table for "Sterbon" wheels, which specifies the grain and grade of wheels to be used for different classes of materials and various operations.

George Cutter Works of the Westinghouse Electric & Mfg. Co., South Bend, Ind. Booklet containing wiring tables and illuminating data relating to the problems of wiring and lighting offices, factories, etc. Tables of foot-candle intensities recommended for different classes of service are included, as well as a discussion of lighting installations. Lighting accessories, such as reflectors, fixtures, hangers, plugs, and receptacles are shown.

Bastian-Blessing Co., 125 W. Austin Ave., Chicago, Ill. Catalogue 23, containing data relative to "Rego" welding and cutting apparatus, including welding and cutting torches, manifolds, welding and cutting regulators, cutting, welding, and soldering outfits, adapters, nipples and fittings, wrenches, etc. A number of new products are shown in this catalogue, and some of the prices have been revised. Copies of the book will be sent upon request.

Diamant Tool & Mfg. Co., Inc., 91-97 Runyon St., Newark, N. J. Catalogue describing Diamant standard punch and die sets, the unit parts of which are made on an interchangeable basis, thus giving an opportunity to select from a wide variety of sets different combinations to suit the parts to be produced. Tables are included giving the capacities and dimensions of the different sets, the standard parts being designated by letters on the accompanying diagrams.

Boston Gear Works, Norfolk Downs (Quincy), Mass. 1921 edition of general catalogue G1, covering 600,000 standardized Boston gears, carried in stock in 1500 sizes. A list of additions to the stock sizes is given on page 4. Complete data including dimensions, prices, etc., are given for brass, iron, and steel bevel and spur gears, worm-gears, sprockets, etc. The booklet also shows ball bearings, steel bushings, gear gages, pulleys, racks, and universal joints.

W. S. Rockwell Co., 50 Church St., New York City. Bulletin entitled "Selection of Fuels," containing a series of papers relating to the selection and use of fuels and equipment for industrial heating operations. The bulletin contains five specific papers, as follows: Factors Governing the Selection of Fuels; Comparative Fuel Prices on B. T. U. Basis; Comparative Heating Value of Industrial Fuel Gases; Composition of Industrial Fuel Gases; and the Utilization of Fuel Resources.

Nazel Engineering Works, 4043 N. 5th St., Philadelphia, Pa. Catalogue entitled "The Nazel Hammer Book," illustrating and describing in detail the construction, operating principle, motive power, and other features of the Nazel air hammer. The different types of hammers are illustrated, and complete specifications are given for each. A diagram of this type of hammer, with the various parts numbered and designated in the accompanying list, is included for the user's convenience in ordering repair parts.

Greenfield Tap & Die Corporation, Greenfield, Mass. New 400-page catalogue No. 46, describing the line of small tools and pipe tools made by this company. The tools shown include screw plates, taps, dies, drills, reamers, milling cutters, bits, arbors, countersinks, hobs, tap and drill kits, mandrels, sleeves, sockets, stocks, tap wrenches, pipe vises, and pipe wrenches. In addition to the descriptive material relative to the tools, seventy pages of tables and general information are included. A copy of the book will be sent to anyone who mentions MACHINERY.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Catalogue 9-C, illustrating and describing the new line of electric furnaces which has been added to the products of the company. The furnaces described include the multiple unit type, small "hevi-duty" furnaces, and "hevi-duty" industrial furnaces. Applications for annealing, hardening, drawing, and enameling are described. Special publication 1643, treating of the application of oil circuit-breakers, including an outline of the characteristics of the several types of Westinghouse oil-circuit breakers.

General Fireproofing Co., Youngstown, Ohio. Catalogue entitled "Saving with Shelving," containing illustrations of the different types of GF all-steel shelving and their application in storerooms, vaults, tool-rooms, libraries, and for a wide variety of uses. A complete list of sizes is included. This shelving is made on the unit principle, a few fundamental pieces forming a foundation from which may be developed installations of many sorts to handle various kinds of loads and materials. Catalogue entitled "Efficient Record Protection," containing illustrations and specifications covering the all-steel safes made by this company for the preservation of business records.

Heald Machine Co., Worcester, Mass., has published a book comprising a treatise on cylinder regrinding, the purpose of which is to assist those entering the business of regrinding automobile cylinders. The book contains 116 pages, 6 by 9 inches, and the material is divided into eight chapters. The first chapter deals with the field for cylinder regrinding, outlining the advantages and possibilities, and giving actual figures concerning the possible profits, as well as information on shops best adapted for regrinding, and where work of this kind can be obtained. The second chapter treats of the equipment required by an average shop for regrinding and fitting pistons, rings, and pins, and describes in detail Heald cylinder grinding machines. The third chapter discusses why motors should be reground, and the fourth chapter gives a number of kinks of value in regrinding work. The fifth chapter contains a detailed description of the operation of the Heald cylinder grinding machine. The sixth chapter covers advertising and publicity. The seventh chapter treats of assembling the motor and, though short, is considered very important, as many a regrinding operation is spoiled by improper assembling. The eighth chapter contains general information relating to the Heald line. The data contained in the book should be of considerable interest and value to those entering this field of work.

TRADE NOTES

Peter A. Frasse & Co., Inc., 417 Canal St., New York City, have been appointed sole agents for the Metropolitan district for Sibley drilling machines made by the Sibley Machine Co., South Bend, Ind.

Oxweld Acetylene Co., Newark, N. J., manufacturer of "Oxweld" welding and cutting equipment, has removed the offices of its foreign sales department from Newark to 30 E. 42nd St., New York City.

Tool-Bit Specialty Co., Syracuse, N. Y., has been organized to manufacture high-speed steel tool-bits. A full line of sizes will be carried in stock. The bits are made by the hammering process, it being claimed that this method produces a better bit than can be obtained by the rolling process.

Frostholm-Treiber Co., Rochester, N. Y., has been incorporated with a capital of $24,000 by C. C. and J. H. Frostholm and W. C. Treiber to manufacture tools, piston rings, and kindred products. For the present, correspondence should be addressed to Frostholm Bros., 221 Washington Square, Syracuse, N. Y.

Brown & Sharpe Mfg. Co., Providence, R. I., announces that its annual vacation, starting July 29, will be extended this year to September 6. During this time the stock-room and offices will remain open as usual, and essential operations will be carried on in the shop, so that satisfactory deliveries can be made on supplies and on any of the Brown & Sharpe standard products.

Garvin Machine Co., Spring and Varick Sts., New York City, manufacturer of milling machines, screw machines, and numerous other types of machine tools, announces the resignation of its sales manager Frank A. Power, and the appointment to this position of Lyman M. Waite, formerly with the National Acme Co. and recently with the Springfield Automatic Screw Machine Corporation of Fitchburg, Mass.

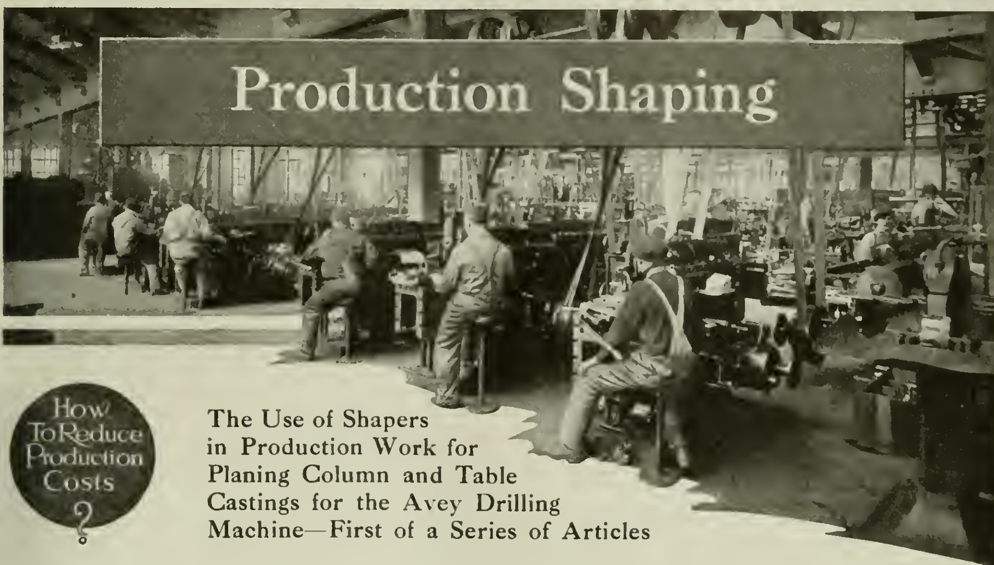
Webster & Perks Tool Co., Springfield, Ohio, has sold the grinding and polishing stand and accessory department of its business to the Hill-Curtis Co., Kalamazoo, Mich. This change has been made in order that the company may concentrate all its facilities on the exclusive manufacture and sale of the W & P line of universal and plain cylindrical grinding machinery. The Hill-Curtis Co. is an established concern operating a foundry, forge, and machine shop, and is well equipped for manufacturing this line.

Dodge Sales & Engineering Co., Mishawaka, Ind., manufacturer of transmissions and heavy oil engines, announces that work on its new $1,000,000 building at 49 Park Place, New York City, has been started, the excavation being practically completed. Present plans call for a twelve-story building, but the foundation and construction will permit of an additional four stories, if needed. The new building will occupy 165 feet frontage on West Broadway, 50 feet on Murray St., and 75 feet on Park Place.

W. A. Jones Foundry & Machine Co., 4409 W. Roosevelt Road, Chicago, Ill., at a recent meeting elected T. A. Jones president of the company to succeed the late William A. Jones. The other officers elected are as follows: W. G. Jones, vice-president and treasurer; J. A. Sizer, secretary; and G. W. Page, assistant secretary. The general policy of the company is in no way altered by these changes and W. G. Jones continues to hold the position of general manager in addition to acting as vice-president and treasurer. T. A. Jones, the new president, has been associated with the company for many years as its secretary and treasurer.

Reeves Pulley Co., Columbus, Ind., announces that arrangements have been made with Manning, Maxwell & Moore, Inc., 119 W. 40th St., New York City, whereby the latter firm assumes the exclusive agency for the Reeves variable-speed transmission in the New York territory. Manning, Maxwell & Moore will carry a complete assortment of repair parts for these transmissions for immediate delivery. They will also carry a large stock of complete variable-speed transmissions of various sizes and types, and will have a completely organized variable-speed transmission department in charge of capable engineers. Manning, Maxwell & Moore will also handle and carry in stock the Reeves wood split pulley.

Production Shaping



How To Reduce Production Costs?

The Use of Shapers in Production Work for Planing Column and Table Castings for the Avey Drilling Machine—First of a Series of Articles

SHAPERS are extensively used in tool-rooms for such work as the forming of die-blocks. By employing the various combinations of feed movements provided on machines of this type, pieces of intricate form can be machined—hence, the name "shaper." It is a general impression that the profitable use of these machines is restricted to tool and experimental work and similar operations, but although shapers are not extensively used on production work, there are many shops which have found them efficient for the performance of short planing and other similar operations on a production basis. For work that comes within their range they have several advantages. Among these may be mentioned a low initial investment, small maintenance cost, small amount of floor space required, and simplicity of operation, enabling them to be attended by low-priced labor.

The majority of the production jobs which are satisfactorily done on the shaper are those where the nature of the work is such that it is impracticable to take advantage of the increased efficiency resulting from the stringing up of a number of pieces of work on the table of a planer. It will be evident, then, that in cases where a choice must be made between setting up a single piece of work on a planer or on a shaper, the lower item of overhead that must be charged against the latter type of machine is usually of sufficient importance to represent a determining factor, provided the production time is not unreasonably high.

At the plant of the Avey Drilling Machine Co., in Covington, Ky., the possibilities of the shaper as a production tool are well demonstrated. This firm uses shapers for five different manufacturing operations on the top column, the lower column, and the table of drilling machines, and as the dimensions of these parts vary considerably for different sizes of machines, it is necessary to have a number of shaper fixtures available.

Before starting upon a detailed description of the operations performed on these shapers, it may be well to make a general statement concerning the nature of the shaper work that is done. Obviously, planers are used in building Avey drilling machines, but there are certain castings, such as those for the table and the lower column for multiple-spindle machines, which are too wide to pass between the housings of any planer in this shop. Consequently, the machining of these castings presented the alternative of either purchasing a larger sized planer or of devising some other means of handling the work.

As there were only a moderate number of these pieces to be planed, the management felt that the investment in a planer of sufficient capacity for this work would not be warranted. A study of this problem made it apparent that, as the length of the surfaces to be planed on even the largest castings was quite short, a shaper with a 32-inch stroke would have sufficient capacity to handle the work, provided it was equipped with a fixture that would support the casting rigidly under the shaper ram. Such a machine could be purchased at a lower first cost and it would possess the further advantage of occupying less floor space.

The other type of planing operation for which shapers are used in this plant, is the machining of surfaces on castings that have a shoulder at the end of the finished surface, which makes it impracticable to set them up in a row on a planer table. For jobs of this

---

Shapers are not generally thought of as production machines, because their more common application is for tool-room, experimental and repair shop work; but it is a fact that shapers are capable of giving highly satisfactory results for the performance of short planing operations on a production basis, and for other production work within their range. This article describes the classes of work of this kind for which the shaper is adapted, and gives specific examples of advanced practice in production shaping.

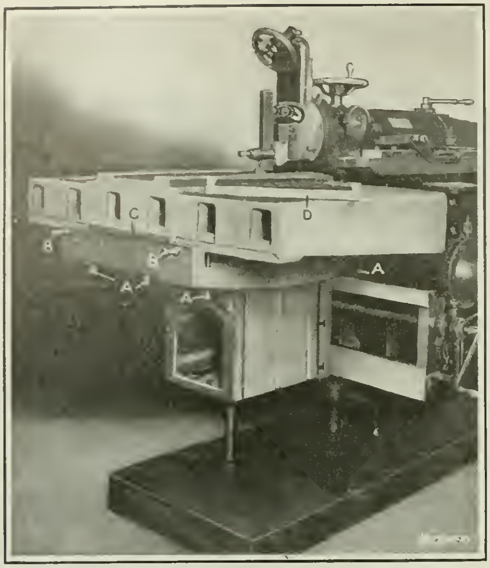


Fig. 1. Thirty-two-inch Shaper equipped for planing the Table Bearing on Columns of Multiple-spindle Drilling Machines

kind, the shaper is often found a more desirable tool than the planer because of the absolute control of the stroke, and as previously stated, when only one piece of work can be machined at one time, the smaller amount of floor space taken by the shaper is also an advantage.

Planing Dovetailed Bearing on Drilling Machine Column

Fig. 1 illustrates a 32-inch back-geared crank shaper built by the Cincinnati Shaper Co., Cincinnati, Ohio, which is used for planing the dovetailed table bearing on the lower column of an Avey No. 2 six-spindle drilling machine, this being the first operation performed on the casting. This dovetailed bearing is used as the locating point for the performance of subsequent operations. Naturally it must be located in approximately a central position on the casting and planed in accurate alignment with the side walls. To insure obtaining these results, a preliminary setting is made by first measuring from the two extreme outer edges to locate the center line of the casting, and then setting the tools in the proper position to plane the dovetailed bearing central with this line.

After this preliminary location has been accomplished, the casting is leveled up by means of five screws, four of which are shown at *A*. At the rear, the casting rests against two horizontal screws which may be adjusted to square it up with the line of travel of the shaper ram. The final clamping is accomplished by means of two screws *B* which are tightened against the casting and secured by means of lock-nuts. The tools are set for planing the dovetail by means of a gage *C*, and after the operation has been completed, the accuracy of the finished work is tested with a gage *D*.

In planing this dovetailed bearing, one roughing and one finishing cut are employed. Round-nosed roughing tools are used on the horizontal surfaces, while special rough-dovetailing tools are used on the angular faces. For taking the finishing cuts, the horizontal surfaces are machined with a square-nosed tool, while special finish-dovetailing tools are used on the angular faces. The fixture shown in Fig. 1 is also adapted for use in planing the lower columns of Avey No. 3 drilling machines with either four or six spindles. It will be seen that this fixture is set up on the regular table of the shaper.

Planing Dovetailed Column Bearing in Drilling Machine Table

Fig. 2 shows a 32-inch Cincinnati shaper equipped with a special extension at the front of the base to adapt it for the use of a fixture for holding the tables of Avey No. 3 four-spindle drilling machines while the dovetailed column bearing is being planed. As the castings come to this machine, a planing operation has been performed on the working surface of the table, which is at the back in the illustration; and the lower edge *A* of the casting has also been planed. These surfaces are utilized as locating points for setting up the work on the shaper. The operation consists of planing a dovetailed bearing at one side and a square seat for a dovetailed gib at the other side of the table bearing on the column. This bearing must be centrally located, and with that object in view, the casting is centered in the fixture by measuring from the two ends of the planed working surface of the table.

The casting rests in the fixture on blocks *B* that support the planed edge *A*, and by using blocks of different heights the same fixture may be employed for planing tables for different sized drilling machines. It will be apparent from the illustration that this work-holding fixture is of the so-called box form, and that the casting is slid in from one end and lowered into place on the supporting blocks *B*. This fixture is hung on the saddle by bolts in the T-slots, and takes the place of the regular table of the machine. When ordering a machine for handling this work, a special extension base *C* was specified, so that a support could be used at the front of the fixture to carry its weight, which is quite considerable. The work is clamped back in the fixture against a finished face that is arranged to come in contact with the previously planed working surface of the drilling machine table.

After adjusting the position of the casting so that it is properly centered, a preliminary clamping is accomplished by means of two screws *D* that force the casting back against the locating face at the rear of the fixture. Two screws *E* are next tightened to hold the casting down, and a screw inside the fixture is then raised under the center of the part to be planed, in order to support the thrust of the cut. Finally, the main clamping screw *F* is tightened, this screw being relied upon to accomplish the major part of the clamping action. In order to place control of adjust-

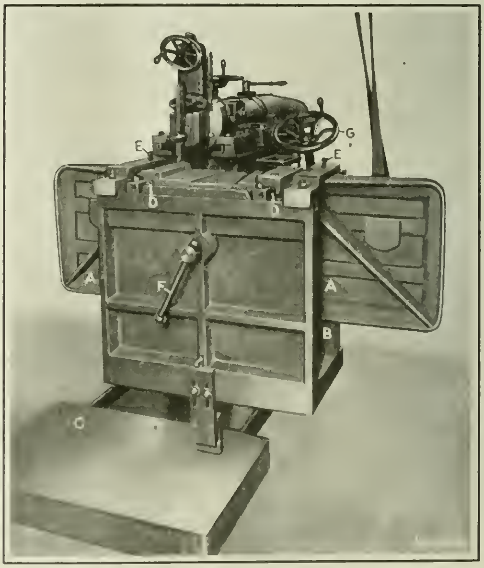

Fig. 2. Thirty-two-inch Shaper equipped for planing the Column Bearing in Tables of Multiple-spindle Drilling Machines

ments of the saddle on the shaper cross-rail within easy reach of the operator while at the front of the work-holding fixture, a special set of gearing, manipulated by a handwheel *G*, has been placed on the machine.

In planing the surfaces of the table bearing on the column, one roughing and one finishing cut are required. For the horizontal surfaces at the bottom of the bearing, a round-nosed roughing tool is employed, while a square nosed tool is utilized for running down the vertical side of the bearing, and a special rough-dovetailing tool is used for taking the first cut on the inclined side. For the finishing cuts, a square-nosed tool is used on the horizontal surfaces and for running down the side of the vertical surface, while a finish-dovetailing tool is utilized on the inclined side. The recess between the finished horizontal surfaces of the bearing is roughed out with a round-nosed tool, and no finishing cut is taken. The dovetailed bearing planed on this shaper is 12 inches long by 18¾ inches wide by 1¼ inches deep. The material is cast iron, and the time required for the job is about two hours.

Planing Top Columns for Avey Drilling Machines

There are three planing operations to be performed on the top column of Avey drilling machines. Two of the surfaces to be machined are located in such a way that there is not sufficient clearance for a tool to pass over a string of castings when set up on the table of a planer. Consequently, the necessity of handling one casting at a time makes it a more economical proposition to perform this work on a shaper, for reasons that have already been mentioned. The third surface to be planed on these parts is the relatively small bottom face, where the top column is connected to the lower column member; and the fixture for holding the work for this operation is so designed that three castings may be set up at a time. In this way, the shaper is able to give a very satisfactory rate of production, and the output from a single machine is adequate to fulfill the requirements of the production schedule on this class of work.

Method of Setting up Top Column Castings for the First Operation

The first operation on these castings consists of planing the dovetail for the drilling head, and as this bearing is not only an important factor in governing the efficiency of operation of the drilling machine, but is also used as the locating point in setting up the work for all subsequent operations, it will be evident that great care must be taken in setting up the work and in planing this important bearing surface. Referring to Fig. 3, which shows a Cincinnati 24-inch shaper equipped for the first operation, it will be seen that the work is held in a box type of fixture that is bolted to the saddle T-slots in place of the regular shaper table.

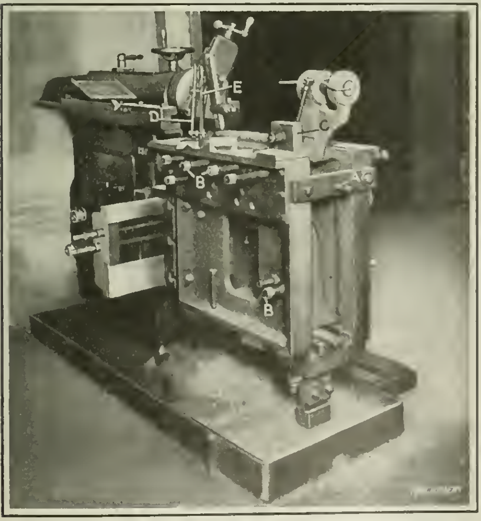

Fig. 3. Twenty-four-inch Shaper equipped for planing the Drilling Head Bearing on Columns of Single-spindle Drilling Machines

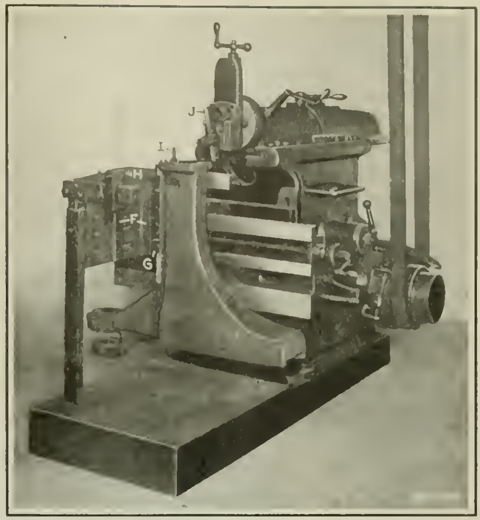

Fig. 4. Twenty-four-inch Shaper equipped for planing the Base of the Columns of Single-spindle Drilling Machines

Inside the box fixture there are two adjusting screws on which the casting rests, and they may be manipulated to provide for leveling the work so that the dovetailed bearing will be planed in proper relation to other fixed points. At the end nearest to the machine, there is provision for using a clamping bolt and strap (not shown) to hold the casting down, and at the opposite end of the fixture there will be seen a cross-bar and screw *A* for supporting the end thrust of the tool. Sidewise location and clamping of the casting in the fixture is accomplished by five bolts *B* at each side, which are tightened against the casting to locate and hold it in the desired position for planing.

Aligning Casting with Line of Travel of the Shaper Ram

Attention has been directed to the importance of lining the casting up accurately before starting the planing operation. The methods by which this result is accomplished are as follows: First, it is necessary to so locate the work that a line from the center of the spindle bearing hole to the center of the base of the column is parallel to the line of travel of the shaper ram. For obtaining this alignment, use is made of a special gage *C* that is carried on a base having a shoulder that fits over the inner edge of one of the top rails on the work-holding fixture, which is accurately finished for this purpose. A wooden plug is placed in the spindle bearing hole and rubbed with chalk so that the center of this hole can be marked, with reference to both the center of the opening and the outside of the boss.

Similarly, a chalk mark is placed on the top of the casting at the opposite end, so that a central line can be scribed in this chalk. After the fixture has been set up with the finished edge of the top rail in alignment with the line of travel of the shaper ram, gage *C* is used, as shown in Fig. 3, to compare the position of the scribed center of the spindle bearing opening with the center line scribed on the base of the column. The arm on which the measuring bar of gage *C* is carried is mounted on a pivot so that it may be swung against the tension of a coiled spring. In this way, it is an easy matter to first reach the spindle opening, and then move the gage to the opposite end of the casting and swing the measuring bar down into engagement with the work. This tool affords a convenient means of measuring the distance from the edge of the top rail of the fixture to the two scribed lines. If the work has been properly aligned for planing, these two distances should be equal.

Adjusting the Horizontal Position of the Work

The next step in setting up the work is to bring the casting into a horizontal position, that is, to have it so located that as the casting lies in the work-holding fixture, the center of the spindle bearing hole will be at exactly the specified distance above the top surface of the opposite end of the casting, namely, 7⅛ inches for the size machine referred to. The test for this setting is accomplished by means of a surface gage and a special gage-bar on which there is scribed a graduation mark at 7⅛ inches from its lower end. The surface gage *D* is first set so that, with its base standing on the top rail of the work-holding fixture, the point of the scriber comes into contact with the center scribed on the wooden block in the spindle bearing hole. Then the special gage-bar *E* is stood vertically at the center of the opposite end of the casting, and the surface gage is moved over so that the position of the spindle center may be transferred to this gage. If the horizontal setting of the work is accurate, the point of the scriber will come into contact with the 7⅛-inch graduation on the gage-bar; otherwise, the horizontal position of the casting must be adjusted by means of the screw on which it is held in the fixture.

Testing Vertical Setting of Work

One other adjustment is still necessary to bring the work into the desired position for planing, namely, to ascertain whether it is standing in a vertical position. By first placing gage-bar *E* at one corner of the rear end of the casting and testing the position of the graduation line with the surface gage *D*, and then repeating this test with the gage-bar at the opposite corner of the work, a comparison can be made of the positions of the opposite corners of the casting relative to the horizontal top face of the work-holding fixture. The point of engagement between the scriber on the surface gage and the graduation line on bar *E* should be duplicated for the two settings if the work is properly located for planing. When all three of these adjustments of the setting of the work have been made, the screws *A* and *B* are finally tightened to maintain the accuracy of the location.

After the casting has been set up according to the previously described method, the outline of the dovetailed bearing to be planed is laid out on the work, in order to indicate the amount of excess metal that must be removed by planing. The first cut across the horizontal surface at the top of the bearing is taken with a round-nosed tool, and then a special rough-dovetailing tool is used on the inclined surfaces. The horizontal surfaces are next finished with a square-nosed tool, and a special finish-dovetailing tool takes the final cut on the inclined surfaces, thus completing the first operation. The production time on this job is forty-five minutes.

Planing the Bottom Surface on the Top Column

Mention has already been made of the fact that the dovetailed bearing, previously planed on the top column casting to receive the drilling head, is used as the locating point in setting up the work for performing subsequent operations. Fig. 4 shows a 24-inch shaper built by Gould & Eberhardt, Newark, N. J., on which this work is performed; and in this connection, attention is drawn to the fact that although the shaper fixture is designed to hold three castings at a time, only one casting is shown in position in order that the arrangement may be more clearly illustrated. The method of setting up the work and the actual machining operation to be performed are quite simple. On the fixture there are three strips *F*, each of which has an inclined surface to bear against the angular face at one side of the dovetailed bearing that has been planed on the column.

After a piece of work has been slipped into place under locating strip *F*, a second adjustable strip *G*, which is secured to the fixture by bolts, is pushed into place against the opposite side of the dovetailed bearing and drawn up tight by the bolts, thus securing one piece of work in place for planing. Three pieces are set up in this way, and when they have all been set up, a clamping screw *H* is tightened to hold them securely in place and to support the end thrust of the tool. The planing operation is quite simple, consisting of facing off the bottom of the casting and of planing a tongue to fit into a groove planed in the top of the lower column casting.

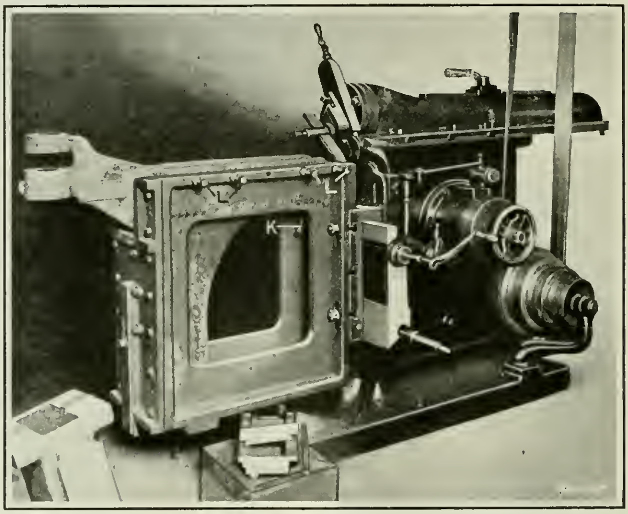

Fig. 5. Twenty-four-inch Shaper equipped for planing Bearing for Top Carriage on Drilling Machine Columns

The sequence of cuts taken during the performance of this operation is as follows: A round-nosed tool takes a roughing cut at the top of the casting, and the same tool is fed vertically downward to produce the necessary clearance at each side of the tongue. A duplex straddle tool is next used to finish-plane the sides of the tongue, and the accuracy of this job is tested with a snap gage *I*. Finally, the top of the work is finished with a round-nosed tool which has had a small flat surface stoned on its point. This tool is set at an angle, as shown at *J*, for convenience in reaching the work as it is held in the fixture. The production time on this job is twenty-five minutes.

Final Planing Operation on the Top Column

The final planing operation on the top column of the Avey drilling machine consists of planing the dovetailed bearing for the top carriage. This operation is performed on a 24-inch shaper as shown in Fig. 5, which is built by the Milwaukee Shaper Co., Milwaukee, Wis. This machine is equipped with a box jig similar to the one used for the first operation, except that the work is set differently. For taking the final cut, the casting is located from the dovetailed bearing planed in the first operation, the arrangement being similar to that explained in connection with the work-holding fixture illustrated in Fig. 4, with the exception that in the present case the dovetail in which the casting is held is located at the forward end of the fixture.

Castings are brought to this fixture by a trolley hoist and lowered through a space in the top, after which the clamping bolts are tightened. After a preliminary setting has been accomplished in this manner, the weight of the casting at the opposite end is supported by tightening a screw *K* that engages the under side of the work; and screws *L*, which are furnished with lock-nuts, are next drawn up in order to hold the sides of the work and prevent them from springing away from the cut. This is a matter of importance, because the walls of the casting are thin at the point where the dovetailed bearing for the top carriage is planed, and they require support in order to prevent distortion of the work.

After the roughing cut has been taken, it is also a matter of especial importance to loosen up the clamping bolts, which were tightened with a wrench before taking the roughing cut, and then screw these bolts up by hand until their points come into engagement with the casting, after which the lock-nuts are again tightened with a wrench. The purpose of resetting before taking the finishing cut is to prevent excessive pressure of the bolts which would spring the work out of shape and destroy the accuracy of the planed surface. On this job, roughing and finishing cuts are taken with the same sequence of tools previously referred to for operations on dovetailed bearings. The production time is seventy-five minutes.

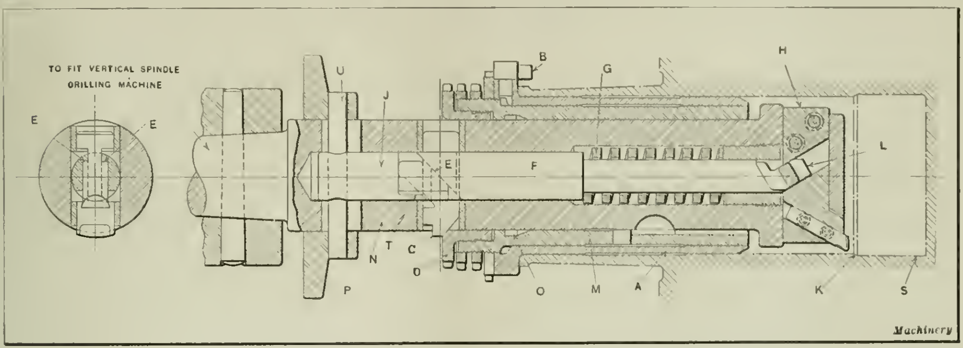
* * *

ROUGH-RECESSING TOOL FOR MOTOR CYLINDER BORE

The accompanying illustration shows a single-point boring tool which was developed to take the place of a wide forming-blade tool employed for the roughing operation in the combustion chamber of a motor cylinder. The wide blade originally used gave a fine finish, but its use necessitated the employment of extremely slow feeds and speeds, and on several occasions it had spoiled the cylinder bores by scoring them while being withdrawn from the work. In addition to these objectionable features, it proved an expensive tool to keep in proper condition. The design shown was adopted with the idea of producing a more satisfactory tool, which would be nearly automatic, positive in action, and not too expensive to make.

It will be noticed that bushing *A* acts as a pilot in the bore of the cylinder and is prevented from rotating by pin *B*, which comes into contact with the tangent wall between the two cylinders. When the spindle is fed downward, dog *C* comes in contact with the angular surface of collar *D* and is thrust inward. This inward movement causes shoulders *E* to bear on push-rod *F* against the action of spring *G*, which develops about 330 pounds pressure when compressed. As push-rod *F* moves forward, compressing spring *G*, the forged angular end *L* seated in tool-block *H* imparts an outward movement to the tool-block. Collar *D* is locked to bushing *M* which, in turn, is keyed to the main driving bar *N*. As dog *C* travels inward at the same time that it is being carried downward by bar *N*, the point of the tool is moved both radially and axially. The angles of the shoulders *E* and end *L* are, of course, calculated so that the walls of the combustion chamber and the walls of the cylinder bore will be joined by a conical surface *K* of the required taper, which in this case is 30 degrees.

Dog *C* travels downward inside bushing *M* for the full length of the cut or until the point of the tool is in the extreme downward position. At this time the point of the dog drops into slot *O*, or rather, the moment it passes over the slot the action of spring *G* forces it out, at the same time withdrawing the point of the tool from the surface *S* of the work. The stop on the machine also comes into play as a further safeguard, although a click that may be heard several feet away, which is made by the dog dropping into the slot, serves as a signal to the operator that the end of the cut has been reached. When in this position the tool may be withdrawn from the work without danger of scoring the cylinder walls.



Rough-recessing Tool for Combustion Chamber in Motor Cylinder

A new cut cannot be started until the tool has been completely withdrawn from the cylinder bore and placed in the correct position. To do this the operator must elevate the spindle to a sufficient height to bring flange *P* against adjustable pins (not shown), held in the nose of the machine. Flange *P* is pinned to the upper knock-out bar *J* and is a loose fit on the main driving bar *N* which is slotted to accommodate pin *U*. The force of the blow resulting from bringing flange *P* into contact with the pins in the nose of the machine forces the flange downward carrying with it knock-out bar *J* which seats on push-rod *F*. This action also carries rod *F* downward, providing clearance between its shoulders and the shoulders on dog *C* so that the beveled end *T* on the end of the knock-out bar will drop into the angular slot in dog *C*, thus forcing this member inward and allowing the outside nest of bushings to drop down, at which time the tool is ready for another cycle of operations. It will be noticed that the construction of the bushings and lock-nuts is such that a wide range of adjustment is provided.

W. W. R.

* * *

In 1920 Italy imported from Germany machinery and machine parts to a value of nearly 210,000,000 lire, as compared with imports to a value of 70,000,000 lire in 1913. In quantity, the imports amounted to 36,400 tons in 1920, as compared with 46,900 tons in 1913.

THE COST FACTOR IN FOUNDRY PRODUCTION

By J. P. GLYNN
Production Manager, The Elmwood Castings Co., Cincinnati, Ohio

Much of the cost burden entering into the manufacture of machinery can be lightened by putting the foundry on a more efficient productive basis. The manufacturer of machinery has never had a better opportunity than the present to go over the pattern situation and clean out obsolete types of patterns from his equipment. The development of new processes for turning out castings in quantity has done much to promote efficiency in the foundry. The manufacturer should not overlook these developments, but should take advantage of the modern equipment of the foundries and cooperate with the foundry by fitting his patterns so that they can be used for machine molding and other modern foundry appliances. The production of castings by hand methods, using the old type of pattern, is still followed by many manufacturers, and it is a vital consideration from an economical point of view to arrange such jobs for machine molding. In making or in contemplating changes of this kind, the manufacturer should solicit the cooperation of his foundrymen, and he will usually find that information will be freely given. An increase in the foundry production rate will be appreciated more in the days to come, when the labor shortage will again become acute. This shortage will be a big factor, especially in foundries where the percentage of apprentices is very low.

An example will best illustrate the savings that can be realized by making these change-overs. Consider a small bushing, say 3 inches in diameter and 4 inches long, with a 1¼-inch cored hole. Ordinarily this casting would be made by using one wood pattern, and if made on the bench would be run with other small patterns in order to fill up the flask, since in most cases only one pattern is furnished to the foundry. The molder can be expected to ram about twenty flasks per eight-hour day. Consider now this same job produced on a molding machine, under which conditions not less than six patterns would be mounted on a board or plate. It is safe to state that the molder, under ordinary conditions, would put up 100 molds per day, using a squeezer type machine. In many foundries a job of this kind is run on a piece-work basis and an even greater production obtained. It is evident that the old type bench-work patterns make this class of molding expensive and that the manufacturer is bearing this uncalled-for expense.

A certain machinery manufacturer once built and sent to his foundry an aluminum pattern for a 14-inch lathe apron plate. The pattern was to be used in conjunction with a wood follow-board by hand-ramming on the side floor. If the castings had been molded as intended, it would have been impossible to get much more than twelve per day. The pattern cost $50. In making the pattern to be molded this way, the foundry had not been consulted, so when the job reached the foundry a plated pattern was requested to be used on the molding machine, which would involve an additional cost of $62. The customer did not feel disposed to assume this extra cost, so the foundry management considered it economy to have a new pattern made at their own expense and run the job on a squeezer machine. This was done, and the production attained was forty pieces per day, as against twelve by the hand method. The weight of the casting was 43 pounds, so that 1720 pounds of castings were produced by machine instead of 516 pounds, which would have been the production by hand molding on the side floor

One other factor which the production of castings by machine molding brings out is that the castings are drawn with the aid of a vibrator on the machine, and are always uniform in size, showing practically no parting line. This eliminates much grinding and chipping. By hand-molding methods, the pattern is rapped by using a hammer and a bar, and this often causes the castings to lack uniformity of size and weight. The money represented by this lack of uniformity often amounts to more than would be required to re-rig the patterns.

In connection with these changes the core-box equipment should receive attention. A large percentage of the dry-sand core work can be eliminated by changing the patterns to the machine-molded aluminum-plated type, because patterns of this type can often be so made as to produce their own core in green sand. In cases where dry-sand cores are required, the core-boxes should be so arranged that several cores can be made at one operation. There are many types of core-making machines in use, and it is just as important that the core-boxes be properly arranged for quantity production as it is that the patterns be so arranged.

ADVERTISING MACHINE TOOLS

By J. M. HENRY, Engineer, Pratt & Whitney Co., Hartford, Conn.

The editorial "Publicity that Pays" appearing in June MACHINERY refers to the class of information commonly contained in circulars and catalogues of machine tools and accessories. The writing of machine tool advertising is somewhat prosaic at its best, and time-worn shop expressions come naturally to the writer who must necessarily have a technical education in order to write intelligently. The vocabulary is limited to technical descriptive terms and, yet, copy must be so written that it carries an appeal to everyone concerned in the purchase of the machine. The copy must be general enough to interest everyone, and to write it is "some job," to say the least.

General managers and superintendents are concerned with production, longevity, ease of repairs and adjustments, elimination of breakdowns, and quality of materials, while the purchasing agent is mainly interested in the price. Here enters another factor that is frequently commented on: Why are not prices included in descriptive literature and advertisements? The answer is that in nine cases out of ten the customer has certain jobs in mind when looking for a machine. Extra equipment is usually necessary for the operations, and if prices were quoted in the circulars, inquiries would undoubtedly come in asking whether the price included a taper attachment, compound rest, etc. Thus, additional correspondence would be required that otherwise would be avoided when a clear direct inquiry is received for a specific price on a machine with certain equipment.

To convince an engineer that the machine described is the best on the market for his purpose requires clear forceful technical copy and illustrations. There was a time when the showing of illustrations of certain detailed mechanisms, together with clear descriptions of their functions, was considered as playing into the hands of one's competitors. In some quarters this idea still prevails, but it has been largely done away with, because any manufacturer who desires to know the construction of a machine built by a competitor has numerous other convenient ways of studying the machine minutely.

The description of machines must be clear enough to suit the foreman and the operator, and there is no reason why technical advertising cannot be clear, concise, and fully explanatory. The matter of phraseology should be carefully considered; for instance, is a machine "controlled" or "operated" by a lever? Is a brake "automatically applied" when it is dependent on the action of the operator, even though his action does not relate directly to the brake? Many similar examples might be mentioned. If phrases such as "unusual depth" and "ample bearings" are resorted to, suspicion is aroused, but the copy seems bare without them. Cooperation between the engineering and advertising departments is indeed imperative, and the writer does not see how satisfactory results can be obtained when this practice is not followed.

A PHASE OF SHOP PRODUCTION COSTS

By FREDERICK A. POPE, Assistant to General Superintendent, Blake & Knowles Works, East Cambridge, Mass.

While considerable progress has been made in developing systems for determining shop production costs, there are, nevertheless, many details of this work that are not always given adequate consideration. A factor which seriously affects the cost records, but which often escapes detection or is given little attention, is the cost of materials and labor entering into remachining or salvage work. The actual or total cost of spoiled parts that must be scrapped, including the cost of stock and machine work, may be entered in the spoiled-work account to be absorbed as part of the burden; or it may be added to the cost of machining the pieces that pass inspection and the material account credited for whatever scrap is recovered. In either of these cases the fact that work has been spoiled is readily shown by some form of replacement order, or by the scrap card.

The repair or remachining work, however, is a rather elusive element which, nevertheless, creeps into the labor costs in some shops and is not always shown up as clearly as that of work actually scrapped. The extra cost of time spent in remachining, or in some way making usable, pieces which are not correctly machined, but which can be corrected and used, may be considerable. When the work is subjected to a rigid inspection between practically all important operations, the regular inspection reports will give all data regarding necessary salvage work of this nature; so that with a knowledge of the facts thus provided, steps toward remedial measures can be taken by those responsible for production. But in a great many shops where a varied product is made, and process steps cannot be definitely established, such detailed inspection all along the line is not practicable. The duty of inspection then falls heavily upon the department foremen; this is, of course, admittedly unsatisfactory, but sometimes unavoidable.

Furthermore, where the product is of such a nature that much of the work is done without the extensive use of accurate limit gages, the skill and touch of the workman becomes one of the leading factors in the control of quality. Under such conditions it is inevitable that parts will occasionally pass through which are not quite up to standard. For example: A hole bored for a bushing may be found too small when the parts reach the assembling department, so that the piece must be sent back to be rebored; a set of bosses may not be faced off square and must therefore be returned for refacing; or the tapered end of a piston rod may be turned too small for the drive fit and for that reason be sent to the welder to be built up for re-turning. In such cases this work is commonly done on the authority of some department foreman, the regular order number being used. The cost of extra labor required therefore finds its way into the cost of that job.

Segregating Salvage Costs

As in the case of complete spoilage, this salvage expense may be considered, under some conditions, a necessary part of the cost of the job, but it is essential that some means be provided for segregating in the records the cost of all this extra work, at least temporarily, so that weaknesses in the shop methods or incompetence in the personnel may become known quickly and be traced by the management, and the necessity for these corrections reduced to a minimum. Even though the final cost of the job may carry this item and so be passed on to the purchaser, a disregard of its causes will encourage carelessness which results in increased production costs. Attention should be directed to this kind of expense by some special form of job ticket so that later, when making up the cost summaries, that proportion of the labor spent in remachining work will comprise a separate item.

The exact form of the remachine ticket is immaterial, the essential thing being that it include the data indicating the department and person responsible for the incorrect work, and that it have some prominent and distinguishing feature (color or name) so that it can be easily separated by cost clerks from the regulation job tickets.

With such a method, imperfect work may, by a simple routine process involving practically no additional clerical work, be brought to the attention of the proper executives. An analysis, based on this information and incorporated in a report to the various department heads concerned as well as to the management, will place the responsibility for errors where it belongs, and will stimulate greater care in those departments.

It may be remarked that without a separate inspection force, or thoroughly standardized detail costs to check this extra expense, a foreman can, if he wishes, correct and hide defective work before it leaves his department. While this is true to a certain extent, the greater part of such errors in machining will be discovered in subsequent operations by some other department through inability to get a proper set-up, or in the assembly department through failure to assemble parts without excessive and out-of-the-ordinary hand fitting.

* * *

COMPARISON OF WAGES AND PROFITS

Employes, in general, usually have no conception of the profits realized from their labors, and to this ignorance of facts may be attributed many of the prevailing erroneous impressions among employes that their employers make enormous profits. For instance, a workman knowing the selling price of a part which he has produced is likely to deduct his wage and the probable cost of the raw material from which the product is made, and believe that the remainder approximates the profit of the concern on the part. Obviously, this is not so, because he has neglected to allow anything for taxes, insurance, and other overhead charges, or for a reserve or surplus fund so necessary to pay expenses during periods of depression and for enabling enlargements to the business.

Actually, the profits of a concern are small in comparison to the wages paid its employes, and if the latter were educated to understand this, much of the dissatisfaction among wage earners would be avoided. The General Electric Co., Schenectady, N. Y., with its usual farsightedness, gives each employe annually a statement showing the actual profits in cents resulting from a dollar's worth of business, as well as the sum which the employes received. The last statement was an average for the three years 1918, 1919, and 1920.

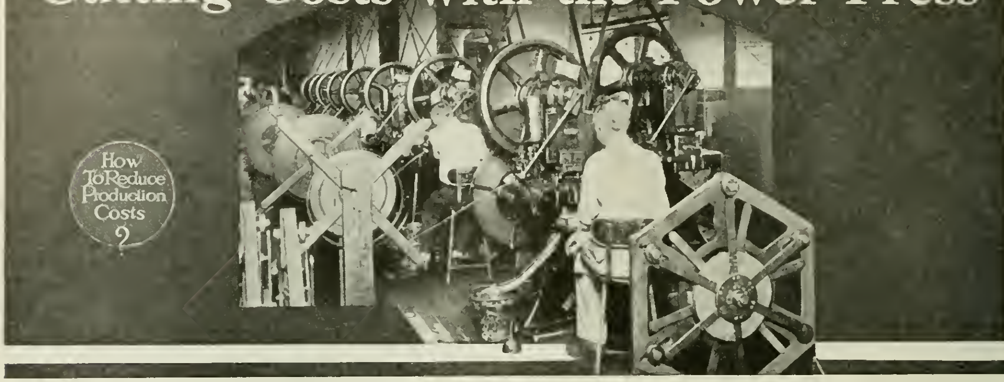
DISTRIBUTION OF EACH DOLLAR OF THE INCOME OF THE GENERAL ELECTRIC CO. FOR 1918, 1919, AND 1920

Distribution	Amount, Cents
Materials, supplies, etc.	40.6
Wages and salaries	41.7
Taxes	5.3
Transportation, telegraph, and telephone charges	2.5
Interest on bonds and notes	1.2
Dividend paid to stockholders	4.0
Surplus fund	4.7
Total	100.0

Machinery

The accompanying table shows the way in which each dollar of income was distributed. It shows that while the sum of 41.7 cents was paid in wages and salaries to the employes, only 8.7 cents was realized as a profit. Of the latter amount, 4 cents was paid to stockholders while 4.7 cents was placed in the reserve or surplus fund. Thus, it is evident that all the stockholders together received only about 9 per cent of the earnings of the employes.

Cutting Costs with the Power Press



How Material and Labor are Saved by the Use of Power Presses

By EDWARD K. HAMMOND

MANY executives in the mechanical industries, who pride themselves upon being well informed as to the latest methods applicable in manufacturing their products, do not realize the rapid strides which have been made in the design of dies for the performance of many operations not ordinarily expected to be done in a power press. Several advantages are to be gained by the substitution of stampings or drawn work for parts produced by other methods. Most important among these are the reduction in the cost of labor and material; the possibility of making parts of equal strength, but with a weight of only one-third that of parts produced by other methods (thus saving two-thirds the amount of metal formerly used); and last, but far from least, when rapidity in the filling of orders is an important factor, the ability of the power press to handle its work with extreme speed. A single downward and return stroke of the ram completes an operation, and, therefore, the rates of output attained in the production of all classes of stampings and drawn work are likely to be far in excess of those secured where the same parts are produced by some other method. For these reasons the power press is often an important factor in reducing costs.

Range of Work Done by Power Presses

Probably there are few machines that are employed for the production of as wide a range of work as power presses. The work handled by power presses extends all the way from small instrument parts, which are frequently made by treadle-operated presses of small size, up to such work as motor car bodies and parts of steel railway cars. Sheet steel of a thickness up to about ½ inch is easily worked under large presses. The machines themselves run all the way from small bench equipment, operated by foot pressure, up to machines with crankshafts over 2 feet in diameter, strokes of 4 feet, and a capacity up to 24 feet between the housings. Some machines constructed during the last few years weigh 700,000 pounds and over. One press for forming motor truck rear axle housings, recently constructed, weighs over 400,000 pounds.

Influence of Welding on the Range of Press Work

Mention of a machine constructed for use in the manufacture of rear axle housings brings to mind the influence of welding upon the range of work for which the power press is adapted. The development of electric and acetylene welding methods has enabled these processes to be employed in conjunction with the power press, for the economical manufacture of many parts that could not be produced in single pieces. As a case in point, consider rear axle housings for motor cars. It is common practice to draw these parts up in two pieces, and then to weld the two halves together in order to give the desired result. Mechanically operated torches are often used to good advantage, as they not only give more uniform results, but also handle the work with greater rapidity than would be possible if the torch were manipulated by hand.

Development of Dies

An investigation of what is actually being accomplished will reveal the fact that there seems to be practically no limit to the complexity of work that can be performed, if the problem of designing suitable dies for the purpose is submitted to an experienced and skillful diemaker. Many parts are now being made in dies, which were formerly made at a greater cost by other methods; and the design of these tools is even more varied than that of the power presses by which they are operated. The extreme range extends from the simple blanking die ring and punch up to the automatic follow-die, which takes ribbon stock and performs a sequence of operations on it, each of which brings the work one step nearer to completion, until it is finally stamped out or cut off. These dies are made

---

During periods of great industrial activity, when there is a strong demand for most manufactured products, and prices exhibit a rising tendency, production costs are not always as carefully scrutinized as they should be; but when business slows down and prices begin to fall, the need for economy in production becomes apparent, and manufacturers begin to examine their methods and seek new ways for reducing production costs. In many instances, it will be found that work formerly produced on other types of machine tools may, by a slight modification in the design of the piece, be performed equally well by the use of the power press at a decided saving in the cost of material, labor, and overhead.

---

with a number of stations under which the work is stopped as it progresses through the die, so that at each downward stroke of the ram one piece is operated upon at each station of the die, and one finished part is produced by each downward stroke of the press ram.

Drawing Roller Bearing Raceways

It has already been stated that one of the chief advantages to be secured by using power presses is the saving of labor and material. As a case in point, consider the work involved in the manufacture of sleeves for the outer raceways of a well-known type of roller bearing. These parts were formerly made from bar steel, worked in a screw machine which bored out the inside and turned the outside of the sleeve, preparatory to cutting it off the bar. The exact percentage of a solid bar of steel that is lost in the form of scrap produced in the making of sleeves by this method would naturally vary according to the diameter and thickness of different sleeves, but it would be safe to say that the average loss of material would be in the neighborhood of 80 per cent. The wages paid to a screw machine operator would also place quite a heavy labor charge against the job.

With a view to reducing the percentage of raw material converted into scrap, a change was made in the method of manufacture by substituting steel tubing for solid bars. The tubes were worked on a screw machine in exactly the same way as solid bars and it was still found necessary to bore the inside diameter and turn the outside of each sleeve before cutting it off. This improvement in the method of manufacture resulted in a substantial saving in the amount of steel that was scrapped, but the labor cost still remained about the same. Recently, a further noteworthy advance has been effected in the making of these parts. It consists of using dies for drawing the sleeves up from cold-rolled flat strip steel. By this method of manufacture, a deep shell is first drawn, and then this shell has the ends cut off, thus bringing the sleeve to the proper length. The dies have been developed in such a way that there is assurance of keeping the inside diameter and the thickness of every sleeve within the required limits, without resorting to subsequent machine work. Sleeves can be produced in these dies at a far lower cost than when the work was turned and bored on a screw machine, and the amount of material that goes to the scrap pile is not excessive.

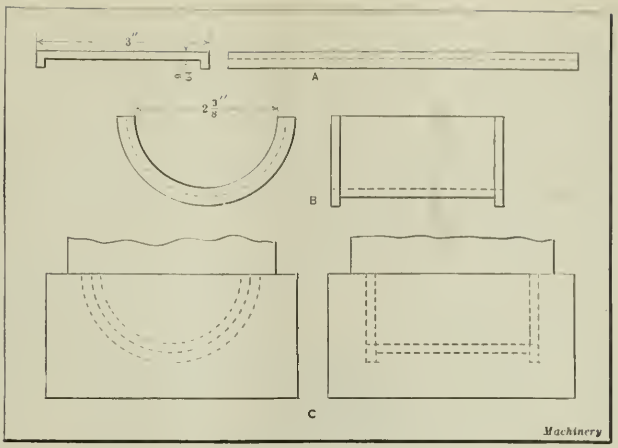


Fig. 1. Diagrams showing Successive Operations in forming Flanged Bronze Bushings

It is of interest to note that in order to obtain satisfactory results in the making of roller bearing raceway sleeves by this method, it is important to use cold-rolled steel of a perfectly uniform thickness. The material is purchased from the steel mill under specifications covering this point, and as it is delivered to the plant, the first step is to subject each strip of steel to a gaging process, in order to ascertain that its thickness comes within the required limits. This is done by passing the strips through an electrically operated gaging machine, equipped with contact points which touch opposite sides of the strip of steel. Any variation in thickness exceeding the specified limits is at once revealed by this machine, and all strips of steel that fail to pass inspection are rejected.

Last but not least among the general considerations involved in the substitution of press work for other methods of manufacture, on such classes of work as this, comes the important fact that, where automatic dies are used in the manufacture of small metal products, the material is fed to the die in the form of ribbon stock. After a machine is set up, it is only necessary for the operator to pay general attention to it. As a result, one man is able to look after about eight machines. This effects a substantial reduction of the labor cost as compared with cases where one operator is required for each machine.

Making Flanged Bronze Bushings

Fig. 1 shows successive steps in the production of bronze bushings which are made in halves and flanged at both ends. These pieces were formerly machined from castings, involving the usual steps of making molds, melting and pouring the metal, cleaning the castings, and machining

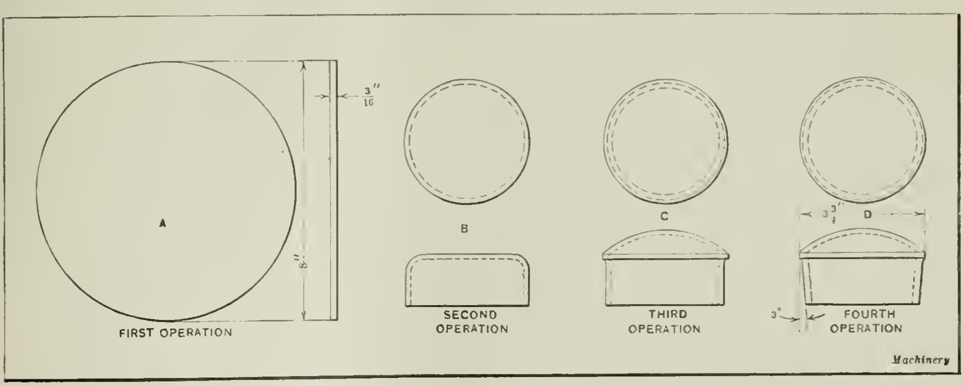

Fig. 2. Steps in the Production of Hand-hole Plugs for Boilers or Petroleum Stills

them. As compared with this procedure, the bushings are now completed, ready for assembly into the machine, by three power press operations. For making this product, strip metal is brought from the brass mill already flanged at each edge. The first operation consists of cutting off blanks *A* to the proper length. This is done on a No. 3 Stiles press. The second operation is performed in a 100-ton Bliss press, and consists of forming the blank to a U-shape, as shown by diagram *B*. Finally, the work, which has now been brought to approximately the required form, is finished in a 600-ton knuckle-joint embossing or coining press, equipped with a punch and die in which the metal is completely enclosed, so that it may be squeezed to the required shape and finish.

Bushings produced in this way do not require any subsequent machine work. Important among the advantages of making them under the power press are that there is a saving of material amounting to approximately 10 per cent of the total cost, while the rate of production under the press is about thirty times as high as that attained by the molding and machining of castings. For the first operation, blanks *A* can be cut off at twice the speed at which the second and third operations can be performed. Hence, the press used for cutting off blanks is only run half the time. Working on this basis, 2400 half bushings can easily be produced in an eight-hour day.

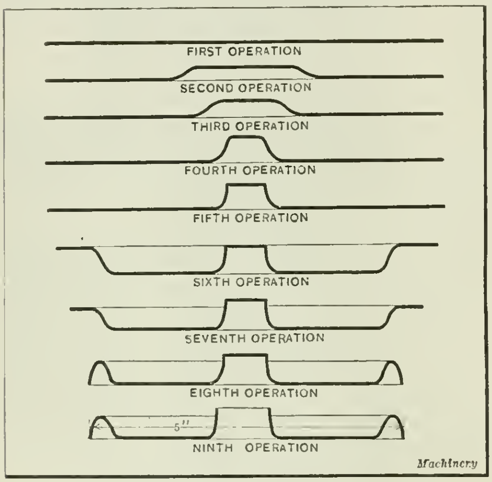

Fig. 3. Successive Steps in producing Half of a Pressed-steel Caster Wheel

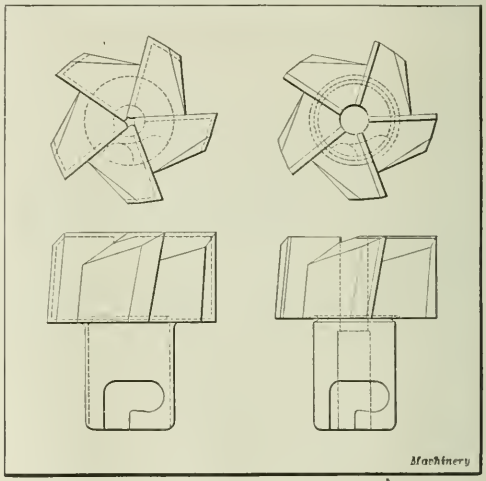

Fig. 4. End-mill Forging, produced on the Power Press within 1/16 Inch of Required Size

Making Conical Shaped Hand-hole Plugs

In the design of some types of stills used for the fractional distillation of crude petroleum, and also in some types of boilers, there is use for a number of plugs of the form shown in Fig. 2. They are pushed into hand-holes which give access to the tubes in the still or boiler, and the pressure from the inside forces each tapered plug into its seat, so that complete sealing of the holes is insured by the pressure applied to the rear of the plugs. When it is desired to have access to the tubes, it is merely necessary to drive the plugs out of their holes. Plugs of this kind are made in various sizes, but the method of procedure in manufacturing is the same in all cases. Before it was shown that this was a job that could be economically handled on the power press, the method of procedure was to make steel castings and then to turn the 3-degree taper on a lathe equipped with the usual attachment for handling such work.

Under the present method of making them, four power press operations are involved. The first step is to cut a blank *A*, 8 inches in diameter, on a No. 5 Bliss-Stiles press. The second step is to draw a straight cup *B* on a No. 76½ Bliss power press equipped with a double die, so that two cups can be drawn at a time. Reference to diagram *C* will make it apparent that there is a small ridge formed on the outside at the closed end of the cup, which forms a shoulder that engages the hole into which the plug is driven. This ridge or shoulder is formed in a coining press, which squeezes the metal in such a way that it is extruded outward to fill an annular groove in the die. Finally, a fourth press operation is performed to produce the 3-degree taper on the outside of the shell; and at the bottom of the punch there are embossed letters which come into contact with the inside of the cup at the bottom and press the trademark into the work. On this job, it is estimated that the power press gives a production over ten times as great as that attainable in making steel castings and machining them in accordance with the method which has been briefly described. By making the plugs under the power press, an operator is able to produce 2000 plugs in an eight-hour day.

Making Caster Wheels from Sheet Metal

Until recently, it has been general practice to make various forms of caster wheels of cast iron or hard wood. Both methods are likely to prove unsatisfactory, as either gray iron or wood is likely to break under heavy pressure or shock, and the cost of making caster wheels from these materials is high. Dies and methods have therefore been developed for making casters of various sizes and styles under the power press. These methods vary according to the size of the caster, but, in general, they are quite similar.

Fig. 3 shows the procedure in making a 5-inch caster wheel, two of the finished blanks of the form shown being riveted together to form this product. A study of the diagrams will make the sequence of operations quite clear. The first operation consists of stamping out the blank. Next come four drawing operations which bring the hub of the wheel successively to the conditions shown. The sixth is a so-called "dishing" operation, which raises the edge of the blank; this is the first step in forming the rim of the wheel. In the seventh operation, the edge of the blank is trimmed off Next, the edge of the blank is turned down to complete forming the rim of the wheel. Finally, a ninth operation pierces the four rivet holes and also punches out the end of the hub. The advantages of a sheet-metal caster wheel of this kind are that its weight is one-third of that of a cast-iron wheel of the same strength, and the material costs only about one-quarter as much as cast iron. The labor charge involved in making a steel wheel is about one-third the cost of molding, casting, and machining wheels from wood or cast iron. On this basis, it is estimated that the cost of making wheels from sheet steel is about 29 per cent of the cost of iron wheels; and the steel wheels are superior on the basis of strength and durability. All the operations are performed on Bliss No. 20 power presses, with the exception of the ninth operation, which can be done on a No. 19 or a No. 18 press. The rate of output is 4800 blanks per day; and two operators can assemble 300 casters in eight hours.

Forging under the Power Press

Power presses are now finding application for the performance of certain hot-forging operations that were formerly done exclusively under drop-hammers. In some cases, this work has been developed along lines which provide for holding the dimensions of the forging within extremely close limits, so that the cost of performing machining operations is substantially reduced. Also, this is the means of effecting a substantial saving in material, which is especially important when a high-priced steel or other metal is being forged. Another advantage claimed for the pressing operation is that a refinement of the grain of the material is obtained by squeezing it while hot.

As an example of work of this kind, consider the forging of tool-steel blanks for end-mills, as shown in Fig. 4. This is done on a Bliss No. 75½ geared press which is capable of developing 100 tons pressure. The blank is forged within 1/16 inch of the desired size on all surfaces, and an experienced operator is able to produce 1200 forgings in an eight-hour day. It will be evident that with a forging having only 1/16 inch surplus metal on all surfaces, instead of a cylindrical blank cut from a tool-steel bar, the cost of producing a cutter will be greatly reduced. Of course, the exact ratio will vary according to the steel being handled, the size and form of the cutter, and other similar conditions.

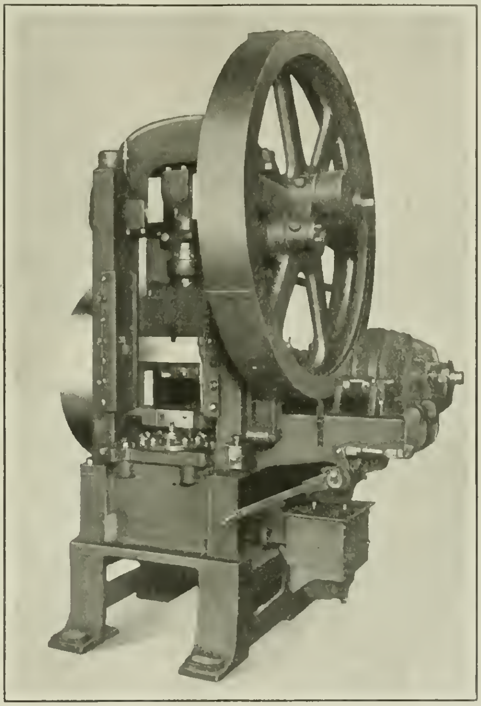

Fig. 5. Power Press with Dial Feed equipped for Broaching Operations on Bronze Bushings

Use of the Power Press for Broaching

Where broaching operations are to be performed on pieces of such a form that the broach need not be of considerable length, the power press may be utilized to advantage. The broach is pushed through the work instead of being pulled through as on a regular broaching machine. The chief advantage of the power press lies in the fact that for many classes of work it is possible to utilize a dial feed mechanism, thus greatly increasing the production.

Fig. 5 shows a Bliss press equipped for broaching bronze bushings 1 inch in diameter by 2 inches long. The press is run continuously, and the operator is merely required to take the cast blanks from the container in which they are delivered to the machine, and drop them into successive pockets of the dial. The dial carries the work around under a broach, which is stepped in such a way that the beginning of the broach roughs the outside diameter while the final teeth complete the broaching operation. The dial then carries the work around to a point where it is brought under a knock-out located above a chute under the hole in the dial. As the finished bushing is knocked out of the dial, it falls down the chute into a container beneath. On this job the rate of production is 18,000 broached bushings in an eight-hour day.

Making Pressed-steel Connecting-rods

It cannot be said that pressed steel connecting-rods are at present finding application as a substitute for machined forgings; but the possibilities of extending the range of the power press to cover this field, in order to take advantage of the economies that may be effected through the rapidity with which the work could be handled, are shown in Fig. 6. This illustration shows the steps in making connecting-rods from pressed steel. The body of the rod is made in halves, and the cap is produced in a single piece. Each of these parts is made under the press by three operations. After blanking, the body or cap is completely formed by the second operation, with the exception of trimming, which is done separately. It is not the intention to make comparisons between the relative merits of rods produced in accordance with standard practice and by this means of manufacture. However, there is no doubt that in so far as rates of production are concerned, the pressed steel parts can be produced at a much lower cost.

Forging Ends of Connecting-rod Bearings

When connecting-rod blanks are made from forgings, the usual procedure is to bore and face the holes for the crankpin and wrist-pin bearings. A variation from this procedure which reduces production costs, has recently been developed. It consists of performing a cold-forging operation on the blanks to make the bearing faces uniform, without the necessity of facing. By handling this work under the power press, it can be done at a lower cost. A press equipped for this operation has dies of the form shown in Fig. 8 with flat upper and lower members which engage the two sides of the crankpin or wrist-pin bearings on two forgings the one to the right only being shown in place; at the center of the dies there are two buttons over which the previously bored hole at the opposite end of the work is dropped prior to swinging each blank into place for the cold-forging operation. On this job the rate of production is 6000 rods in an eight-hour working day.

Cold-forging Parts of Instrument Mechanisms

In Fig. 9 are shown three examples of the successive steps in blanking and cold-forging parts of instrument mechanisms under the punch press, and a study of these examples will reveal the economies that are effected through the adoption of this method of manufacture. Obviously, there is no comparison between the cost of making these parts on the press, and turning blanks and then generating the teeth by hobbing or some other method. The dies in which this work is done are made with a sufficient degree of accuracy so that these instrument parts will possess the required degree of precision.

Little description is required to make the successive operations clear. In each case, there is a preliminary blanking operation, and this blank is worked through successive dies, until the work reaches the desired form. It is interesting to note in this connection the provision that has been made for producing the irregular forms. Take the case of the gear for which the sequence of operations is shown at the top of Fig. 9. To provide for forming the small dog on the hub of this gear, it will be seen that one tooth of the preliminary blank is made considerably larger than the rest, so that sufficient metal is left to give the desired formation. This principle is often employed and is one that will be found useful in handling many jobs of this kind. Formerly, composite parts of this kind had to be made in two separate pieces and riveted together. As compared with such a procedure, the economy of doing the job on the power press will be obvious.

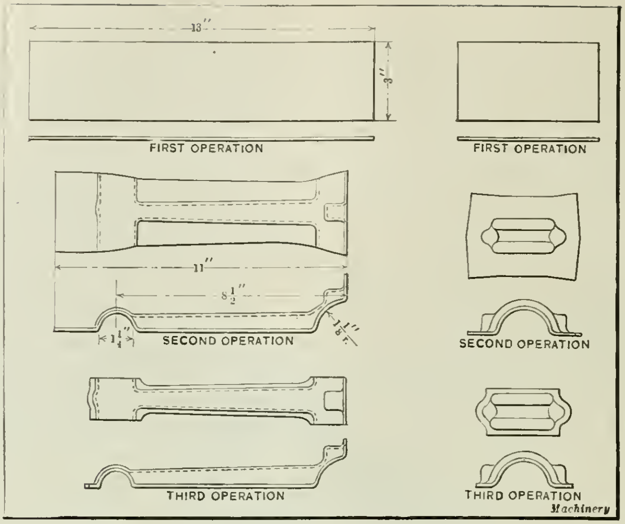

Fig. 6. Successive Steps in the Manufacture of Connecting-rods from Pressed Steel

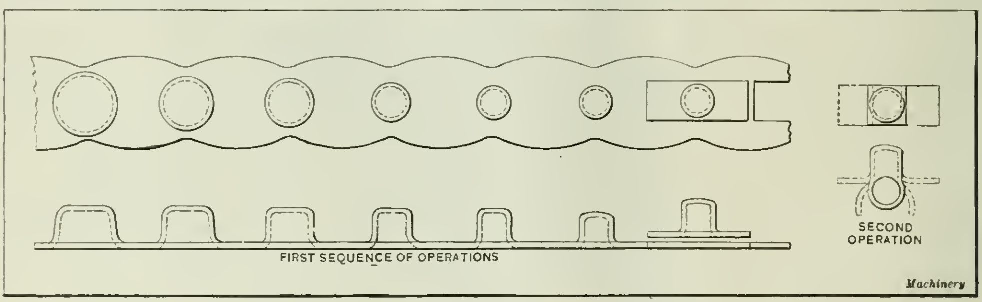

Fig. 7. Sequence of Drawing and Blanking Operations performed in a Follow-die to produce a Cam Pin Blank

Making "Whistler" Valve Cams

In the "Whistler" motor car tire valves made by the Automatic Products Corporation, Long Island City, N. Y., provision is made for setting the valve to hold a given air pressure. When this point is exceeded, the tire begins to blow off, and this is indicated by the whistling of the valve. Provision is made for setting the valve to hold 50, 60, 70, 80, or 90 pounds by means of a graduated cam of the form shown in Fig. 10. These cams were formerly made from brass tubing worked on an automatic screw machine, which graduated the cam with a rolling tool carried on the rear cross-slide and cut it off with a parting tool at the front of the machine. Then the pieces went to a special profile milling machine which cut the edge of the cam to the required contour. The production time was about seven seconds for the two operations, giving an output of 3840 per eight-hour day.

The preceding method of production was not entirely satisfactory, and the problem of making these parts under the power press was submitted to the Nelson Tool Co., of New York City. This concern developed dies for doing the work in two operations, as indicated in Fig. 10, and is now manufacturing these parts for the Automatic Products Corporation. At the first operation, the piece is blanked and graduated; and the blanks produced in this way then go to a curling die which folds them to the finished form, as indicated by the diagram for the second operation. It will be noted that the ends of the blanks are dovetailed, so that after they have been curled they are locked together. By the use of the power press on this job, the high rate of production of 32,000 cams per eight-hour day was attained.

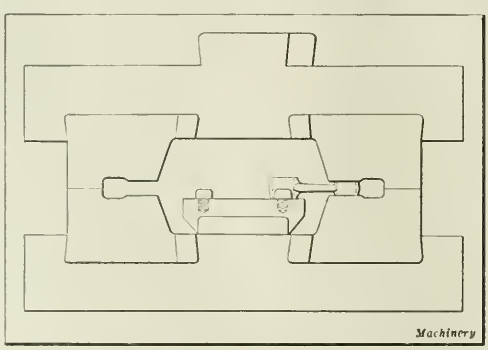

Fig. 8. Dies used for cold-forging Ends of Connecting-rod Bearings, instead of facing the Surfaces

Procedure Followed in Making Cam Pins

At the right-hand side of Fig. 7 is shown the cam pin which runs in contact with the cam of the "Whistler" valve. Formerly these pins were made from square brass bars worked in an automatic screw machine, and when handled in this manner the method of procedure was to turn the round trunnion and then cut off the blank in such a way that a square block was left behind the trunnion. In this condition, the work was sent to a special drilling fixture, which was provided for drilling a hole through the square block. Handled in this manner, the total time for the two operations was about five seconds, making the production 5760 per eight-hour day.

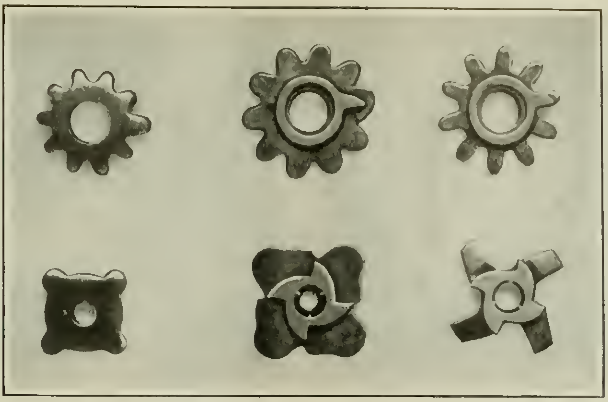

Fig. 9. Successive Steps in blanking and cold-forging Two Instrument Parts

This problem was also taken over by the Nelson Tool Co. The method of procedure finally worked out consists of running brass ribbon stock through a follow-die, which performs six successive drawing operations, and then shears out the blank as indicated by the diagram for the first sequence of operations. The blanks produced in this manner are then sent to a curling die which rolls up the flat ears at each side of the shell that forms the cam trunnion, to produce the bearing that was formerly made for drilling a hole through the square block. On this operation, the rate of output is 500 cam pins per hour for the two operations, making the daily production 4000 in eight hours.

REMOVING DENTS FROM METALLIC SHELLS

By FRANK E. CHACE

In manufacturing articles in the form of thin metallic shells or tubing, great care in handling is required to prevent denting the surface of the work. Even when special care is taken, dents are often made, and the loss from this cause may be considerable, especially if the material is expensive or the work near completion. Therefore, attempts are often made to repair such work in order to make it salable. The methods described in the following for removing dents from metallic shells are interesting, because they are out of the ordinary and are not met with in regular lines of manufacture.

If the shell has an opening at one side, large enough to permit a suitable tool to enter, the dent can sometimes be removed by placing the end of the tool on the bent-in portion and driving outward. If the work to be repaired is a cylindrical tube, a sizing plug may be entered to force the metal outward. If the shell is thin and spherical in shape, with an opening small enough to be plugged, it may sometimes be repaired by first filling with water and then plugging the hole, and lightly tapping the outer edge of the dent with a wooden mallet. By keeping the opening tightly sealed, and allowing no air space in the shell, the blows struck with the mallet will compress the liquid and force the center of the depressed metal outward. This method of procedure, of course, is applicable only when thin metal is being handled.

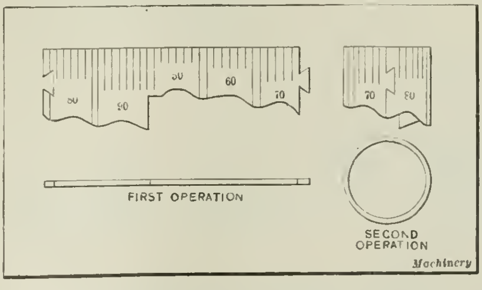

Fig. 10. Blank and Finished Cam for a "Whistler" Tire Valve, produced in Two Operations under the Power Press

The following is a method of forcing out a dent in a shell having a small mouth or opening. This method utilizes the expansive properties of melting rosin. The first step is to fill the shell with melted rosin. As the rosin cools it contracts greatly, and while it is cooling and contracting, more rosin is added so that when it is thoroughly cooled the rosin entirely fills the interior of the shell. When entirely cooled, a hot flame from a blowtorch is applied directly on the depression which it is desired to lift. The rosin beneath the depression will soften and expand, thus lifting the metal upward. Care must be used to apply the heat quickly to the proper spot and keep the other parts cool. The pent up forces are tremendous, however, and if too much heat is applied, an accident may result.

If there is no means of working from within a shell, a wire nail having a large head may be soft-soldered by its head to the surface of the depression. This nail can then be grasped with vise jaws or strong pincers and the metal pulled outward. Still another method of eliminating dents that can sometimes be used to good advantage is to grip at one end, in a bench vise, a round iron or steel rod, several feet long. The length of the rod must be in such proportion to its diameter that it will vibrate or spring vigorously when struck with a hammer. Too large or too short a rod will be too stiff. Too small or too long a rod will be too weak, and will therefore be bent. When the rod is struck a sharp downward tap or blow with a hammer, at a point near the middle, but on the side toward the vise, a vigorous upward "kick" is given by the free end.

A small portion of the free end should be bent at right angles to the rod, and when in position for use this short end should project upward. Two operators may be required to use this device. One operator inserts the rod end into the mouth or open side of the shell, resting the depressed spot upon and directly over the upward projection of the rod end. Another man strikes a sharp blow downward at a spot on the rod between its center and the end gripped by the vise. A vigorous "kick" results, and the metal is driven upward at the free end of the rod.

In some of these methods, when driving outward from within, the metal may of course be driven too far, but since the hump is then on the outside, it is an easy matter to tap it back into place with a mallet, or force it back by other means until the desired contour is produced. Filing or buffing and polishing will hide the lesser tool marks.

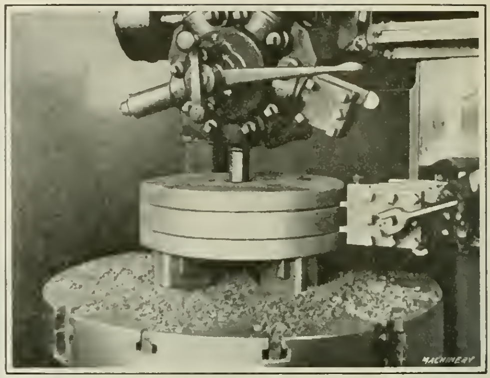

Fig. 2. Piston-ring Groove Turning Operation, in which Two Tools are used in the Side-head Turret

Production Work in the Locomotive Shop

Application of the Bullard Vertical Turret Lathe to Locomotive Shop Practice, with Typical Examples and a Description of the Tooling for Each Job—First of Two Articles

The high cost of production in railroad shops has been the subject of many comments in both the daily and the technical press, in public speeches, and in governmental reports. Costs can be reduced in railroad shops in three ways—by capable management; by the efficiency of labor; and by the employment of labor-saving and cost-reducing machines and methods. The present article deals with the last phase, and shows a number of examples of economical production by the use of the vertical turret lathe in combination with carefully laid out tooling equipments.

THE machining of piston-heads and piston-rings is a common job in the locomotive machine shop. The piston-head machining lay-out shown in Fig. 3 is a typical one for this class of work. It will be seen that this piston-head has a tapered hole for the piston-rod, so that in machining it, a method is involved which is commonly employed when tapered holes are finished on the Bullard vertical turret lathe. Also, it will be seen that this hole is counterbored on the under side, and that special means have been provided in chucking the work to enable this recess to be machined without the necessity of rechucking it. The piston-head is machined complete in five operations, and is chucked by employing special jaws *A* in which there is a stud that enters the hole on the under side of the work. This arrangement furnishes a positive drive, holds the work securely, and allows plenty of clearance space for the boring-bar that was used in the under-cutting operation, previously referred to

Machining Operations on Piston-heads

In the first operation, a tool of special form is employed to face the raised surface surrounding the tapered hole and the remaining end surface of the piston-head. During this operation, the outside diameter is rough-turned by a tool carried in the side-head turret. The second operation is that of rough-boring the tapered

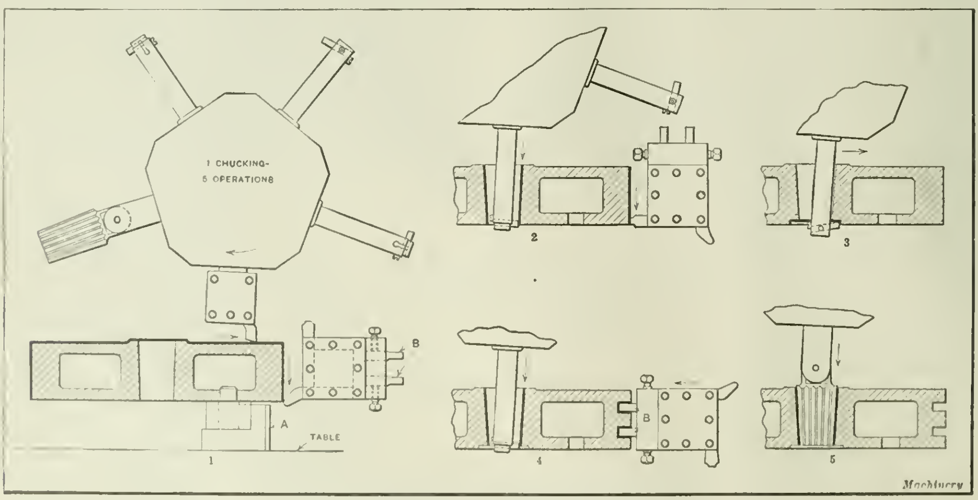

Fig. 3. Tooling Lay-out for a Locomotive Piston-head

hole while another tool in the side-head turret is finish-turning the diameter. It will be noticed that the main turret is set at an angle corresponding with that of the taper of the hole, and that the turret occupies this angular position throughout the sequence of machining operations.

In the third of the series of operations, the under-cut on the lower side of the piston is machined as indicated in the tooling lay-out, using a boring-bar in the main turret. The next operation is that of tru-

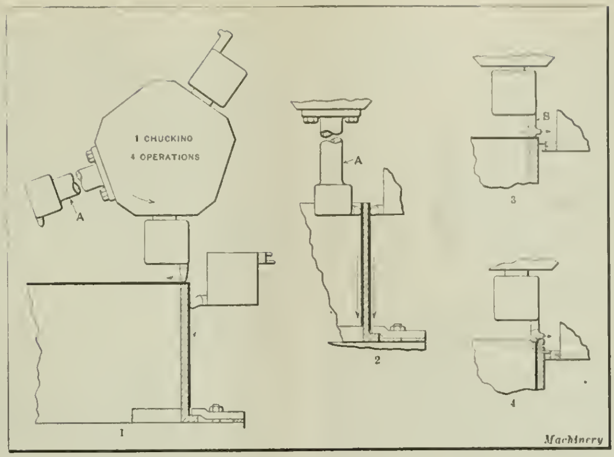

Fig. 4. Sequence of Operations and Tooling Arrangement for producing Piston-rings from a Pot Casting

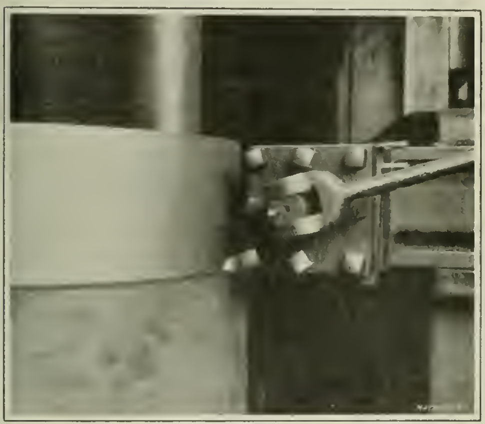

Fig. 5. Close-up View of the Second Operation in machining the Piston-ring Casting illustrated diagrammatically in Fig. 4

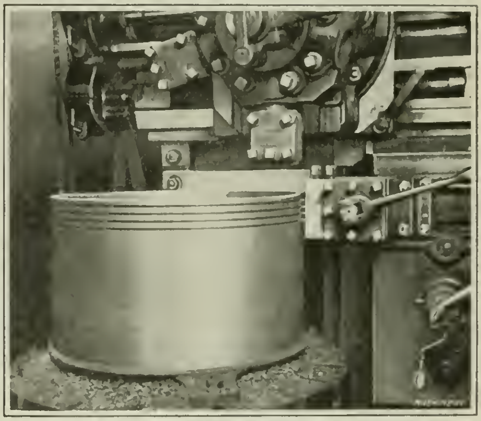

Fig. 6. Using the Set-up illustrated in Fig. 7 for cutting off Piston-rings with a Gang of Parting Tools

ing up the tapered hole, and for this a separate boring-bar is employed. During the truing cut, two tools *B*, carried in a special tool - holder attached to the side-head turret, are engaged in machining the piston-ring grooves.

For the final operation, a floating reamer peculiar to this type of machine is employed. This floating or hinged reamer hangs vertically downward from the shank to which it is pinned, and by its use the resetting of the main turret, which would be required with an ordinary reamer, is unnecessary. In this operation, the previously bored hole is finished. This piston-head is 23 inches in diameter, and the machining time required to complete the series of operations is forty-eight minutes per piston-head, including chucking work.

Figs. 1 and 2 illustrate two of the machining operations on the piston-head. In Fig. 1 the outside of the piston is being rough-turned, while Fig. 2 shows the fourth operation, in which the piston-ring grooves are machined, and the central hole is trued up, simultaneously. These illustrations also show how the work has been raised by the use of special chucking jaws. There is one other detail in the tooling arrangement which might be of interest; that is, the use of a tool in every face of the turret, rather than the use of combination tools, such as a special multi-cutter, boring-bars, and tool-holders, which are often used when conditions require it. In this case, however, the use of a separate bar in each station is an advantage in that the tur-

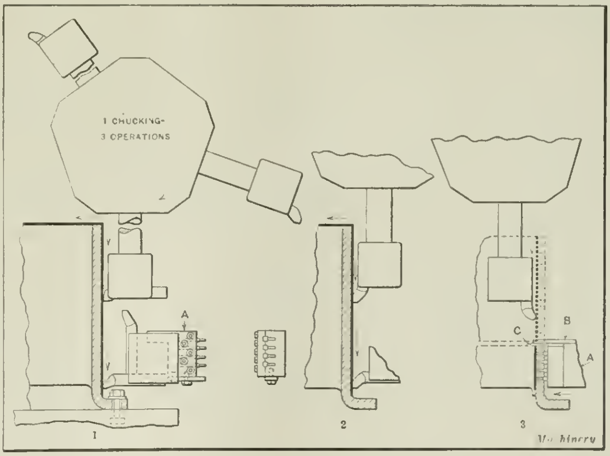

Fig. 7. Tooling Arrangement in which the Piston-rings are cut off with Multiple Tools carried in a Special Holder in the Side-head Turret

ret is thus better balanced. This piston job is fairly representative of work of this kind, and should enable a good idea to be obtained of the adaptability of the vertical type of turret lathe for finishing locomotive piston-heads.

Machining Piston-rings

The machining of piston-rings is a job which may be tooled up in a variety of ways, according to the conception of the set-up man for obtaining the best results. Fig. 4 illustrates one tooling arrangement used. In this instance, the pot casting from which the piston-rings are produced is clamped by suitable straps and jaws to the machine table, and is machined in four operations as follows:

The end of the casting is first rough-faced, and the exterior rough-turned; in the second operation, the tool carried in the extension tool-holder *A* rough-machines the inside of the casting while the exterior is being finish-turned by a tool carried in the side-head turret. A special tool *B* is employed in the third operation, first to finish-face the end of the casting, and then to break down the interior edge. The same tool is employed in the fourth operation, in which the casting is finish-bored. While the finish-boring operation is in progress, two parting tools, carried in the side-head turret, are engaged in cutting off the rings. The parting tools are fed in to a sufficient depth so that as the finish-turning tool feeds down, the rings will be severed. By using only two parting tools, instead of a gang, as is sometimes done, a better job results, because the rings do not have to be faced after being cut off.

Fig. 5 is a close-up view showing the second operation on the piston-ring job. These pot castings are approximately 24 inches in diameter and 16 inches high. The table speed used in producing these rings was 7 revolutions per minute, and the feed 1/32 inch per revolution. The time required to machine this casting and cut up twenty-two completely finished piston-rings was six hours and fifteen minutes.

Another piston-ring job is shown in Fig. 7, and as the illustration shows, three operations complete the job. These piston-ring castings are cut up into sixteen complete finished rings, the tooling arrangement being somewhat different from that described in connection with Fig. 4. The exterior of the casting is rough- and finish-turned by using two tools simultaneously, one carried in the main turret and one in the side-head turret. These are clearly indicated in the first and second operations. The tool carried in the main turret, in each of these two operations, also machines the top of the casting, as indicated by the arrow. In the final operation, use is made of a gang of parting tools, carried in a multiple holder *A*. The proper vertical position of these multiple tools is obtained by the use of a parallel *B* and a size block *C*. It is necessary to employ this means of adjusting the parting tools after each feeding-in traverse of the tools has been completed. Fig. 6 is a view of the beginning of the cutting-off operation, and gives an excellent idea of the appearance of the work and the tools. The time required to produce these sixteen rings is from two to two and one-half hours.

Machining Locomotive Cylinder Heads

A job on which the vertical turret lathe is used to good advantage is that of finishing locomotive cylinder heads. In the illustration Fig. 8, a complete tooling lay-out is shown of both chuckings required to finish this casting. Special sawtooth jaws, by means of which the work is chucked in the first setting, prevent the cylinder head from lifting from its seat on the locating buttons on which it rests.

The first operation of the first chucking is shown in Fig. 9, as well as the complete turret tooling employed. This

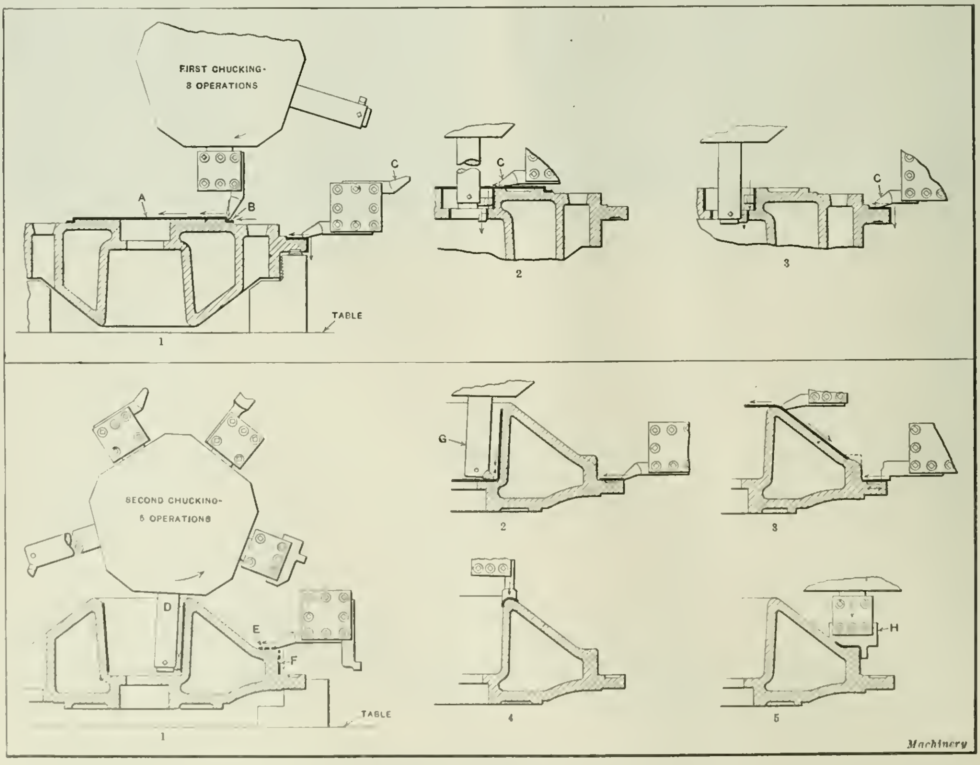

Fig. 8. Tooling Arrangement used in the Two Machine Set-ups shown in Figs. 9 and 10 for machining a Locomotive Cylinder Head

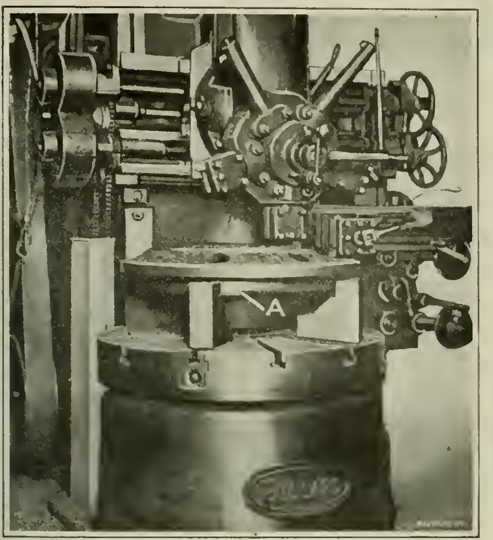

Fig. 9. First Operation on the Locomotive Cylinder Head

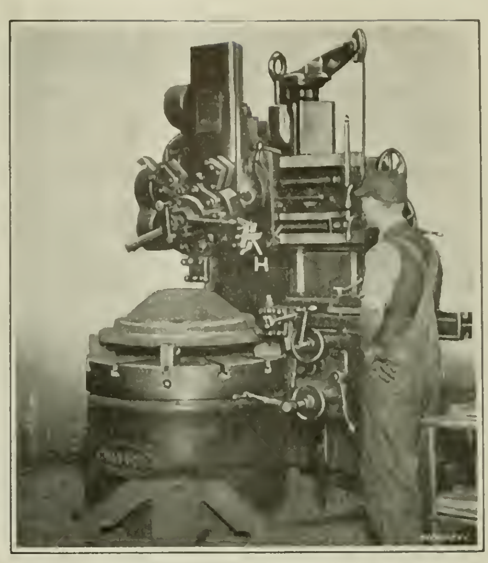

Fig. 10. Fourth Operation on Opposite Side of Cylinder Head

operation consists of rough-facing surfaces *A* and *B*, Fig. 8, and rough-turning the shoulder connecting these two surfaces with a tool carried in the main turret tool-holder, and rough-facing and rough-turning the flange with a tool in the side-head turret. In the second operation, surfaces *A* and *B* and the connecting shoulder are finished with tool *C* in the side-head turret; at the same time the special boring-bar carried in the main turret is employed to rough-bore the two diameters of the central hole, as indicated by the arrows. The last operation in the first chucking finishes the central hole in the work, a finishing cutter being substituted for the roughing cutter, while the flange is simultaneously finish-faced and turned, still using tool *C* in the side-head turret.

In the second chucking, there are five machining operations on the other side of the cylinder head, as shown, the first of which is the rough-boring of hole *D* while surfaces *E* and *F* are rough-turned with the side-head turret tool. The central hole is next finish-turned and cleaned up on the bottom with a special tool carried in the boring-bar *G*. While this tool is in operation, the upper surface of the flange is rough-faced with a side-head turret tool, as shown. In the third operation, both turrets are simultaneously engaged to machine the angular exterior surface of the cylinder head and to finish-face the flange. The fourth operation is that of forming the radius connecting the hole and the angular exterior surface, using a special formed turning tool in the main turret tool-holder. As indicated by the dotted line in the sectional view of the work shown in the diagram of the first operation in the second chucking lay-out, and as also clearly shown at *A*, Fig. 9, there is a built-up section or lug, extending about two-thirds around the circumference at the lower part of the angular surface, which must be machined. In the last operation on the cylinder head, a special form cutter *H* (shown also in Fig. 10) is required to finish this lug and cause it to blend nicely with the adjacent surfaces. This completes the machining of the cylinder head, the approximate diameter of which is 36 inches. The production time on this job is four hours—one hour for the first chucking, and three hours for the second.

In the second and concluding installment of this article the tooling up for machining cross-heads and main throttle valves will be dealt with.

CONVENTION OF THE SOCIETY FOR STEEL TREATING

At the convention of the American Society for Steel Treating held in Indianapolis September 19 to 24, a great number of papers relating to all phases of steel treating were read. The papers were grouped under special sections covering tool steel, metallographic research, heat-treatment of steel, carburizing, management, alloy steel, properties of carbon and alloy steels, heat-treating equipment, and furnaces. Under the heading of tool steel the papers read dealt with tool steel specifications; forged high-speed milling cutters; physical tests on high-speed steel; providing properly rolled tool steel for the steel treater; tool steel manipulation; heat-treatment and uses of high-speed steel; a comparison of American and English methods of producing high-grade crucible steels; and the effect of tungsten content on the specific gravity of high-speed steel. The papers on the heat-treatment of steel dealt with modern methods of heat-treating; the efficiency of annealing overstrained steel; coarse-grained forgings, their detection and correction; the problem of the influence of mass on heat-treatment; the whys of warping; malleable iron; theory of hardening steel; tests showing the effect of high temperatures on malleable iron; a coiling and heat-treating plant for helical springs; fracture test on steel to determine its quality; and "Dow-metal," and its application. A complete list of all the papers and copies of such papers as may be desired may be obtained from the secretary of the American Society for Steel Treating, 4600 Prospect Ave., Cleveland, Ohio.

The following officers were elected for the coming year: F. P. Gilligan, president; F. C. Lau, first vice-president; R. J. Allen, second vice-president; and J. V. Emmons, treasurer. A. E. White, the retiring president, was elected a member of the board of directors, as was also J. J. Crowe. During the year just passed the society has had a satisfactory growth. Today the membership is 3200, a substantial increase over a year ago.

SAVINGS BY THE USE OF JIGS

In these days of interchangeable manufacture, when machines or parts are made in great quantities, jigs and fixtures are universally employed. In the machine tool industry where machines are built in smaller lots, special tools and fixtures are not always warranted, but they could be employed to a greater extent than is usual; and it has been shown in many cases that this would prove economical. The great expense of a complete tooling equipment acts as a deterrent, and many operations are performed year after year in a relatively wasteful way because of the fear of a large original outlay.

One machine tool builder has used the present slackness in business to make a thorough study of his manufacturing methods and to provide special tools, jigs and fixtures wherever it seemed profitable to do so. He has not hesitated to make the necessary investment, even during this period of depression. On one of his machines alone he has reduced the time required in the assembling department from 47 hours to 12 hours by making parts strictly interchangeable through the use of jigs and fixtures, and in addition the machining time has been reduced from 300 hours to 250 hours.

In this case there is a gain of 85 hours on each machine. Figuring at $1.50 an hour, including overhead, the total saving per machine is $127.50, which is a little more than 6 per cent interest on an investment of $2000. Assuming that 50 machines a year of this size were built, it will be seen that an investment of $100,000 might be warranted in jigs and fixtures, if an interest of 6⅜ per cent were considered sufficient and depreciation were not taken into account, as, of course, it would have to be. The tooling equipment for a single machine would seldom be as high as this, the figures being given merely to show that quite a large investment is warranted where an appreciable number of working hours can be saved on each machine.

It is necessary in each case to make an estimate of the number of machines likely to be built annually, the saving that can be effected by the use of jigs and fixtures, the cost of such equipment, and how soon it is likely to become obsolete, before going ahead with the design and building of special tools. It is true that serious mistakes have been made in overdoing special tooling equipments, and in every case a decision must be based on a careful consideration of all the factors involved. But no manufacturer can lose anything today by studying every detail of production in order to reduce costs.

* * *

IMPORTANCE OF SHOP TRANSPORTATION

The problem of transporting materials within the shop is more important than many executives realize. It is expensive to move heavy materials to and fro in a shop, particularly when they have to be lifted by elevators from one floor to another, or transported long distances either by hand or electric truck.

Any plant of appreciable size should be so laid out that the material can move in a continuous route from the receiving to the shipping department. If no consideration is given to the movement of material through the plant, it is likely that routes will gradually develop by which thousands of dollars will be lost annually for trucking and transporting expense. The executive of a large concern was recently asked to help in the reorganization of another plant employing about 3000 hands, and the first thing he called for was a blueprint of the whole lay-out of the plant on which was shown by a red line the route of an average part from the moment it entered the receiving room until it reached the shipping room as part of a completed machine. The blueprint he obtained showed that the part selected for the test had traveled 4½ miles during its course through the shop and crossed its own path forty times.

In another case it was found that in a five-story shop, certain castings went up and down the elevators twelve times, traveling three times from the basement to the top floor. By rearranging the machinery it was necessary to lift these castings by elevators only once from the basement to the top floor, from which they descended by gravity conveyors from floor to floor, as required.

A third example shows that the product of one plant was doubled without adding a single man to the force for trucking and moving materials, simply by systematizing the shop arrangement and the moving methods. In this plant it was found that one part moved nine times from one building to another before its completion.

In one large factory a distinction is made between short hauls and long hauls, and methods have been developed which meet the requirements in each case. For the short haul—that is, movements within the same department—casters are placed under the platform on which the material is moved, so that it can be rolled from one part of the floor to another. Electric trucks are used for the long hauls from one department or one building to another. These trucks are so arranged that platforms provided with casters as previously mentioned can slide directly on the truck, which, being electrically operated, is then quickly moved to its destination. A careful examination of the routes of material in your plant may develop some worthwhile economies.

* * *

UNNECESSARY LOSS OF POWER

To attain maximum economy in the operation of a shop or factory, it is of importance to maintain accurate alignment of the lineshaft bearings. Many manufacturers have their lineshaft bearings lined up at regular intervals, thereby keeping the friction load as low as possible; but this practice is not general, mainly because the amount of power wasted through inaccurate alignment of the bearings is not realized and because tests to show the actual loss are expensive and difficult to make.

In a few instances where such tests have been made, the value of periodically lining up the bearings has been conclusively proved. Needless to say, the alignment of lineshaft bearings should be undertaken only under the supervision of a man experienced in this kind of work. Whenever possible, the power required to drive the shafting under the friction load before and after re-alignment should be determined as accurately as possible. When bearings which are badly out of line have been re-aligned, it is found that the saving in power is quite considerable throughout the year. It is the attention to details like this that often makes it possible to show a favorable balance at the end of the year. It is not only the big savings that count, but the aggregate of the smaller economies; and power, after all, is not one of the minor items of the cost of running a manufacturing plant.

Reducing Production Costs

Through More Efficient Equipment and Methods

PRICES have come down on practically every article produced directly or indirectly by means of machine tools—from automobiles to lawn mowers. Costs must follow until a balance of costs and prices is reached. The tides that rise regardless of the marooned are not more certain or indifferent in their destructive power than this law of business which destroys those who are unable to adjust themselves to its reactions.

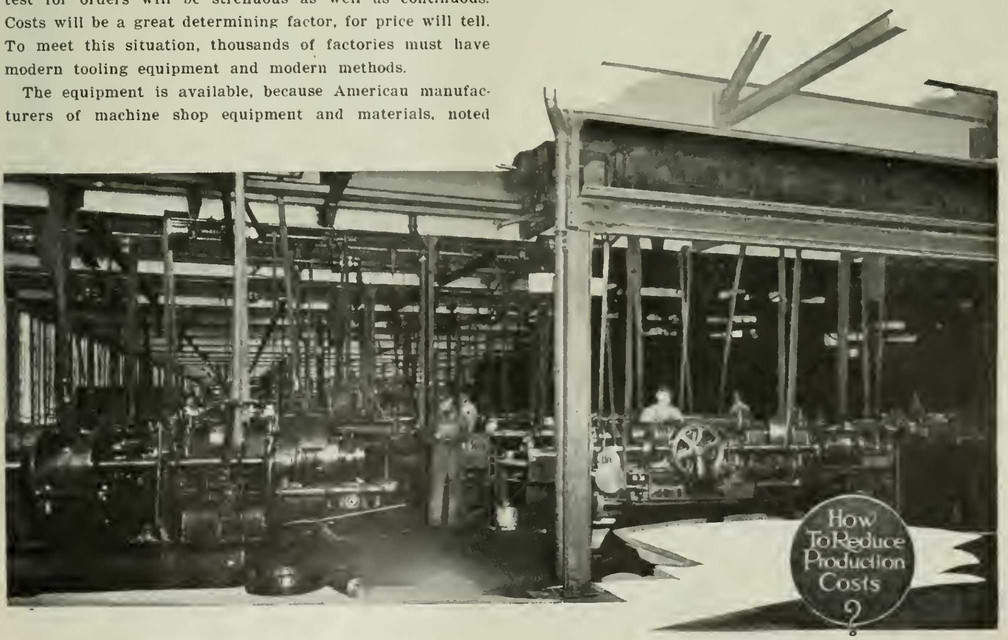
Cost reductions will come partly through more systematic and efficient management and reductions in wages; but in the field of metal-working manufacture, at least, they must come chiefly through more efficient manufacturing methods, through the use of up-to-date cost-reducing machines, tools and tooling equipment, through modern means for handling material in the plant, through using the divers time- and labor-saving methods and devices which characterize the most efficient practice. These cost reductions cannot be made with equipment that was all right a few years ago. The changes have been great as well as swift. There are new methods, devices and facilities. The pace is faster. Results are totally different from what were considered good only six years ago.

Hundreds of metal-working shops throughout the country are badly handicapped with equipment and methods which should have been discarded long ago. These factories will have to re-equip with more efficient tools and will have to bring their practice up to date. Economic law is a great steam roller. Under its cold, incessant and remorseless operation, the able and enterprising thrive and the others fail. We are in a new period of searching test—a buyer's market—with the buyers still very scarce. The contest for orders will be strenuous as well as continuous. Costs will be a great determining factor, for price will tell. To meet this situation, thousands of factories must have modern tooling equipment and modern methods.

The equipment is available, because American manufacturers of machine shop equipment and materials, noted always for inventive genius and progressiveness, made great practical use of the severe but invaluable lessons they learned in the strenuous war period, when production was the first consideration. They are ready with tools and devices capable of reducing production costs to a point hardly believed possible a few years ago. They have worked out important changes and improvements which are incorporated in the metal-working equipment now on the market.

Exhortation to reduce costs is timely and valuable, but it is better still to show the way. MACHINERY is endeavoring to do this, and in four numbers, of which this is the first, this journal is concentrating on specific descriptions of existing methods, machines, systems, tooling equipments, etc., that make definitely for economy in production. The data covered in this number and in the succeeding issues represent practical results achieved in leading shops throughout the country. Machine tool manufacturers, with their well-equipped plants and capable organizations, will be able to reproduce in any plant the unusual results recorded in these numbers of the Cut-the-Cost series.

Periods of depression like periods of prosperity are never static. The world is ever moving, and is now moving toward business recovery. This is a great and vital period of preparation. The factories best equipped when business is going well again will gain an advance over competitors. Forward-looking manufacturers are reducing their costs. There has been, very naturally, hesitation and indecision, but now the time is ripe for active preparation. The plant in need of new equipment for reducing manufacturing costs cannot afford to delay. It is a buyer's market.



The Foreign Situation and the Machine Tool Industry

By JOSEPH KUCERA

The author of this article left for Europe early in 1919 and studied economic conditions there for over two years, paying special attention to the conditions in the machinery trade and the demand for machine tools and industrial machinery in general. After having visited twelve different countries for this purpose, he returned to the United States in the spring of this year. He went to Russia in August, 1920, and left there in December of the same year, after having visited both Moscow and Petrograd. Mr. Kucera is well acquainted with the machine and tool fields, having been connected in an executive capacity with several tool and gage concerns in New York City since the outbreak of the war in 1914.

UPON my return from Europe, I found that many machine manufacturers failed to grasp the international situation, which has a direct bearing on business conditions here. Most manufacturers, referring to the present industrial crisis, made various predictions as to its duration; these predictions, however, were based on their experience with the preceding depressions of 1908 and 1914. That was six months ago. Since then, because we have had time to study the international market, we have come to realize that our industries, being partly dependent on the prosperity of the industries in Europe, cannot expect to revive fully until the old world places her factories on a pre-war footing, at least. Had we done nothing else but study the international markets for the last few months, it would have been worth while. An optimist may even go so far as to claim that the industrial depression was the best thing that could have happened to us, since it made our study of international markets compulsory, thereby fitting us to cope successfully with a situation which we shall have to face in the near future.

There are still some manufacturers in the machinery line who hold the pessimistic view that their business will be the last to come back to a state of prosperity. They claim that other industries will be able to run with their present equipment for a long time to come, keeping the machinery, particularly the machine tool demand, at a minimum for a long period. These men, fortunately, are becoming less in number, for our compulsory international education makes new graduates every day.

German Competition and Credits

So much for the general conception of the present outlook. When we consider details, from a pure business standpoint, another pessimistic argument comes up, as follows: Germany, because of money exchange in her favor, is capturing all the European machine tool markets. But the fact is that Germany is not doing this. True enough, we have evidence of Germany exporting machine tools to other countries at prices far below our competitive capacity. She can well afford it, since her labor cost is only one-sixth of ours. But there is one thing that Germany cannot afford to do, and that is to grant credit, which means that she is not in a position to supply the demand. Therefore, the German export of machine tools will meet a very small percentage of the demand, and will remain at this point for many years to come.

Long-term credits on a large scale are necessary for the rehabilitation of Europe. Only the big financial interests of the United States can and will extend these credits, since non-productive Europe means the ruin of many industries in America. As a common-sense business principle, this credit will not be advanced to a competitor—in this case Germany. The credits will go to consuming nations, excluding Germany as the intermediary that she was before the war, if for no other reason than that the present limited purchasing capacity of Europe cannot afford to have business pass through so many hands.

Personal investigators and statistics may prove that Europe is not in great need of machine tools—that prior to these she wants raw materials to put idle machinery into motion. That is true enough; yet Europe is coming to realize that her economical rehabilitation does not depend only on resuming pre-war production, but on producing far in excess of that, not only in order to pay her debts, but also to regain her pre-war living standards, poor as they were compared to the standards in the United States. And to attain this end will require the Americanization of production, with American machine tools to begin with.

Russia as a Potential Market

Even though Europe were satisfied to retain her present economic standards, and not become the eager customer for our machine tools that we expect, there is still one country that cannot get along without our machines, and that is Russia. Russia needs everything, but particularly machinery of every description, including machine tools. She will be able to get along for a few more years with her old clothes and to live on small rations; but she must have railroad equipment, locomotives, mining machinery, and machine tools to begin with, if she expects any credit from the United States at all.

Russia is richer in natural resources than the United States. Considering this as an asset, we might say that Russia is the only solvent country in Europe. Yet she must go into the hands of a receiver if machinery is not put into motion to exploit her wealth immediately, for her wealth is worthless unless it is turned into products. Directing the export of our foodstuffs and clothing into Russia, without at the same time providing the country with the machinery of production, would be equivalent to giving credit to a concern in the receiver's hands. It cannot be done.

For the time being we may discard our worries in regard to political complications. Even though Russia remains under the present régime we shall, nevertheless, finally be obliged to do business with her. If she should abolish her present system of government before we entered into commercial relations with her, the international economic situation would remain very much the same as it is today. However, since we are considering political eventualities, suppose that the present régime were overthrown some time after we had begun to do business with Russia. It might be thought that if the Bolsheviki were overthrown a new destructive struggle would arise in Russia. People well informed on the Russian situation, however, are convinced that the Bolsheviki are too exhausted for any formidable struggle in the event of their overthrow by the Russian people. In such a case trade with the United States would go on as usual, and the economic life would not be deranged any more than by a change of cabinets in other countries.

Germany cannot reconstruct Russia. It will be done by the only nation today capable of a work of such magnitude —the United States. Germany and other countries in Europe have been doing business with Russia for over a year, yet Russia is still sending calls of distress for everything necessary to save a sinking nation from complete economic shipwreck. Why have Germany and these other nations not exported to Russia at least enough to keep the wealthiest country in Europe from appealing at this hour for help to save it from destruction by famine? Because Russia needs credit, which no other country but America can afford to give her.

Conditions in Russian Industries

During my stay in Russia in 1920, I visited a great many factories. In the clothing industry, I saw people doing the work in their homes, sewing entirely by hand, and this was being done even in the garment factories, while many sewing machines stood idle. One of these machines, I observed, was in perfect order, except for the flywheel bracket. Bringing this to the attention of the superintendent, I expressed amazement at the piece of cast iron not being replaced, so that the machine could take the place of a few of the hand workers. "I know," he replied instantly, "but where will we get the cast iron?" This is typical of the situation throughout all the Russian industries—where to get the cast iron—while there is enough of it in Russia to supply half the world.

In a machine shop in Moscow, equipped to employ several hundred men, I saw an engine lathe idle because it had no apron. The foreman stated that it had been taken off because it contained a pinion that was needed elsewhere. I saw rust eating away a shaper—one of those heavy European imitations of an American machine—apparently for no other reason than that a gib, which presumably was taken to be used on another machine, was missing. I could give endless examples of instances in which machine tools are idle and useless, and becoming fit for nothing but scrap, simply because the Russian workmen have no more mental or physical energy left to think out a way of making at least one working shaper out of several of similar make.

The same conditions prevail in the textile industry—in fact, everywhere in Russia where a wheel used to turn. Imagination is not sufficient to picture the industrial breakdown of Russia. I had to see it with my own eyes—machines without gears, gears without teeth, a huge scrap heap. Germany and other European countries have been selling agricultural machinery, motor trucks, and other machinery to Russia for some time past. These, of course, have all been spot cash transactions, mostly in gold. Today Russia's ready gold is exhausted, and she has nothing in the line of raw materials to offer. Therefore, it is left entirely to the United States to put the Russian industrial scrap heap on a productive basis, and in this task the American machine tool will play the most important part.

Pre-war Trade Channels

Russia's total exports in 1913 exceeded her imports by 240,100,000 rubles (gold). Her imports from Germany alone, however, exceeded her exports to that country by 190,100,000 rubles, while her exports to all countries except Germany exceeded her imports by 430,200,000 rubles. These figures prove clearly how Germany made other countries pay for her business in Russia, particularly for German machines, since machinery and manufactured goods formed the bulk of the Russian purchases abroad, while her exports consisted chiefly of foodstuffs and raw materials. In the past Germany was practically the exclusive agent for American machine tools on the continent, and it goes without saying that she naturally discouraged the purchase of American goods for the sake of stimulating her own production. In Russia, a German concern acting as agent for an American manufacturer charged $1350 for an engine lathe bought for $600 F. O. B. New York.

Credits the Chief Problem

As the situation in Russia stands at present, it will require untold millions to meet the country's needs in machinery alone. Even assuming that western Europe is capable of supplying half the requirements, there will still be a market for large quantities of machinery from the United States, and this source of supply will be drawn upon in preference to any other, because the United States will extend credits. In mentioning credit to Europe or Russia in these days, it does not mean that any individual manufacturer or group of manufacturers is expected to advance credit, as has been customary in the past. It is being generally appreciated that our economic problems of today are a part of the problems of the whole economic structure of the world, and cannot be solved by any group of industrial or financial organizations alone. The solution lies in concerted action, and arrangements are already being made to approach this difficult subject.

The best proof of European inability to extend long credits to Russia today is the attempt made to solve the Russian economic problem by barter, which amounts to an exchange of goods or raw materials in kind—in other words almost a cash transaction. In Sweden, corporations with two hundred million dollars capital have combined for the explicit purpose of doing business with Russia on the barter basis, and no doubt other countries will follow Sweden's example, especially now since many of them have already had experience in business by barter. There is no doubt that the United States will launch much of her international business on a bartering basis. Of course, barter is only resorted to in this emergency because the trust in the capability of certain countries of meeting bills has been shaken, and as soon as positive signs of the restoration of an economic balance are in sight, it will be abandoned. In the meantime, in order to facilitate the economic regeneration of the world, the industries will have to draw on the capital that is left, and that is concentrated in the United States. This country cannot escape from extending credits; otherwise, our industries will have to run at a low capacity. And it takes machine tools to act as an insurance on this credit—to facilitate quick payments on the money advanced. It takes production to pay the debts, for no one will advance money to an idler; yet Russia cannot begin to produce until she is fitted out with machinery. It is a problem of vast proportions, and one not easily solved; but it will do a great deal of good to begin thinking about it.

* * *

FRENCH BUREAU OF INDUSTRIAL AND SCIENTIFIC RESEARCH

During the war France mobilized her scientists and laboratories into a Bureau of Industrial and Scientific Research and of Inventions. The French Government has decided to maintain the existing organization, and to adapt it to the needs of peace. It works in conjunction with both public and private laboratories, and encourages inventors, assisting them to turn their often vague and impractical ideas into concrete and useful form. Proposals of inventors are first brought before a committee which eliminates Utopian ideas and those without practical value. The promising projects are referred to competent technical committees, who get in touch with the inventor, aid him in his research, assist him in making models, guide him to a definite embodiment of his conception, and, in some cases, point out to him practical applications that he has not previously thought of. Since 1919 more than 500 proposals have been considered.

Another phase of the work is the assisting of scientists who have a valuable idea, but lack material, apparatus, or other means to conduct experiments, until it is embodied in a practical application. The bureau is also ready to assist the industries, and a constantly increasing number of managers of industrial concerns are submitting problems.

New Type of Thread Gages

An Accurate Method of Determining the Correctness of Screw Threads by Vision as Well as by Touch

By B. M. W. HANSON, President, Hanson-Whitney Machine Co., Hartford, Conn.

Fig. 1. New Type Thread Gage with U. S. Form of Thread

THERE are four dimensions that are important in the making of a good screw: First, the lead; second, the diameters on the top, at the pitch line, and at the bottom of the thread; third, the shape or angle of the thread; and fourth, the roundness and parallelism of the screw. All these dimensions can be determined by separate gages used by a skillful operator, and when accurate work is required, the inspection of all these dimensions becomes expensive and tedious.

The common practice of gaging screws, as is well known, is to use a thread gage composed of a tapped hole, sometimes solid and sometimes adjustable, and to determine the size and correctness of the screw by simply screwing it into the gage. If it goes in without shake, it is generally accepted as being of correct size. If it does not go in, the screw is regarded as too large, and the thread cutting tool, of whatever construction it may be, is adjusted so as to reduce the size of the screw until it goes into the gage; but it is impossible by this method to determine whether the screw thread has proper contact with the gage. The bottom of the screw thread may fit the thread in the gage on its smallest diameter and yet not fit anywhere else. The top of the screw may fit the largest diameter of the thread in the gage and the rest of the dimensions have no fit, and the angle of the screw cutting tool may be different from the angle of the thread in the gage. A screw may go into the ordinary thread gage a few threads and not go any farther, not because the shape and diameter of the thread are wrong, but because the lead of the thread on the screw is different from the lead of the thread in the gage. A screw may be out of round, and will fit the gage at two points, but not fit all the way around. All of these conditions cannot be tested by a thread gage of the type generally used.

Assume that a hole is tapped with an accurate tap and is deep enough for the screw to go in two diameters. Assume further that the screw has been gaged with a gage that is three-fourths of the diameter of the screw in thickness. While the screw may fit this gage, it does not necessarily mean that the screw will go in the full depth of the hole. The difference in the lead of the thread on the screw and the thread in the hole may cause trouble. If, on the other hand, a gage is made the same thickness as the depth of the hole, the screw is supposed to fit. In that case the operator generally reduces the diameter of the screw until it will go in the full depth, and if the work is important and an accurate fit is required, the screws may all be spoiled, as the operator has no means of determining the accuracy of the lead.

The illustrations in connection with this article show a thread gage that will determine whether all dimensions of a screw are accurate or not. This gage is composed of a C-shaped frame in which are mounted two hardened jaws, each jaw having grooves corresponding in shape and pitch to an accurate screw plug. These grooves are finished correctly after hardening, so that they are parallel with each other and at an angle corresponding with the lead of a plug gage. In one of the jaws there is a groove that crosses the thread grooves at approximately right angles. The opposite jaw has no such groove and is adjustable on the frame for different diameters. The adjustment is accomplished by a wedge at the front end of the jaw and a push-screw at the rear end of the jaw. The jaw has a tongue that fits in a groove in the frame, and two screws enter the jaw approximately in the middle of the tongue and pull it tightly against the wedge and the push-screw.

A double-ended plug, accurately finished, is furnished with the gage, for setting it correctly, as shown in Fig. 2. One end of this plug is generally made the maximum diameter desired, and the other end is finished to the minimum diameter required on the screw. In setting the gage, the front end of the adjustable jaw is adjusted with the wedge to the maximum diameter of the plug, and the rear end of the jaw is adjusted with the screw to the minimum diameter of the plug. Therefore, it is clear that this adjustable jaw is set at a slight angle to the opposite jaw, in order to obtain the maximum and minimum dimensions on the gage.

In gaging a screw, it is simply passed into the front end of the gage, and if it goes in without passing through the opposite end of the gage the screw is correct as to diameter within the limits desired. The groove running crosswise of the threads in one jaw aids in determining by touch when the screw has reached the ideal diameter; if the screw crosses the groove into the remaining part of the thread the operator can determine how near it is to the minimum diameter. The thread grooves in both jaws being at a slight angle corresponding with the lead of the thread, and the angles being opposite to each other on the two jaws, it would be impossible

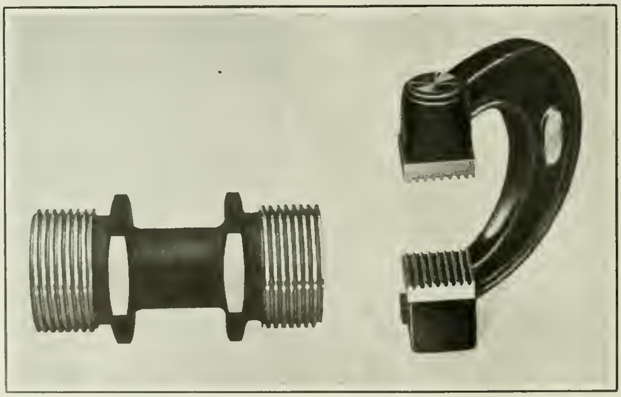


Fig. 2. An Acme Thread Gage with Plug for setting to Size

to pass a screw through the jaw if the jaws were rigidly connected with the frame. Therefore, the construction is such that the jaw opposite the adjustable one can slide in the direction of the axis of the screw being gaged. This slide is accurately finished, and the jaw is held against the frame by spring tension, so that no dirt can work in between the jaw and the frame at any time.

The C-part of the frame being at an angle of approximately 45 degrees with the grooves of the jaws, makes it possible to hold the gage up to the light without having the frame obstruct the view. Therefore, when a screw is put in the gage, by holding it up to the light, it is possible to see how the thread in the screw corresponds with the thread in the gage. If the bottom of the thread in the screw touches the top of the thread in the gage, it is easily detected by holding it to the light. The same is true if the angle of the thread does not correspond with the angle of the gage, or if the lead of the screw does not correspond with the lead of the gage. By turning the screw around in the gage it is easy to feel whether it is round or not.

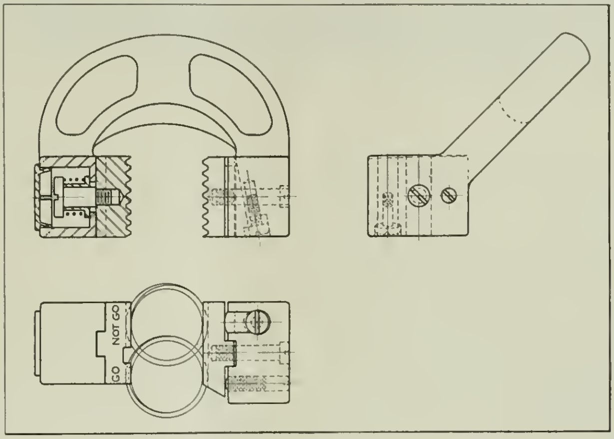

Fig. 3. Construction of the New Hansen Thread Gage

The frame is so designed that the gage can be snapped on a screw of any length, as it will not obstruct the passing of the gage entirely over the screw. The width of the jaws can be made to any desirable dimension, but the practice is to make the jaws for all screws over ½ inch in diameter, 1 inch wide; for screws between ½ and ⅛ inch in diameter, ½ inch wide; and for screws smaller than ⅛ inch in diameter, ¼ inch wide.

In places where thousands of screws have to be gaged every day it is an expensive and tedious task to do this work with an ordinary gage. By the use of this new gage the work can be done speedily and with very little effort. When setting up a screw machine, the screw can be gaged before it is cut off from the rod in the machine, and the die can be adjusted until the correct size is obtained. Fig. 1 shows a gage for the U. S. standard form of thread, and Fig. 2 for the Acme form of thread, but any form of thread gages can be just as easily made.

After long usage, the jaws of the gage may become slightly worn. In that case they may be readjusted to the plug very quickly. If they have been used so much that the measuring points are worn away, new jaws may be attached to the frame, as all the jaws are made interchangeable with the frame. From the illustrations and description it may be seen that in gaging screws with this type of gage, vision as well as touch is used, and that the speed and accuracy of gaging are very valuable features of this gaging method. A number of gages of this type are now in use, and have proved to be entirely practical. They are manufactured by the Hanson-Whitney Machine Co., Hartford, Conn.

* * *

Indications of increased activity are apparent in the Canadian iron and steel industries. Two of the largest steel plants in Canada are working on orders which will keep them busy for some months, and several of the large steel plants are now occupied at about 70 per cent of their capacity, according to a recent report by Consul F. S. S. Johnson.

LET US GO TO WORK

By J. E. KELLEY, General Sales Manager, Simonds Mfg. Co., Fitchburg, Mass.

For the last twelve months we have been liquidating. We have all been wearing out our old shoes and our old clothes, patching up our tools, reducing our stocks, and getting along without purchasing, except for essentials absolutely necessary to carry along our very much depleted business. We have cut out extravagance in so far as purchasing materials is concerned, but statistics prove that we have added another far greater piece of extravagance to our list than any heretofore indulged in, and that is the extravagance of wasted time. We have reduced our energies in greater proportion than our expenses, and most of us find ourselves today wastefully waiting and watching for the gold nuggets to come to us. In other words, we have stopped hustling.

It was the writer's personal privilege to visit Japan shortly after the Russo-Japanese War, going as far north as the island of Hokkaido and as far south as Nagasaki, and at that time all Japan had been advised by a circular letter from the Emperor to curtail all expenditures possible—to get along with as little as possible. They were certainly doing that. People were without shoes in the coldest part of winter and were using ordinary sacking to wrap their feet in. They had no knives and forks to eat with, no chairs to sit on, and hardly any of the ordinary comforts of life. They were getting along without much of any expense, but they were not producing. They were undergoing hardships and were not profiting by it. They had allowed the idea of curtailment and penury to supplant action and work.

As I view the last twelve months here, I can see a considerable similarity to conditions in Japan after the Russo-Japanese War. We can get along on very little if we force ourselves to do so, but what do we gain by it? The world needs products, and all kinds of products. In our opinion the best thing for all of us to do is to take our losses and start in to work and build up again; mark the prices of our goods down, and cut the price of labor down; and insist on more hours work from every employe and more active work from all salaried employes. By the reduction of prices those working for a lower wage will procure as much, or nearly as much, as during the war period. We all need to stimulate activity in business. This slothful waiting is going to hurt everyone.

Let us think this over and see if we cannot adopt a new trend of thought which will help us to get busy, for that is the one thing that will change present conditions.

* * *

American automobiles dominate the South African market. In 1920 nearly 7500 cars were imported, and in 1919 over 4000. These imports are practically double those of all other countries combined. Canada is credited with having exported 2350 cars to South Africa in 1920. These are, however, from Canadian branches of American companies, the cars being shipped from Canadian factories whenever possible, because of lower freight rates and lower import duty.

Production Control by Graphics

A System Employing Graphic Charts for Controlling Shop Operations, in Use in the Plant of the Hopedale Mfg. Co., Milford, Mass.

By FRED R. DANIELS

How To Reduce Production Costs?

THE system described in this article was formulated to suit the requirements of the Hopedale Mfg. Co., builder of cotton looms and automatic attachments for looms, by L. V. Estes, Inc., Chicago, Ill. The success of this system, as of all systems, lies in the definite functioning of the members of the organization after a plan has been accepted as suitable. At the time of installation it was realized that certain readjustments and changes in equipment were necessary in order to pave the way for the work which the system was designed to control. First, the control of material was felt to be of such vital importance that proper storage space was sought which would facilitate the handling of all material in storage. In the designing of the stock-room, certain features were incorporated which aid greatly in receiving material, making inventories, and delivering stock. A portion of the stock-room is shown in Fig. 1. Desk room is provided for the storekeeper at the left and there is a similar open area beyond the bins for the storage of large bulky material.

At the rear of the bins there is a passageway running along one wall of the building from which steps lead up to sets of bins located about four feet from the floor level. Between these sets of bins are other passages on the floor level through which the material is transported to and from storage. Other bins are located on each side of these passageways, accessible from the floor, the arrangement permitting all bins to be reached without the use of step ladders; good natural lighting is obtained from the windows in the passageway at the rear.

General Principles of the System

The details of the control system require the use of graphic charts, the information for these being obtained from a standard part analysis, which is made for every part that is handled. Boards carrying the cross-section paper used for charting are erected, which are capable of handling rolls of fifty yards of paper, so that as the graphs are laid out the paper may be rolled on the left-hand roll. The boards are arranged to slide vertically to suit the convenience of the control board operator. These boards will accommodate several rolls of paper, and are installed in the office of the production department, under whose direct supervision the control system functions. Fig. 2 is a view of a section of one of these control boards. In conjunction with the operation of the control boards a dispatch board is used. The dispatch board is dependent upon the operation of the control boards, and forms the link between the planned and the accomplished work. Each of these elements in the control system will be dealt with in detail in this article.

The dispatching and scheduling of jobs to work stations, or machines, gave rise to the necessity of rearranging many of the machines and numbering them by groups, or individually, as determined by the production supervisor. The tote boxes are also numbered, for the distinct location of jobs going through the factory requires not only that the work station be designated but also that the particular receptacle in which the parts are contained be recorded. Three branches of the organization are involved in the system.

The engineering department makes up master specifications of all parts to be made. These master specifications are one of the three controlling factors of the system, and furnish the manufacturing committee and the production department with information for conducting the routine.

The manufacturing committee, with the aid of the master specifications, determines upon the rate of production, and establishes a production period which is of such duration as to enable work in process to reach the shipping room in time to meet the promised delivery. In the present case this period is taken as one month, and all orders for material such as castings are based upon this monthly period.

The production department, under the direction of the pro-

Without an adequate production system and suitable means for controlling and checking up production, even the best machine tool equipment and the most advanced methods may prove of little value in reducing production costs. If the superintendent or production manager cannot at all times keep in close touch with the flow of production through the plant by means of an adequate system, it is not possible for him to rectify errors quickly and stop wasteful practices that may clog the channels of production. In a large plant especially, costs are reduced not merely by up-to-date equipment and a well-trained corps of workers, but also by proper methods of following the results obtained in production, so that steps can be taken immediately to check any waste and leaks that would prove costly in the long run.

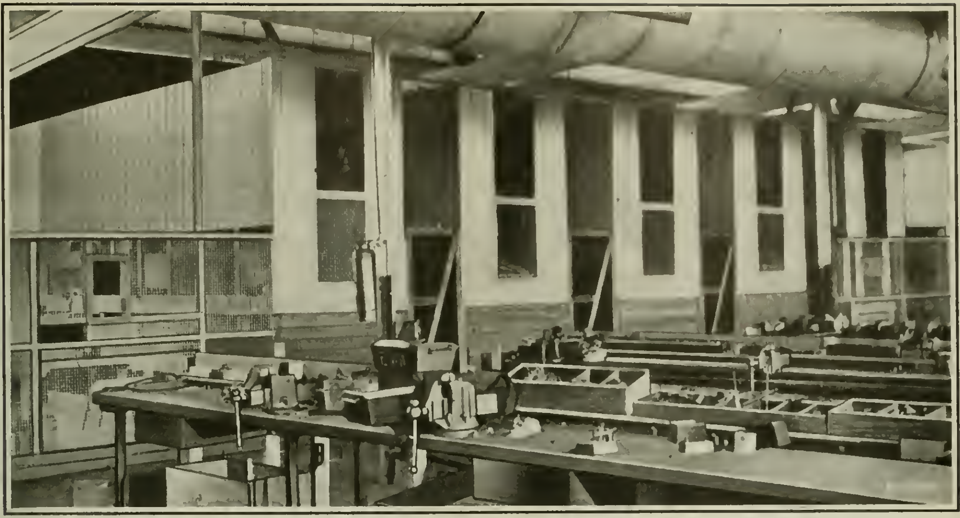

Fig. 1. Stock-room arranged so that the Bins may be reached without the Use of Ladders

duction supervisor, is responsible for all material both in process of manufacture and in stock. The routine within the storage room before and after making and at the dispatch board during the process of manufacture, as well as the actual laying out of the graphs on the control boards, is directly under the supervision of the head of the production department.

Important Factors in the System

There are three important factors that form the basis for the graphic control of parts in process of manufacture. These are (1) master specifications; (2) stock records; and (3) standard part analyses. The master specifications are simply complete lists of all units and sub-assemblies which are used in the construction of any one product. They furnish the production supervisor with definite knowledge regarding quantity.

In conjunction with the master specifications, records must be made on the stock record card, Fig. 3. This card shows at a glance if material must be requisitioned to meet an order, or what part of the order must receive such attention. The upper right-hand corner of this card gives the information relative to the location of the material in the stock-room, and does not pertain to the control elements of the system. The entries in the upper left-hand corner "Minimum to Carry" and "Maximum to Carry" furnish the production department with the information for determining the number of pieces required to be ordered.

In the present case the card shows that it is necessary to carry fifty friction collars H-892 as a reserve, but that it is permissible to carry as many as two hundred of these parts. The closer the limits between the minimum and maximum quantities permissible to carry in stock, the better, because it is inadvisable to tie up a considerable amount of money in stock except when this is necessary to safeguard against shortage in filling an order. This maximum quantity is usually established by estimating the largest amount that would be needed at any time to carry the shop along for a period sufficient to complete another lot.

The entries in the requirements section are first made, and if these requirements cannot be met by the balance available (see the column at the extreme right) and still leave a reserve above the minimum, an order is immediately entered which will supply the deficit and bring the balance available up to the requirements. For example, the first entry shows that 475 parts were required and that but 500 were carried in stock at that time, so that there would be a balance of only 25 castings, which is below the minimum specified. It was therefore decided that an order of 325 would bring the balance available (after meeting the requirements of order No. 520) up to a point which would be considered safe.

The disbursements for the first item entered under the requirements section were made on the 5th and 6th of the month, respectively, and the quantities properly deducted as shown. At the same time receipts are shown to have come in on order No. 1325, which was entered on the 3rd of the month, and these are carried over and included in the new available balance. This procedure enables the quantity

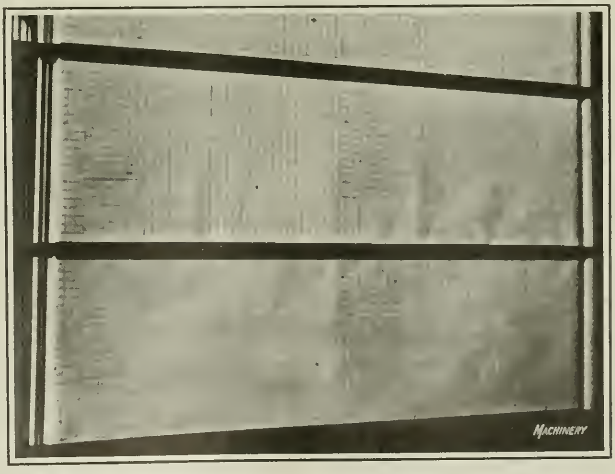

Fig. 2. Arrangement of Control Board for holding Charting Paper on Rolls

actually in storage to be determined at any time, this being the last entry under the "Balance Available" heading—in this case 150 friction collars.

The rough stock and the finished stock are recorded on the same kind of cards, except that they are of different colors. The entries on these cars are made from foundry manifests, material requisition slips, etc., the requirements being determined by the production supervisor. In the case of rough stock, the immediate procedure, after consulting the stock record card, is to issue a foundry order, if the rough stock is not adequate to fill the order, and the data on the foundry order are then placed on the stock record card.

The Standard Part Analysis

The standard part analysis is an indispensable factor in the operation of the system, and forms the basis from which the time to start work upon subsequent operations, care must be taken to allow sufficient time so that the finished pieces from the preceding operation will continue to flow at a steady rate, making it unnecessary to wait for them and thereby lose time.

The overlapping of the operations is termed "compacting," and as will be seen from the comparison at the bottom of Fig. 4, the total time required for finishing all the operations upon a lot of pieces is considerably reduced by this overlapping. In the present case fifteen hours are gained —all the operations are performed on the 100 pieces in fifteen hours less time than would be the case if each operation on the entire lot was entirely completed before the following operation was started. Compacting is permissible and recommended in assembling work, but in the machining of a part it is inadvisable to start lots of less than 100 before the operation on the preceding machine has been fin-

H M Co FORM L.V.E 138

Fig. 3. The Stock Record Card which shows the Balance Available at Any Time

the time element is derived. Figs. 4 and 5 show the form in which these analyses are made. Fig. 4 is for a friction collar assembly, and the information regarding duration of time for this and all other standard part analyses is taken from a time study of each operation. The time unit used is the hour, and the quantity of parts upon which the analysis is based is 100 parts.

It will be seen that the first operation is performed at the work station or machine number B-41, and that ten hours are required for the operation. The time is shown graphically by a horizontal line, extending from 0 to 10, and the time for the subsequent operations is shown in a similar manner. The time allowed for the subsequent operations so overlaps the time determined for preceding operations that when an operation has been completed on a certain number of parts in a lot, the subsequent operation is started before the entire lot is completed. This is shown by the overlapping of the graphs in Fig. 4. In this way it is possible to finish all the operations on a lot of pieces in a much shorter time than would be possible if one operation was completed on all the pieces before the following operations on the same lot were started. In determining upon

ished. In assembling, however, dividing the lots into quantities as small as twenty-five will not result in confusion, but on the other hand, will greatly aid in maintaining the continuity of flow of finished work.

An inspection of the standard part analysis for the friction collar H-893, Fig. 5, shows that no attempt is made to save time by overlapping the operations, although in handling quantities of 500 or 1000 it is permissible to split the order into lots of 100 and compact the operations without causing confusion. Thus the total schedule time and the operating time in this case are equal. Attention is called to the fact that the time required for setting up and taking down a machine for each operation is also included in these part analyses. By so doing it can be definitely established when a machine is again ready to handle another operation. It will also be seen that a section of the form is provided for the cutting speeds and feeds, as these data are of value in establishing standard time factors.

The Graphic Scheduling of Material

Two different control boards are used for scheduling material and operations. The material is scheduled by graphics on standard cross-section paper, and this chart is called a material and flow board. The scheduling of operations, or "loading" as it is called, is graphically shown on a similar control board, called the load board. Scheduling and flowing is the first phase in production control by graphics, and applies only to the turning out of finished work. For this reason attention need be centered only on the last operation, and it is the scheduling and flowing of the last operations which are entered on the schedule and flow board and which definitely determine the starting and finishing hours for all operations later entered on the load board. On both charts colored crayons are used to differentiate between scheduled or anticipated time and the flow or actual attainments. Fig. 6 shows a section of the material and flow board, illustrating how the friction collar assembly HA-892 and the friction collar H-893, which is used in the assembling, are scheduled. Three distinct colors are used for the graphs—blue for rough material; red for finished material; and green for spoiled material.

The right-hand vertical blue lines show the anticipated time for completing the last operation, these being located correctly with reference to dates determined from the date of shipment. For the friction collar assembly it will be seen that there is no horizontal blue line, showing that there is no rough material to be considered, and the horizontal red line is all that is required to show the flow of this operation between the dates determined by the schedule. In the case of the friction collar, however, the horizontal blue line representing rough material and the red line for the finished material appear side by side from time to time, as the receipt of these materials has been made known to the production department.

To better illustrate the methods employed in showing graphically the relation between anticipated and actual production, examples will be selected and followed through from the master specifications to the final assembling. The July master specifications, when delivered to the production department, may show that there are required 500 friction collar assemblies and a like number of friction collars, and that these should be ready for shipment on July 20.

The production department determines that ten day's work will be required on the assembling floor so that the machining operations should be completed at the end of July 9. This is indicated by a vertical blue line as shown in the chart. Reference to the standard part analysis shows that the last operation on the friction collar assembly requires five hours for a lot of 100; consequently twenty-five hours would be the time allowance for 500 of these subassemblies. For convenience, ten hours is here considered as the length of the working day, so that noon on July 7 is indicated by another vertical blue line as the starting time for the flow of this last operation.

Reference to the stock record card shows that there are 100 of these sub-assemblies in stock; also, that a minimum of 25 must be retained, so that it is permissible to apply 75 of these units to the production schedule. The vertical line which indicates the start of the flow is referred to as the zero hour. To the left of the zero hour the reserve is indicated in red, and to the right the 75 units which are applicable to the schedule are similarly indicated. The length of these lines corresponds to the time required for machining these quantities. This shows that the actual time for commencing the operations is about 4:45 P. M., July 7, rather than at noon as indicated by the zero hour.

The continuing of this red line is the duty of the man in charge of the control board, and the extending is done during the process of manufacture, the information being furnished from a daily report made out by the timekeeper to whom the reports of the actual work accomplished are submitted. This detail will be referred to later in connection with the routine of dispatching. Before the graphs can be made for the friction collar, it is necessary to consult the load board in order to establish the starting time for the first operation on the friction collar assembly, for it is in relation to this starting time that the schedule on the last operation of the friction collar is established.

Fig. 4. Standard Part Analysis Form, showing how Operations are overlapped

How the Operations are Represented Graphically

A section of the load board is shown in Fig. 7. Information relative to the delivery of work from one machine to another and the daily production rate is entered above the graphs. The standard part analysis Fig. 4 has shown that the last operation on the friction collar assembly is performed by machine No. B-44; consequently opposite B-44 on the load board the starting and finishing time for this operation are indicated. In order to preserve continuity and steady flow of operations, it is advisable to have one day's production ahead of the schedule; also a cértain time should be allowed for inspection and handling the work. The latter factor will be determined by experience and knowledge of the actual conditions, but for the purpose of illustration it may be assumed to be one-half day. This means that Operation 4 will start one and one-half days, or fifteen hours, in advance of the actual scheduled time for start of flow as defined on the material and flow board, Fig. 6. Fifteen hours in advance of 4:45 P. M., July 7 brings the actual starting time for this operation to 10:45 A. M. on July 6, and this is indicated on the load board by a vertical line as shown.

The total consignment calls for 500 units, but since 75 have been taken from stock for this order, it is only necessary to make 425 new units, and this is the amount which will be shown graphically on the chart. It requires 21¼ hours to make 425 units, based on the time estimate for this operation as determined from the standard part analysis, Fig. 4. This makes the finishing hour at 12 o'clock, July 8. Having established the limits within which this operation should be completed, and loaded the starting and finishing dates properly on the chart, the other operations are loaded against their respective work centers in the proper time relation, as defined on the standard part analysis for this sub-assembly. The notation 720 is the order number, 7 standing for the month and 20 for the year, and all parts entered on a July order bear this number. The part number is also shown, as well as the operation number, the machine to which the material is next delivered, and the estimated daily production.

Further Details in the Charting of Materials and Operations

This loading of the operations has placed the starting hour for assembling these units at 11 A. M., June 28, and it is in relation to this date that the starting time for machining the collars required in this assembly is determined. It is advisable to have one standard lot, or 100 finished units, of friction collars H-893 in readiness for assembling before the first operation in assembling is commenced, which, with a time allowance of ten hours for handling and inspecting the parts, makes a period of seventeen hours that Operation 4 on part H-893 should start in advance of the assembling work. This fixes the zero hour as 9 A. M., June 25, and this is indicated in Fig. 6 by a vertical blue line. Fig. 5 shows that seven hours are required to finish 100 parts on Operation 4. The anticipated date for completion is then indicated by another vertical blue line thirty-five hours to the right of the zero hour, since it requires that length of time to perform the last operation on 500 units.

ALL TIME CALCULATIONS ARE BASED ON HOURS

Fig. 5. Another Example of the Use of the Standard Part Analysis Form

The stock record card for the friction collars, shown in Fig. 3, indicates that there are 150 of these collars available for use, but that 50 must be held in reserve. The 100 friction collars that may be applied to the production schedule are indicated graphically to the right of the zero hour in Fig. 6, and this brings the time for actual machining to about 5 P. M., June 25. The reserve of 50 is also indicated in red to the left of the zero hour. There are 400 friction collars required to be ordered from the foundry, and the production clerk immediately issues a foundry order for this quantity to be delivered by June 24, and at a daily rate which will be in accordance with the daily rate of production. The foundry order will stipulate the minimum daily shipment and the date on which shipment is to start.

It can readily be seen that this method of recording the progress of finished work relative to the receipt of rough material from the foundry enables the production depart-

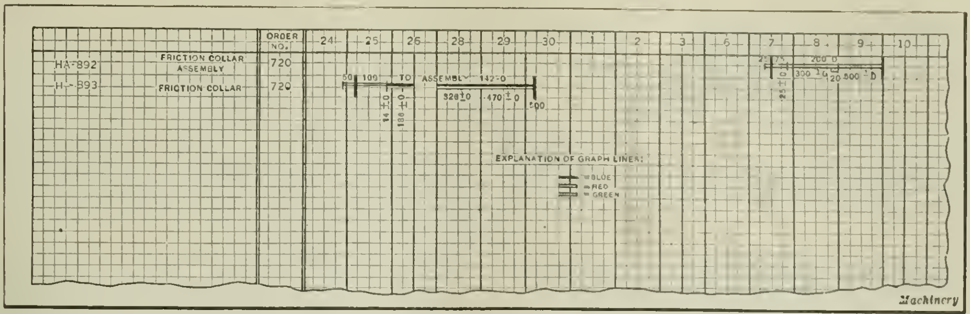

Fig. 6. Section of the Material Schedule and Flow Chart for showing graphically the Relation between Anticipated and Actual Accomplishment

ment to be in constant touch with the actual conditions, both in regard to the material being received and the relation of the progress of each operation to the established date for completion of the work.

Referring again to Fig. 7, it will be seen that the starting point of the last operation is loaded against work center 202 and scheduled to start at 5 P. M., June 25. The time for completion of the operation is also indicated by a vertical black line, this being done for each operation and the several operations being overlapped. An inspection of this load board will show that, due to compacting, 43 hours from the time that Operation 1 was started, the friction collars were completed. If overlapping or compacting were not resorted to and the standard part analysis, Fig. 5, strictly adhered to in loading, it can readily be seen that it would require 88 hours (4 × 22) to machine this lot of 400 collars. This represents a gain of 45 hours. The time required for setting up and taking down a machine is shown in advance of and at the end of each operation, respectively, this being indicated by a black line so that the exact time at which a machine will be available for a new job is at once seen.

Forms Used in Routing the Work

No actual flow of material has yet been charted—merely the loading of the operations against the various work centers in Fig. 7, and the scheduling of the last operation in Fig. 6. With the starting and finishing times indicated on both the schedule and flow board and on the load board, the control board comes into use for recording the actual production. Before production is started, however, three forms are made out by the production department. These are the productive material requisition, Fig. 8, the routing card, Fig. 9, and the dispatch order time cards, Figs. 10 and 11. These three forms are made out at the same time, and reference is made to the standard part analysis when issuing the cards.

Productive material requisitions are issued in duplicate copy and are used only for material that goes into the regularly manufactured product of the company. One copy of the routing card is made out, its purpose being to identify the work in process and to furnish the information for delivering the work in the proper sequence from operation to operation. It will be seen in Fig. 9 that provision has been made on this card for splitting lots, as would be done in machining the friction collar H-893; the routine recorded on this card is made out from the standard part analysis. When a lot is split, information relative to the number of the tote box and the quantity contained in it are entered on the card; also the quantity in the entire lot, and the number of the box from which the material was taken. When

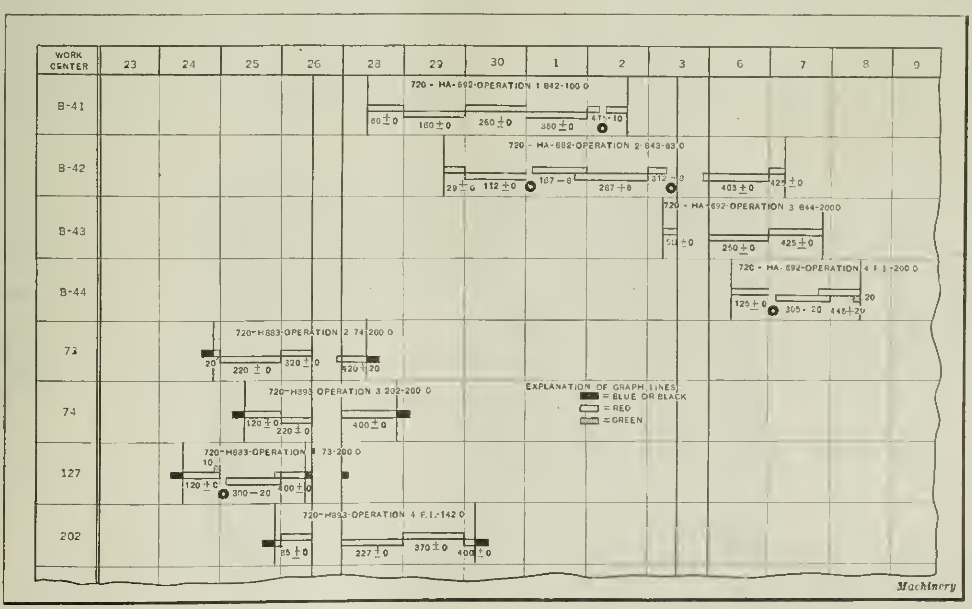

Fig. 7. A Portion of the Load Board on which the Schedule of Each Operation is indicated graphically Relative to Dates and Work Centers

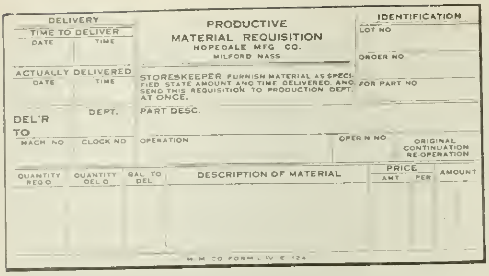

Fig. 8. Form used for requisitioning Productive Material

an order is split, a duplicate card is issued and the proper entries are made in the deliveries section in order to permit the various lots on the order to be traced during the process of manufacture.

The dispatch order time card is issued in duplicate, the original in white, Fig. 10, and the duplicate on a buff card, Fig. 11. It will be seen that the original, Fig. 10, has provision for inspectors' reports under the headings "Deliveries" and "Spoiled" in place of the space on the buff card, Fig. 11, for the stamping of starting and stopping times by a clock recorder. These cards—the productive material requisition in duplicate, the routing card, and the dispatch order time card, also in duplicate, are then clipped together and placed in a clip on the dispatch board.

The dispatch board is the center from which the orders for material and the shop orders are dispatched, and also the center from which the machining of the work is controlled. Divisions are made on the board for each work station, properly indicated by number, and all work either about to be made or in process of manufacture, is relegated to this section of the board. This is in charge of the dispatcher, and his duties are primarily to maintain a systematic steady flow of operations, and prevent the occurrence of idle machine time. Under each machine division on the dispatch board there are three wire clips which are designated as "jobs planned," "next job," and "jobs done." The dispatch order time cards, with the routing card and productive material requisitions attached, are then filed in a "to do" file at the dispatcher's desk, and this file is drawn from as jobs are placed on the dispatch board.

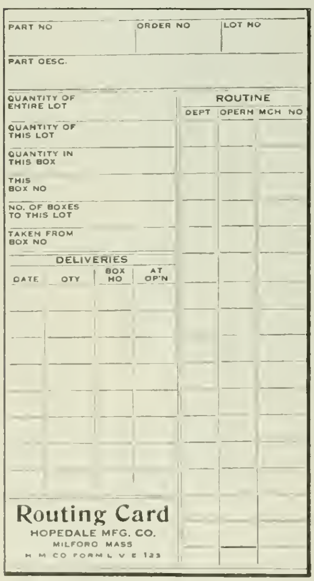

Fig. 9. Routing Card which accompanies the Material through the Plant

Dispatch Board Routine

As time goes on, the dispatch order time cards are advanced to the "jobs planned" clip for the machine on which it is desired to perform the work, but before this is done the original copy of the dispatch order time card is placed in a "jobs working" file on the timekeeper's desk where it is filed numerically. This original (Fig. 10) will later carry the inspector's reports and will furnish the information (after the completion of a job) for the control board operator to indicate the flow on the material and flow board. After a job has been completed, the dispatch order time card is placed in the "next job" clip. When the dispatch order time cards reach the "next job" clip, the dispatcher removes the material requisition, Fig. 8, and the routing card, Fig. 9, and forwards both to the storekeeper. The operator's clock number and name are then entered on the buff dispatch order time card, Fig. 11, which is then placed under the "next job" clip.

As soon as the storekeeper has received the material requisitions and routing card, it is his duty to forward the material to the machine designated, together with the routing card, and send the duplicate copy of the material requisition to the production department, retaining the original for his own files. It is of course necessary to so organize the trucking department that the material will be delivered as designated on the routing card.

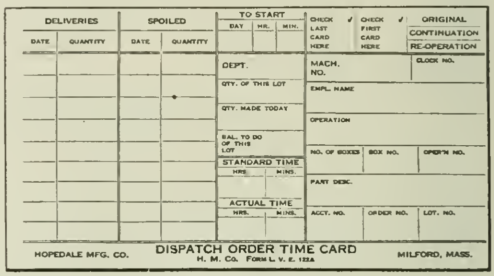

Fig. 10. Original Dispatch Order Time Card with Provision for Inspector's Report at the Left

When an operator is ready for a new job he goes to the dispatch board, removes the buff card, Fig. 11, from the "next job" clip, stamps the starting time on it, and then proceeds to his work, retaining the card until after the operation has been finished, or until the end of the day, when all dispatch order time cards have to be turned in. Upon reaching his machine, the operator should find the material already delivered from the storekeeper. After the operation has been finished, or at the end of the day, the operator enters on the card the quantity made, and the balance to be made, and stamps the stopping time on the card, placing the card in the "jobs done" clip and taking a card from the "next job" clip. He then proceeds with the second job as before.

As soon as the card appears in the "jobs done" clip it is a notice to the dispatcher and trucking department that material is ready for transfer from a particular machine. The truckers then remove these cards, drop them into a box provided for the purpose at the dispatch board, and proceed to make the transfer of material. In making the transfer,

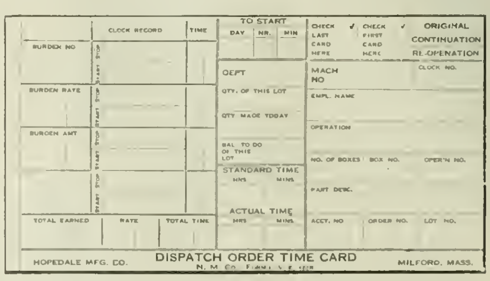

Fig. 11. Duplicate Form of Dispatch Order Time Card with Spaces for Time Recorder Stamp

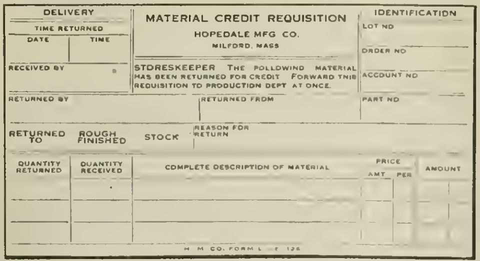

Fig. 12. A Material Credit Requisition used when returning Overdrawn Material to Stock

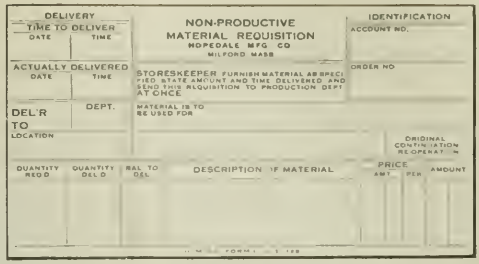

Fig. 13. Requisition for Material used for other Purposes than for Regular Manufacture

the routing card, which has remained with the lot, furnishes the information for routing the material. If it so happens that a job is not finished at the end of the day, the time card is placed in a box on the timekeeper's desk, and the timekeeper will then issue a new dispatch order time card (in a different color). When the operator starts the job again the next morning, he will find the new card properly located in the "next job" clip, where it has been placed by the timekeeper the night before.

After the dispatch order time cards have been made use of by the timekeeper they are forwarded to the payroll department for computing the operator's wages. The information which the timekeeper obtains from the dispatch order time cards is arranged in report form and delivered to the production department every morning. It is this report to which the control board operator refers when indicating the flow of finished work. As previously stated, the flow of rough material (that is, its receipt from the foundry) is obtained daily from foundry reports.

It will be seen that if this procedure of reporting every morning to the production control center is followed in each department in the plant, complete information will be obtained of exactly what is happening throughout the entire plant, and this can best be shown by the use of charts.

Load Board Routine

On the morning of June 25 the production report for the 24th is delivered to the control board operator, showing that Operation 1 on the friction collars was completed on 120 units; this is accordingly shown graphically in red on the control board to the right of the starting hour, 11 A. M., and opposite machine 127. This report carries also the number of spoiled parts, as determined from the inspector's report entered on the original of the dispatch order time card, Fig. 10. There were ten defective collars on June 24, and this is indicated by a green line, the amount being written directly above it (Fig. 7). Below the red line the notation 120 ± 0 is made, which means that 120 collars were produced with no excess or under production. On the morning of the 26th the report for the preceding day shows that work did not start at 7 A. M., due either to absence or tardiness of the operator. When such a condition exists, the failure to start is immediately noticed by the departmental foreman, who then notifies the production department that work has been held up on machine 127, giving the reason therefor. This fact is immediately indicated on the load board in the form of a red and blue bulls-eye, located at the gap where the interrupted production occurs.

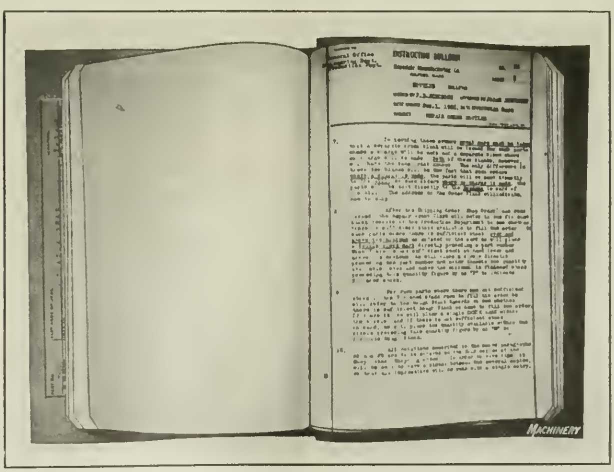

Fig. 14. Inspection Bulletins bound in Loose-leaf Form

The next day's report shows that production was resumed on the machine at 8 o'clock and that 180 units were machined on the 25th, this being indicated as shown, with the space left indicating the idle machine time. The production of 180 is then added to the preceding day's production and the notation 300 — 20 is entered as shown, to indicate that the 300 figure is 20 below the estimated production for the two days. The daily report for the 26th, which was received on the morning of the 28th, shows that 100 units were turned out, which is 20 in excess of the schedule requirements for that period of time. In charting this production, the excess 20 units is indicated by extending the line to the left of the space provided for the 26th of the month, so that it overlaps the preceding day's production. The accumulated total is 400 ± 0.

Although the entire lot of 400 has been turned out within the scheduled time, it is seen that there are ten defective pieces, leaving a balance of 390 perfect castings. This shortage can be conveniently handled by drawing on the reserve, or ten additional units can be made. In the latter case, the dispatch order time card will have indicated on it in the upper right-hand corner (see Figs. 10 and 11) that this is a reoperation job.

The remaining operations are indicated graphically in a similar manner, and above each graphic representation there is entered a notation giving the order number, part number, operation number, machine or work station to which the next operation passes, and the required daily production.

The control board operator is thus furnished with the information which will enable him to inform the production manager regarding all cases where failure to meet the production rate has occurred. A daily report issued to the production supervisor by the control board operator shows definitely the extent and seriousness of any falling behind in production, and enables immediate steps to be taken to remedy the trouble. The red and blue bulls-eye on the load board focusses attention upon any stoppage of production.

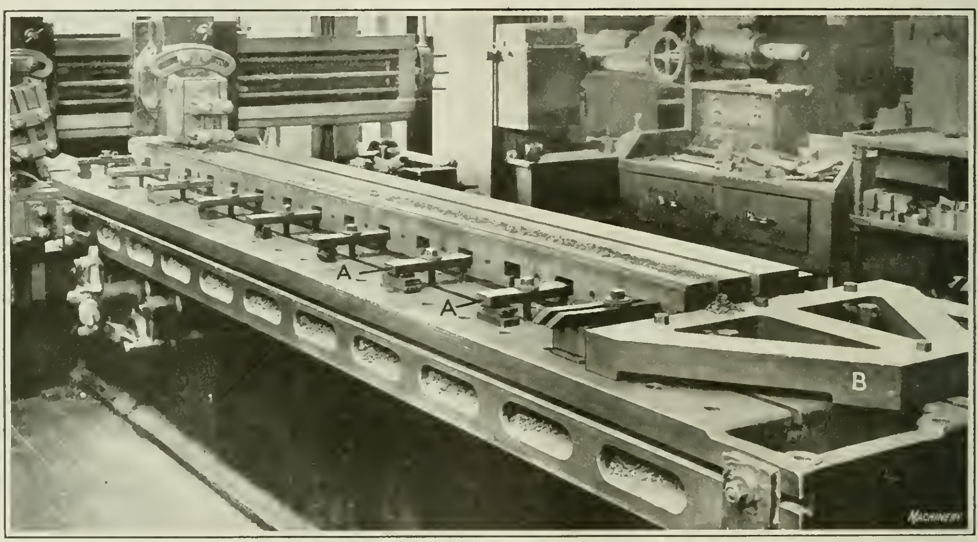
Measures for Preventing Haphazard Methods

It will be realized that in addition to the few forms which have been shown in this article, numerous other cards and requisitions are required in order to take care of exigencies that arise in the functioning of the system. For example, there is the material credit requisition, Fig. 12, which is sent to the storekeeper whenever material is to be returned to storage, enabling the stock records to be readjusted. Such a condition is frequently encountered when material has been withdrawn from storage and charged to a non-productive job. A non-productive material requisition, such as that illustrated in Fig. 13, must be issued for the withdrawal of stock which is to be used for non-productive purposes, such as repairing and general mill-wrighting. A definite knowledge of all material which goes into any branch of the industry, be it productive or non-productive, must be under the control of the production department. There is also the issuance of non-productive time cards for such workers as truckers, stock-room men, house electricians and carpenters, millwrights, oilers, watchmen, etc.; and further, the readjustment of ratings, the handling of repair orders, the issuance of foundry orders, and the routine connected with the control of stock within the stock-rooms.

These several auxiliary parts of the system are all correlated, and must each be definitely taken care of. When the graphic control system was installed, these facts were fully appreciated, so that it became at once apparent that some definite clearly defined routine would be necessary. Consequently all correspondence from the heads of the various departments and the executives relating to any phase of production is required to be handled in the form of instruction bulletins. These instruction bulletins have been issued on every phase of the system, and have to do with all internal house routine. They are neatly prepared and bound in loose-leaf form, as shown in Fig. 14. It will be seen that copies of these instruction bulletins go to all departments concerned in the issuance of any instructions. These instruction bulletins are numbered and carry at the head the subject and the names of those responsible for the issuance of the bulletin, together with the current date and the date effective. Written instructions are insisted upon.

PLANING CROSS-SLIDES FOR NATIONAL-ACME AUTOMATICS

On automatic screw machines built by the National Acme Co., of Cleveland, Ohio, the cross-slide for the forming side of the machine is required to interchange with the cross-slide on the cut-off side. To insure this interchangeability, a high degree of accuracy must be attained in the performance of the planing operations on these castings. The accompanying illustration shows a string of the forming slides on which a T-slot is being planed, and the particular point of interest in connection with this job is the method of setting up the work. In addition to applying the multiple set-up principle, which enables a substantial increase to be attained in the rate of production, it will be seen that advantage is taken of the fact that each slide has been undercut at both sides to afford the necessary means of supporting it on the machine. As the castings are set up for planing, these under-cuts come together, forming the equivalent of a T-slot into which the end of straps *A* may be inserted in such a way that each strap grips both of the shoulders on two castings and holds them firmly in place. End thrust is taken by a stop *B*, which is carefully finished to engage the finish-planed end of the first piece of work, thus substantially assisting in the set-up, by forming a reference point from which to start to align the string of castings with the line of travel of the planer table.



Multiple Set-up used in planing the T-slots in Cross-slides

COST REDUCTION A FACTOR IN THE FUTURE OF THE AUTOMOBILE INDUSTRY

In a comprehensive study of the automobile industry and its future, made by Leonard P. Ayres, vice-president of the Cleveland Trust Co., Cleveland, Ohio, the conclusion is drawn that extensive price adjustments will be made in that industry in the next few years, and this conclusion, if accurate, makes it inevitable that the automobile business will finally be concentrated into fewer competing hands and curtailed more than it is now. For a long time to come the machine tool market offered by the automobile industry will not be on the same basis as it was in the past, during the great development of the industry. The survival of the concerns now in the automobile field will depend upon their ability to reduce costs of production; that means that there should be a market for machine tools of high productivity.

Economic Value of Factory Investigations

By ALBERT A. DOWD, President, and FRANK W. CURTIS, Chief Engineer, Dowd Engineering Co., New York City

A FEW plants are taking advantage of the present dull period to overhaul their equipment and make improvements here and there in their methods of handling work and materials, thus taking a step in the right direction in their preparation for future business. It is the progressive man who realizes that something of this sort is necessary. Others will continue with obsolete machine tools or those that need overhauling, and will wait until business really improves to such an extent that they will need their equipment before they spend any money in preparation work. This attitude simply means that they are not far-sighted, and will get skim-milk while their more progressive competitors take the cream. Methods and tool equipment should both be considered in any planning for future work, and those who are doing this preparatory work now will be rewarded when business improves, for they will then be ready to operate and make early deliveries.

Matters of this sort are of vital interest to every manufacturer in planning for future business, and there are a number of points that he must consider with care. The labor problem is one; the question of salaries for office workers and wages in the factory must be given consideration. The conditions under which the men will work, together with such things as heating, lighting, ventilation, and the sanitary provisions for the workmen's comfort should be looked into. Now is the time to think of these matters in a broad-minded way, and at the same time to put into operation some of the ideas for improvement that may be suggested by past experience. It is no time to be idle and to say that one cannot afford to waste money by doing any of these things now when there is no business. It is really the opportune time to do preparatory work.

The Value of Outside Perspective

The majority of manufacturing plants need a certain amount of reorganization at the present time, largely on account of the changes which have taken place in business conditions in the last few years, especially the changes that the last year has brought about. The reorganization which is required may be either radical or moderate. If the factory has been greatly enlarged and many departments added to handle other kinds of work than those for which the factory was originally intended, it is necessary to look over the equipment carefully and see for what class of work it is best suited, and then make an attempt to obtain or manufacture work of this class.

Investigation of the factory by an outside engineer, together with an analysis of matters as he finds them, has been found to be of great value at this time. Ordinarily the executive says: "I know my own plant best. No one can tell me how to operate it, as I know every machine in it." It does not always follow, because an executive feels this way about it, that the statement is really accurate. The outside engineer, if he is a capable man with sufficient mechanical experience, can look over a factory and see many things in it which would be entirely overlooked by the executive who might be familiar with all of them, yet underestimate their importance. The outsider brings an open mind into the situation, and is therefore impressed by things as he finds them, and not by matters as he expects to find them, as may be the case with the executive familiar with the conditions. Largely for this reason, the investigating engineer is able to look at the matter without being influenced by anything except the conditions as he finds them, and as a consequence his report is of great value on account of its freedom from restraining influences.

Such an investigation at the present time may seem, at first, an unwarranted expense which will not be likely to produce any immediate results. So-called "efficiency experts" are not always expert, nor do the results achieved meet the expectations. But there are consulting engineers who know their business, and the executive can investigate before he engages a man.

The Investigator and His Work

A consulting engineer can be brought in from outside for one day a week, or two days a month. All he does is to go through the various departments, noting conditions and making a report on them with suggestions, at a cost that is not excessive. The total cost may run to from $1200 to $2400 a year. It is quite possible that with an arrangement of this kind great savings may be effected in the methods of manufacture, provided the man selected for the work has had sufficient experience to enable him to analyze conditions as he finds them and suggest improvements where needed.

Some executives consider it more or less of an insult if any suggestion is made by a director or stockholder of the company regarding an investigation of the methods used. As a matter of fact, this attitude is a mistaken one, because a capable executive should welcome any assistance either from the inside or outside which will tend to reduce production costs. Instead, therefore, of being antagonistic to the idea, he should give careful thought to the subject and look at the matter in an open-minded way. As an executive, he should certainly welcome any suggestion which would show him how to increase his production from 10 to 25 per cent without adding to the production cost, or, what is the same thing, to reduce costs a corresponding amount without reducing production. In looking into the matter, therefore, let us see how the investigator works and how he obtains his results, keeping always in mind the fact that the outside viewpoint enables the engineer to look at a thing fairly as well as analytically.

Cost Reductions Resulting from Factory Investigations

Let us take two or three specific examples of savings which have been effected by the suggestions of an outside investigator in factory work. A small spur gear, approximately 2 inches in diameter by 3/16 inch thick, had been made for some years from a steel blank, bored, reamed, the keyway cut, faced, and finally teeth cut on a gear-cutter. A method suggested to replace this was the use of punches and dies, the work being turned out in this way in somewhat less than half the time formerly required. The work was also held within very close limits of accuracy by the use of shaving dies. The number of machines required was reduced and their cost was much less than that of the types formerly used. The old method gave a production of 1200 per day and utilized five machines for the purpose, namely, one screw machine, two engine lathes, one broaching machine, and one gear-cutter. The new method gave a production of 2600 per day with four punch presses. These machines are much cheaper than those used in the other operations, and it will be seen that the actual saving in time was more than 50 per cent. The cost of dies was somewhat more than the tool equipment previously used, but this extra cost was soon absorbed by the savings effected.

Another revision of methods which brought about extensive savings was that of a small shouldered stud 1¼ inches in diameter by 2½ inches long, which was formerly made on an automatic screw machine. This method required considerable forming and a slow cutting-off operation. The production obtained was 120 pieces per day. By making this part in the form of a drop-forging and handling it by another method consisting of short simple operations on the drilling machine and engine lathe, respectively, a production of 200 pieces per day was found to be easily possible. In addition to this, the new method did not waste as much material as the old so that there was a saving in this regard also.

Improved Method of Manufacturing a Long Rod

Another factory had as an important item in its manufacturing schedule, a rod 48 inches long by ½ inch in diameter having a head on one end with a ½-inch hole drilled through it. The old method of manufacturing this unit was to bulldoze the end of the rod to flatten it out, and after this to mill both sides of it and drill a hole. The operation of bulldozing was not so very slow, but the work was awkward to handle in the subsequent operations of milling and drilling, thus making a very slow method of handling. In the improved method the end of the rod was made in a punch press from ¾-inch flat stock, blanked and pierced with the hole required. After this operation, this end was welded to a rod cut off to the proper length. The only thing then remaining to be done was to dress off the fin at the joint where the work was welded. The new method gave a production more than double that obtained by the old process.

These examples are given specifically in order to show the opportunities for improvement which may be brought about by a wide-awake man in the investigation of methods in the factory. A number of other important matters not directly connected with the machining of the work are also subjects for analysis. Several of these points are mentioned in the following in order to show the scope of a thorough factory investigation.

Definite reductions in costs have been shown to result from factory investigations. In one case a production of 1200 small spur gears per day was increased to 2600 per day, and a less expensive machine tool equipment was used for the greater production. In another case a production of 120 shouldered studs per day was increased to 200 pieces per day by a change in the machining methods; and in still another case production was doubled by making a part in two pieces and welding them together, instead of making it entirely from one piece as had formerly been done. Next month additional examples of cost reduction by increased production through the use of improved methods will be given in another article by Mr. Dowd and Mr. Curtis.

Handling Materials

There are very few factories where the material is handdled with maximum efficiency. Work is often piled up where it is in the way of both operators and trucks. Simple conveyors which often may be gravity-operated, together with suitable racks and stands for placing the work so that it can be conveniently handled, are always of assistance in carrying the material through the factory without waste of time. The investigating engineer studies the requirements and determines how the work, both raw material and finished product, can be most conveniently arranged and carried from one department to another.

Inspection and Salvage

The inspection of the raw material and the finished product are important factors in production. Much unnecessary work may be done in the machine shop due to a careless method of inspecting the raw material. Defective castings may be put through and machined, with the result that they will be scrapped before or after completion. The study of these matters is often the means of saving considerable money. Work that goes through the factory and does not pass inspection on account of errors in machining may often be salvaged in one way or another, so that the material and the time expended in the manufacture are not totally lost. Much depends upon the nature of the work as to how it may best be adapted or refinished to suit some other condition. A hole which is bored over size in a casting may be again bored and the hole fitted with a bushing of the correct size in order to save the piece. Many other opportunities are found by the careful investigator, which reduces the amount of work scrapped to a minimum.

Many products require painting or japanning in order to give them a certain finish after the machining work has been done. The methods used for the process of painting are often very wasteful, both of time and paint. A process of spraying may be found economical for the application of paint in connection with suitable dryers and conveyors. In japanning, the work may be automatically dipped and carried through the baking ovens by means of conveyors. By thus considering each process, the investigating engineer can suggest economies not always apparent to the owners.

Time Studies

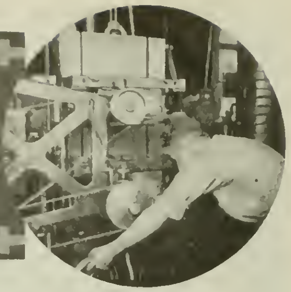
Time studies showing the length of time necessary to perform this or that operation are often not favored by the shop executive because they may be objected to by the shop men. It is possible, however, to institute such a system for this purpose that no trouble will be caused. In the establishment of piece-work prices, time studies are an important factor in determining a price which will be fair to manufacturer and operator alike. The matter of speeds and feeds for the various machines is an extremely important matter and it is safe to say that a large part of the losses in production in the average factory are the result of incorrect feeds and speeds.

Assembling

The assembly department often presents to the investigator many problems for solution. A great deal of labor is wasted by inefficient methods, and there is more hand fitting than there should be. Time saved in the final fitting of parts which are to be assembled is an important item of manufacturing, and the cost of the product is often greatly reduced by efficient work in the assembly department. The process of gaging and the limits used have a pronounced effect on assembling. If allowances and tolerances are not correctly determined in the first place, the final assembly is much hampered, and considerable extra fitting becomes necessary. This part of investigation work requires diplomatic treatment and a careful analysis.

The various points mentioned in this article are intended only to give an executive a general idea regarding the value of an investigation of his factory by an outside engineer. No attempt has been made to go into detail regarding the various methods used by the investigator, although it will be realized that a certain amount of diplomacy is necessary in order to avoid conflict with foremen and operators. Much of the work mentioned can be done by a comparatively rapid survey, but many results of value can be obtained only by a careful and logical analysis of conditions as found, resulting in suggestions for improvements in methods which do not appear to be as efficient as they might be. The belief that present-day practice is not susceptible of improvement is often the reason for high production costs.

Design and Making of Drop-forging Dies



Methods of Heating, Quenching, and Drawing Carbon and Alloy Steel Dies

In August and September MACHINERY the design of dies and modern diemaking methods were described. The present article on drop-forging dies deals with the heat-treatment. It was stated in August MACHINERY that the blocks when received from the steel mill are usually in the annealed state; but sometimes they are so heat-treated that they do not require any further heat-treatment and are put into immediate service after the impressions have been sunk. The types of dies which are heat-treated at the steel mill are those that are unusually large or those alloy steel blocks that demand in their heat-treatment certain methods which the steel manufacturer is better equipped to use than is the die manufacturer. The scleroscope reading of these heat-treated die-blocks ranges from 40 to 50, which is the limit for machineability, under ordinary circumstances. The present article deals almost entirely with the heat-treatment which annealed untreated blocks require after the die impressions have been sunk.

Heating for Hardening

After the impressions have been sunk, the annealed blocks should be heated in the following manner preparatory to quenching for hardening: The blocks should be allowed to heat gradually, absorbing the heat already in the furnace from the previous run, before the heat is again turned on. The initial temperature of the furnace should not be more than 600 degrees F., and if care is not exercised in permitting the blocks to become thoroughly permeated with the low furnace heat, rupture is likely to occur, because it is during the low temperature changes that the most trouble in this respect is encountered.

Before placing the dies in the furnace, they should be set, face down, in a shallow iron box or tray, the bottom of which has been previously covered with powdered charcoal, or spent bone. The tray should have projecting lugs, to accommodate the arms of the truck used in transporting the loaded tray in and out of the furnace. When it is necessary to harden unusually large die-blocks, it may be impracticable to use a pan, and in such cases the blocks are set directly on the furnace hearth, shank down in order to facilitate handling them, the truck arms straddling the die shank and extending under the die when it is being moved. The faces of the dies should be covered with a thin layer of powdered charcoal, held in place by a suitable iron plate. This precaution prevents the formation of scale and the decarburization of the impression surfaces.

After placing the dies in the furnace, the temperature is raised steadily to from 1375 to 1500 degrees F., and the blocks are permitted to remain in this heat until all dark spots have disappeared. Although the heat-treater is governed considerably by experience, in judging the time for leaving the blocks in the furnace, the appearance of the red-hot block furnishes a more definite indication of the proper withdrawal time. A 12-inch cube of steel will heat thoroughly, starting from a furnace temperature of 600 degrees F., in about seven hours, and other sized blocks in proportion.

The furnace, which for convenience should be located near the die-sinking department, should preferably be of the under-fired semi-muffle type, although there are a number of standard furnaces on the market which are designed especially for handling this kind of work. Excellent results have been obtained from specially designed furnaces, burning either gas or oil, constructed with a high arch and with provision for conducting the heat to the die by radiation rather than by direct contact.

Quenching

Carbon steel blocks may be quenched for hardening either in water or oil. All dies should be quenched immediately from the hardening heat (1375 to 1500 degrees F.). Good results will be obtained if the blocks are permitted to become only partly cooled in the bath, so that when withdrawn a finger can be held in the deepest impression for several seconds, after which the blocks may be immediately drawn on a hot plate, before the dies have had time to cool completely. Of course, if the blocks are completely cooled in the quenching bath, they may be drawn to the correct hardness by reheating in a furnace or oil bath, and quenching. The recommended tempering heat for the steel (about 450 degrees F.) should be employed.

If the blocks are massive and are hardened in water, a quenching tank should be employed which can accommodate a plentiful supply of circulated water. The blocks should be dipped face downward to a depth which will bring the deepest impression about an inch below the surface of the water. The tanks should be equipped with means for spraying water against the die face, to prevent steam pockets and uneven shrinkage.

The proper heat-treatment of drop-forging dies is perhaps one of the most important steps in the economical operation of a drop-forging plant, for nearly all other economies may be nullified by improper heat-treatment. On the one hand, careless handling in the heat-treatment may spoil the dies and cause a waste not only of the material from which they are made, but of all the labor that has been put into the sinking of the impressions. On the other hand, even though the dies may pass from the hardening room in what may appear to be first-class condition, if they are not of the right hardness and toughness, they will not stand up under the hammers anywhere nearly as long as if correctly treated, and as a result the cost of dies will increase rapidly. Too much attention cannot be paid to the heat-treating department in any plant, and this is especially true in a drop-forging plant where dies are hardened and drawn; hence, the emphasis laid on this subject.

If the face of the block is approximately square, a 2-inch outlet for this stream will be about right. If the block is long, the stream should be so distributed that it will extend at least the full length of the block. While the die is being quenched in this manner, the shank should be cooled by playing a stream of water on it as a means of preventing distortion, and this stream may be so manipulated as to keep the shank level. As the face cools, the amount of water applied to the shank should be gradually diminished. By this method the amount of distortion can be controlled so that the shank will not be out of level more than 1/32 inch on a large die. These precautions are not required when oil is used as a quenching medium. Any convenient means may be employed for suspending the dies, but if they are heavy and awkward to handle a cradle is sometimes employed, attached to the side of the tank, which may be adjusted to hold the block at the proper height relative to the surface of the liquid.

The die may be ruined in quenching, especially when water is used; consequently this work should be carefully performed, and should be entrusted to no one but a man who has had extensive experience in hardening dies. If the die impression is at all intricate and has sharp corners and edges, these should first be "checked" with a piece of water-soaked waste or a piece of soap. The shank should be dipped long enough to chill it, and the die then turned over and quenched, face down. Water should be splashed on the sides of the die while the face is cooling in the water.

Although water is generally used for hardening when carbon steel dies are being quenched, oil is often used for dies that do not require such a degree of hardness as is obtainable with water. In quenching alloy steel dies, oil should always be used in preference to water. Oil will produce less distortion and cause less risk of breakage than water. The oil should be circulated through coils in the tank and maintained at a temperature of about 100 degrees F. In quenching alloy steel blocks, they are entirely submerged, face downward, until they are covered to a depth of 12 inches. The blocks should be kept in motion and remain in the quenching oil until they have cooled to a temperature of 300 degrees F., when they are drawn. The determination of this temperature may be obtained by the use of a thermometer or by applying tin-lead alloy shavings, which melt at a temperature slightly above that required for withdrawing the block.

Drawing the Temper

All die-blocks should be drawn immediately to a hardness of from 50 to 80 scleroscope, the exact hardness depending on the work to be done, the nature of the impression and the material the dies are made from. Oftentimes, the hardness requirements are determined solely by the hardener's personal experience and judgment, so varied are the factors to be considered. Under no conditions should dies be allowed to lie on the floor after heating, as they are likely to become injured or accumulate a coating of rust before being drawn. Practice regarding the drawing of die-blocks varies in different shops, and is influenced considerably by the size of the block. In one shop where all blocks are drawn back in a furnace, they are permitted to cool completely in the quenching bath, and are then drawn at a temperature of from 400 to 500 degrees F. for a period of about three and one-half hours and allowed to cool in the furnace. It has been found that this procedure will give the desired scleroscope reading for the particular kind of steel used.

If the die-blocks are drawn before they are permitted to cool completely, as mentioned in an earlier paragraph, excellent results will be obtained without the use of a furnace. The method used for small and medium-sized carbon steel blocks is to place the blocks, still very warm, shank downward on a hot iron drawing plate, leaving the impression in full view, and permitting scleroscope readings to be taken from time to time as the color indicates the approach to the proper hardness. The drawing plate may be heated by placing it on a gas or oil-fired brick oven, or by any other convenient means. Readings should be taken in several places, the surfaces being wire-brushed before the readings are taken. An allowance should be made of from three to five scleroscope numbers for the steel to gain in hardness during cooling. This amount will be governed somewhat by the size and shape of the die and the kind of steel from which the block is made. As soon as the desired hardness is obtained, which will be after the die impression becomes blue, the die is removed from the plate and the draw checked by pouring oil in the die impression.

The following modification of the treatment frequently used, will give excellent results for large annealed carbon steel die-blocks, this being the only heating that the dies receive. After heating, quench the dies, face downward, all over for a few seconds in circulating water; then raise until the face is submerged about 3 inches, keeping a spray of water, which rises from within the tank, in contact with the face of the die for about 1½ minutes. The shank will then show a dull red, caused by the heat radiated from the center of the block, which has been reduced but slightly by the quenching. In drawing alloy steel blocks without using a furnace, they should be quenched all over in oil to reduce the red exterior heat to a dull red color. The dies, whether carbon or alloy steel, are then set shank down on the floor and permitted to cool gradually. It is during this cooling period that the refinement and drawing back of the face occurs. The heat for drawing the temper is that retained in the center of the die.

Records of Heat-treatments

The following detail connected with the hardening of dies is followed by a large drop-forging concern located in the Pittsburg district. The dies are numbered and a card index file is kept, by means of which there are recorded the length of service of the die before it is necessary to resink the impressions, and its entire history as regards the nature of the work produced and the number of forgings received from the impression. This is an excellent check on the hardening process, and may be used to good advantage to so modify or alter the hardening procedure that failures rarely reoccur on the same type of die-blocks. In this way, if any question as to the proper heat to use or any data relative to quenching should arise, the correct method may be determined by reference to the record of similar cases.

The actual production of drop-forgings will be dealt with in a later article of this series, which will appear in November MACHINERY, in which a description will be given of the method of drop-forging different classes of work. The information contained in this series of articles has been furnished mainly by the J. H. Williams Co., Brooklyn, N. Y., and the Union Switch & Signal Co., Swissvale, Pa.

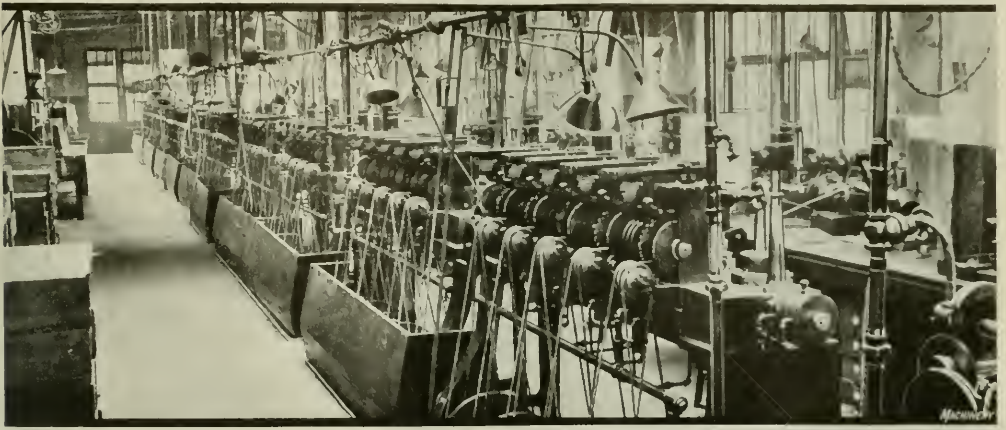
BRITISH ENGINEERING STANDARDS ASSOCIATION

At the annual meeting of the British Engineering Standards Association recently held in London, the annual report presented reviewed the work of the association. There are now more than 1500 engineers who give their time and experience to this important work in Great Britain, often at great personal expense and inconvenience. While engineers generally have taken the keenest interest in the various problems submitted to the association, business men, it was stated, have not been as thoroughly impressed as they should be with the commercial value of standardization. Last year about $60,000 was expended on this work, of which the industry of Great Britain contributed about $40,000, the remainder being government grants. The various national standardization committees are assisting the trend of international agreement in engineering matters, as far as practicable.



Automatic Machines in a Watch Factory

Machines, Devices, and Methods Employed in the Plant of the Waltham Watch Co., Waltham, Mass.—Third of a Series of Articles

THE automatic machines described in the first two articles of this series (see August and September MACHINERY) are used in performing the various machining operations on pillar plates, barrel and train bridges, and balance cocks, which enter into the construction of a watch. A number of additional ingeniously constructed automatic machines are described in the present article.

Pinion-making Machine

One of the interesting machines is that used for producing the various pinions of a watch complete from bar stock. Some of these pinions are so small that a piece of dough is used to pick them up, and they are removed from the dough by tweezers. It is interesting to note that these tiny pinions are in most cases machined with two cuts for each surface—a roughing and a finishing cut—just as in machining larger work.

A view of the top of the pinion-making machine is shown in Fig. 15. Each pinion has a number of leaves (or more properly, teeth) and this machine also cuts these leaves. The end of the stock can just be seen at *A* projecting from the chuck. The chuck which holds the work is air-operated, and can be advanced or receded to carry the work under the cutters which mill the leaves and to return it for the beginning of the next cut. The circular cutting tools, of which there are nine, are carried in a circular cutter-head. The cutter-head is indexed by means of a ratchet, located at the center of the cutter-head spindle and covered by a guard. The ratchet indexing mechanism carries a retainer pawl for locating the cutter positively, when the cutter-head is indexed. A set of individual stops provides for setting each tool after grinding, so that in relocating the tools, the previous position of each will be maintained. The collar which carries the set of stops is indicated at *B*.

Two cuts are taken in machining the teeth in a pinion, a slitting saw and a forming cutter being carried on one cutter-spindle *C*, with provision for proper location of each, this being determined by the feed movement of the slide on which the cutter-spindle arm *D* is carried. These milling cutters are fed down by air pressure exerted through the cylinder *E* and the finger *F*, and the cutters are raised by a spring to permit indexing of the work preparatory to taking the next cut. The index mechanism is a ratchet device which operates when the air countershaft is reversed, during which time the driving belt slips on the pulley. The cam shown at the front of the machine actuates lever *G* to advance and recede the work during the machining of each pinion. There is another cam in back of the spindle-feed cam which controls the operation of the cutter-head slide by the regulation of the air valves by means of which this movement is actuated.

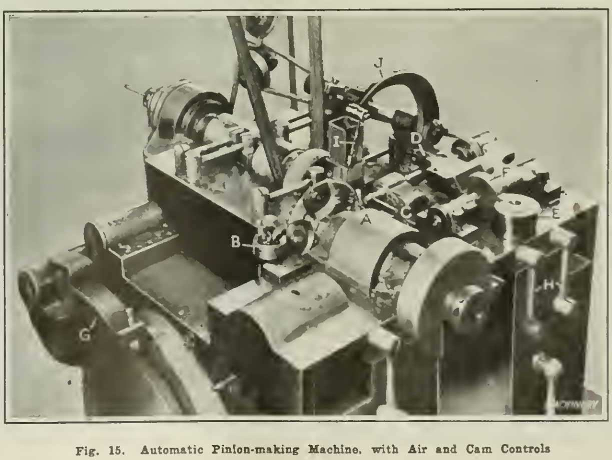


Fig. 15. Automatic Pinion-making Machine, with Air and Cam Controls

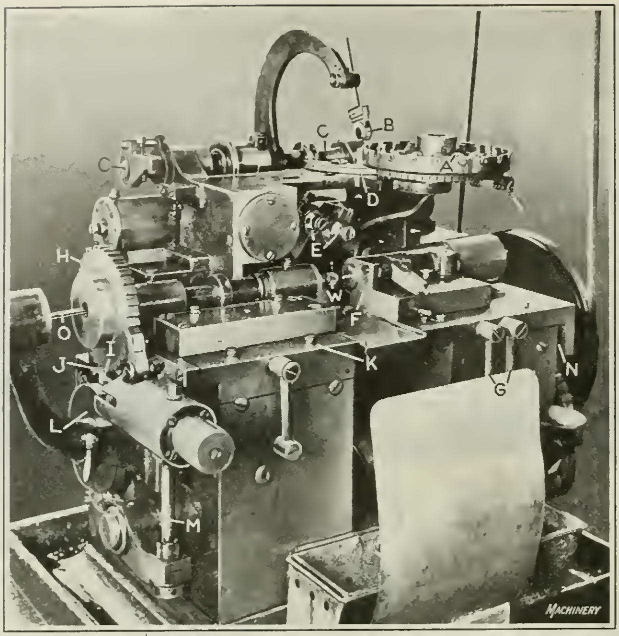

Fig. 16. Automatic Machine in which the Teeth are cut in Steel Wheels or Pinions

The air connections which deliver the air directly to the slide are shown at *H;* similar air delivery tubes are also shown at the opposite end of the machine.

A wire clip *I* picks up each piece as it is being cut off, and this clip is swung into position by an air valve which controls the movement of the shaft to which the over-arm *J* is attached. As soon as the pinion has been severed and picked up and the arm has been raised to the elevation shown, the shaft is given a quick longitudinal movement which results in snapping the pinion from the clip, and letting it drop into a receptacle. The work which this machine produces must be accurate to a very high degree, because the ends of the pinion staff pivot in the jewels or bushings of the watch, and the limits of manufacture allow no variation in size, although it is, of course, necessary to select the jewel bearings so that the holes will receive each pivot properly.

Steel Wheel Cutting Machine

A machine which cuts the teeth in steel wheels, or gears, for watches is illustrated in Fig. 16. Ten or twelve of these wheels are loaded on an arbor, and the arbors are located in suitable pockets in a disk feeder-plate, as shown at *A*. The arbors are picked up by a clip *B* attached to an over-arm that is fastened to shaft *C*. This shaft may be oscillated to swing the work held in the clip down in line with the centers between which it is held during the cutting of the teeth. An air-operated plunger produces this downward movement and the arm is returned to its normal position by spring action. The shaft is also moved to the right pneumatically, when picking the arbors out of the feeder-plate, and this movement causes pawl *D* to index the plate and bring the next arbor into position to be picked up by the clip. The movements of this shaft are governed by the cam action which releases the various air valves.

There are two cutter-heads *E*, one for roughing and one for finishing, each of which is lowered into the operative position by a connecting arm. These connecting arms are operated by air cylinders, one at each side of the machine. The tailstock *F* has a female center to engage the work-arbor, and is given a sliding motion, to permit the arbors to be loaded, by the direct application of compressed air. The two tubes by means of which the air is delivered from the cylinder to the tailstock are shown at *G*.

The work *W* is indexed by ratchet *H* and a retainer and take-up pawl. The take-up pawl *I* is especially designed with a heel that forms a wedge between the engaging toe of the pawl and pin *J*. The reciprocating motion of this pawl is air-actuated, and constitutes a locking device which locates the work positively as it is indexed. The air cylinder for operating the indexing mechanism is shown at the left-hand end of the machine.

After each index movement has been completed, and during the time that the saws are in the operative position, the slide *K* is fed forward by cam *L* and a fulcrum lever which raises and lowers stud *M*. The end of this stud bears against a lever which operates the air valve by means of which the feed motion is actuated. A single air tube which delivers air directly to the slide is clearly shown in the illustration. At the opposite end of the slide, in the space shown at *N* are placed two springs which return the carriage after the feeding movement has been completed. An air cylinder and plunger *O*, supported by an outboard bracket at the left end of the machine, constitutes the knock-out mechanism for displacing the arbors from the spindle at the completion of the operation.

Plate Numbering Machine

Train bridges and pillar plates carry identification numbers, and these numbers are stamped by an automatic machine, such as illustrated in Fig. 17. By the use of this automatic machine, it is possible to number forty-three pieces per minute, with six figures each. Slide *A* carries the holder *B* in which the plates are located, and this slide is fed back and forth under the numbering tools by cam *C* on the end of the camshaft and a lever *D*, the fulcrum point of which may be changed by relocating the knurled pin *E* in one of three holes, in order to vary the rate of feed as

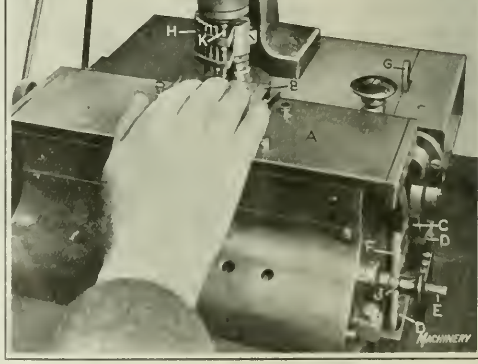

Fig. 17. Numbering Machine for Pillar Plates and Train Bridges

required for different spacings of the numbers. The fulcrum lever operates the vertical stud *F*, the upper end of which bears against a lug on the under side of the slide to produce the forward movement, and springs at the opposite end of the slide provide for its return. The camshaft of the machine extends through the frame at the rear, and is driven from the driving shaft at the front by gears, the gear on the camshaft being operated by a friction clutch to engage or disengage the two shafts. Lever *G* operates this friction clutch, permitting the feed of the slide to stop, as well as the movement of the turret. Under ordinary operating conditions, however, the machine runs continuously with the friction clutch engaged.

The turret *H* is reciprocated by cams or numbering dials carried on shaft *J*. A series of pawls and ratchets, operating in conjunction with springs, positions the number dials so that various stops carried on collars located between the ratchets control the timing and positioning of the angular movement of the turret. There are ten numbering tools or holders, the downward movement of which is actuated by the hammer *K* and the return by individual springs. The hammer is operated in both directions by air, the air cylinder being shown at *I*. The rapid trip-hammer action which is produced by this mechanical arrangement results in accurately spacing the numbers, which progress consecutively by the cam arrangement that brings different numbering tools under the hammer.

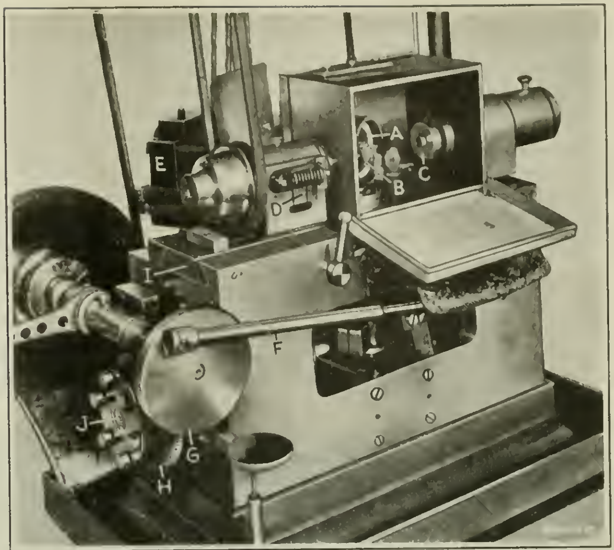

Fig. 19. Air-operated Radial Grinding Machine on which the Screw-heads are ground Convex

Wheel Reboring and Recessing Machine

Small brass wheels, used in the gear trains of watches, have their central hole produced on the machine illustrated in Fig. 18. The operation performed on this machine is that of enlarging the previously drilled hole and of cutting a recess around the hole, forming a shoulder with the rest of the hub. The wheels are loaded into a vertical magazine *A*, and are fed upward by the application of air and gripped by a pair of jaws on arm *B*. The jaws are operated by a toggle-jointed lever *C* when a pin *D* is brought against the vertical post *E*. The position of this post may be adjusted by releasing a pin-lever, which clamps the plate on which the shaft is carried.

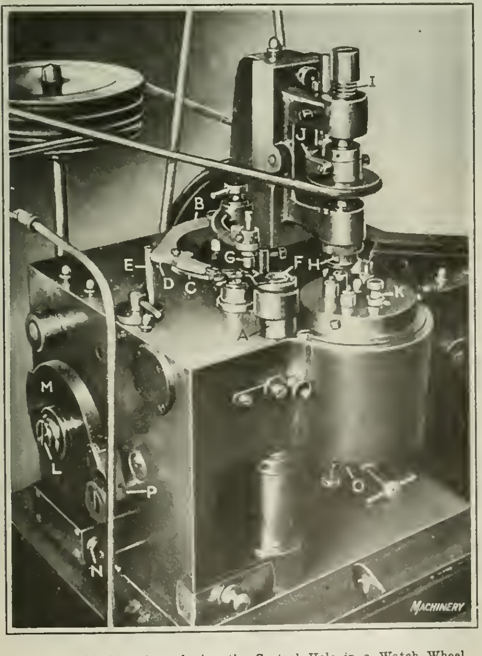

Fig. 18. Machine for reboring the Central Hole in a Watch Wheel and cutting a Recess around the Hole

The air in the vertical magazine forces up the wheels (one of which is shown at *F*) until they contact with stop-pin *G*, at which time they are gripped and deposited in the chuck of the machine. The arm which carries the stop-pin is lowered by cam action and raised by means of a spring, the mechanism being enclosed within the machine frame. The turret of the machine is indexed from station to station, but the tools do not revolve during the cut. To permit the wheels to be deposited in the chuck, it is necessary to stop the spindle so that an opening *H* will always be in the same position, so as to permit the work to be passed through it. The spindle is stopped at a definite place by a cam which controls the vertical feed movement of the spindle head, so that the spindle will be raised by the coil spring *I* to a higher point than it would be ordinarily between each index movement. The additional upward travel brings a dog, on the top of the pulley, into engagement with a finger at the rear of the spindle yoke *J*. This not only stops the spindle in the correct position, but also locks it during the loading operation, the belt slipping while the spindle is thus locked.

The nose of the spindle chuck has a back taper so that as the wheels are released from the jaws, after arm *B* swings the work through opening *H*, they drop down and are supported from the outside diameter, seated against the tapered surface of the hole, in which position they are held down by a spring plunger. Post *K*, mounted at the first station of the turret, acts in conjunction with the spindle plunger to seat the wheels evenly in this back-tapered spindle hole. At the completion of the various operations post *K* is raised by means of the cam, thus dislodging the wheel from its position and permitting it to be swept to the right into a chute.

In addition to the upward feed of the spindles, which is produced by lever *O*, controlled by cams, there is a slight lateral feed movement imparted to the spindle that carries the facing tool by means of which the recess is cut. This movement is taken care of by a specially designed cam, which is timed by the turret index device. This mechanism is operated by a sector gear actuated by air, the turret being locked by the familiar ratchet and pawl arrangement. The machine is equipped with the usual worm and worm-wheel drive to the camshaft *L*, which carries the various cams to trip the air valves, as well as the feed-cam for governing the vertical travel of the spindle. The feed-cam *M*, working in conjunction with air plunger *N*, operates lever *P* on which the feed-lever *O* is carried. The production rate of this machine is from 210 to 250 wheels per hour.

Finishing Watch Screw-heads

The steel screws used in a Waltham watch have convex heads, which are finished by a rather ingenious method to produce the mirror finish required. Referring to Fig. 20, it will be seen that these screws are assembled into steel balls. These balls, which are hardened and ground, contain holes in which the screws are carried during the finishing of the heads, and the method of loading these balls is of considerable interest.

A quantity of screws is placed in a hopper *A*, when the spindle frame is in a vertical position, and then the spindle frame and hopper are swung to a horizontal position, as shown in the illustration. The steel balls have a central tapered hole and are placed on the end of an arbor in sliding spindle *B* and advanced into the hopper and brought into contact with the screws. An agitator is provided for the hopper, and the spindle is hollow, so that by applying a suction air line to the spindle and providing suitable holes in the nose of the tapered arbor on which the ball is assembled, the screws will be sucked into the holes as the ball is revolved. A thirteen-pound pressure produced by suction is employed, and by simply sliding the ball into the revolving hopper and withdrawing it, every hole in the ball will carry a screw, although occasionally the operator is required to reset a screw which is not properly entered in a hole. After the ball has been withdrawn to the position shown in the illustration, it is treated to a solution of silicate of soda and placed on the spindles as shown to the right, directly over a hot-air line connected to an electric stove *C*. The spindles on which the balls are thus suspended are driven by a belt and pulleys. As the balls revolve, the silicate of soda is dried on, and the screws are thus prevented from being dislodged when the heads are subsequently machined.

The heads of the screws are machined by stoning on a pneumatically operated radial type grinder, using a cup-wheel *A*, Fig. 19. A loaded ball *B* is shown located on the work-spindle. The loaded balls are pressed on the work-head spindle by the air-operated head *C*, which positions the ball accurately relative to the center of rotation of the wheel-head *E*. The spindle bearing has provision for locking the spindle after the position has been established, and for releasing it when a ball carrying unground screws is to be located. The locking of the spindle is accomplished by the application of air to the slotted section *D*, and the release by a coil spring attached to the front of the bearing.

The wheel-head *E* is oscillated through its angular travel by the connecting-rod *F*, which has a telescopic connection with the head and which is given a crank motion by connection to the disk *G*. The disk is driven through a clutch on the worm-shaft so that it may be disengaged from the constantly running worm-shaft. Worm-wheel *H* is attached to the outer end of the camshaft *J* and is driven by the previously mentioned worm. On this shaft at the opposite end of the machine there is a cam which operates a lever arrangement for feeding the work-slide *I* forward as the grinding wheel is oscillated over the heads of the screws. The release for the friction clutch which connects disk *G* with the worm-shaft is controlled by a cam on the outside of the worm-wheel.

After the heads have been stoned, they are finally polished by mounting the balls received from the stoning operation on the spindle of a similarly designed machine, which has two opposed spindles that are operated by hand-levers. The polishing is done with boxwood laps, cylindrical in shape and cupped out on the end to conform to the curvature of the steel balls. These wooden laps are charged with "Acme" polish, made by the George Zucker Co., Newark, N. J. This abrasive is of finer grain than either flour emery or crocus. The production time for both the stoning and polishing operations on average size work is 250 balls per day. These balls have a holding capacity of from 30 to 150 screws each.

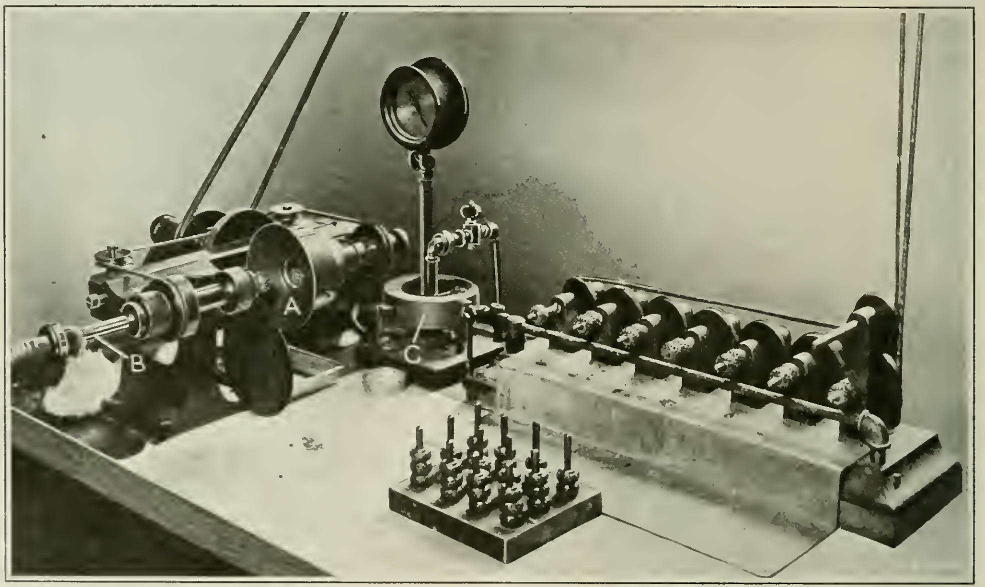

Fig. 20. Equipment used for loading Steel Balls with Watch Screws preparatory to grinding and polishing the Heads

ADAPTING MACHINE TOOLS TO MOTOR AND SILENT CHAIN DRIVE

By EDWARD H. TINGLEY

While there may be a difference of opinion as to whether it is preferable to drive machine tools by a belt from a countershaft, or by a direct motor drive, or a motor drive through a silent chain, the conditions are frequently such that a silent chain drive is the only type of drive that can be used satisfactorily. The advantages of a silent chain drive need not be enumerated here, but in working out new designs, machine tool builders should take into account the fact that many of their customers will use chain drives with their machines. The application of motors and chain drives to a variety of machine tools in a certain shop brought up the following problems.

Method of marking Ends of Machine Tool Drive Shafts

Changing Machine Tools from Belt to Motor Drive

The first problem encountered in changing a machine from belt to motor drive is that of determining the proper speed of the drive shaft. The latest catalogues of the machine builders usually give the speeds for new machines, but when a machine which has been driven by belt for several years, for instance, is moved to another part of the shop where conditions make it impossible to use a countershaft, and a motor and chain drive have to be installed, it becomes something of a problem to determine the proper shaft speed. Old catalogues are not always available and new catalogues in most cases do not give specifications for old type machines. The speed at which the drive shaft has been driven is not an indication of the speed that should be employed with a chain drive.

A chain drive once installed is not easily changed, while in the case of a belt drive it is a simple matter to change the pulleys in order to obtain a change in speed. Nowhere on any of the machines which were converted from belt to motor drive, in the shop referred to, was there any information relative to the speed at which the designer intended the drive shaft to run. Therefore, it was necessary first to determine the spindle speeds, then calculate the drive shaft speed, taking into consideration all gearing or intermediate belt drives, and install the chain drive accordingly. Why is it not possible to have the manufacturers of machine tools mark the correct speed in the end of the drive shaft? The speed should not be painted on the belt guard nor printed on a tag tied to the countershaft, as more than likely neither will be in evidence a year or more after the machine is purchased. It is also necessary to know the direction of rotation of the drive shaft when setting up a machine. The accompanying illustration shows how the end of a drive shaft could be marked to give the necessary information regarding speed and direction of rotation.

Correct Motor Speed

Some manufacturers have already adopted the plan of marking the ends of the drive shafts of their machines. The marking of a shaft in this way is most important in machines that depend on the splash system of lubrication for the gearing. The daily loss in production resulting from too slow a speed may be hardly noticeable, and yet the yearly loss may reach a considerable amount. Many machines of the latest design have a constant-speed drive shaft with change-gears to obtain a variety of speeds. This type of machine can be easily equipped for operation by a constant-speed induction motor. However, designers should so determine the drive shaft speed of a machine that it will have the proper ratio to the 1150 or 1750 revolutions per minute of standard motors. About the smallest motor pinion used with silent chain drives contains nineteen teeth of possibly $\frac{1}{2}$- or $\frac{5}{8}$-inch circular pitch.

Using the two customary motor speeds—1150 and 1750 revolutions per minute—the drive shaft speed must be such as to allow a sufficient number of teeth in the silent chain gear to provide for the necessary mechanical construction of the hub, flange, etc. A speed of 400 to 450 revolutions per minute of the driving shaft will give a satisfactory ratio with motors having a speed of 1150 revolutions per minute. Most manufacturers of chain drives advise against using a high peripheral speed of the chain, as this has a tendency to lift the chain off the teeth. Experience seems to indicate that (considering repairs to motors, interchangeability, and general adaptability of motors to machine tools) 1150 revolutions per minute is the best speed for all shop motors, either belt or chain drive, and 1750 revolutions per minute is satisfactory for direct gear-driven automatic machines.

Location of Motors

Another problem encountered in installing motor chain drives is that of finding a suitable place on the body of the machine on which a bracket for the motor can be mounted. If the drive shaft is located near the floor, the motor can be bolted to the floor, provided the center distance between the motor shaft and drive shaft is not more than 30 inches. If the drive shaft must be located a considerable distance above the floor, provision should be made in the design of the machine to permit the mounting of a suitable sized motor bracket. A flat surface or machined pads cast integral with the frame of the machine will make the work of mounting a motor much easier.

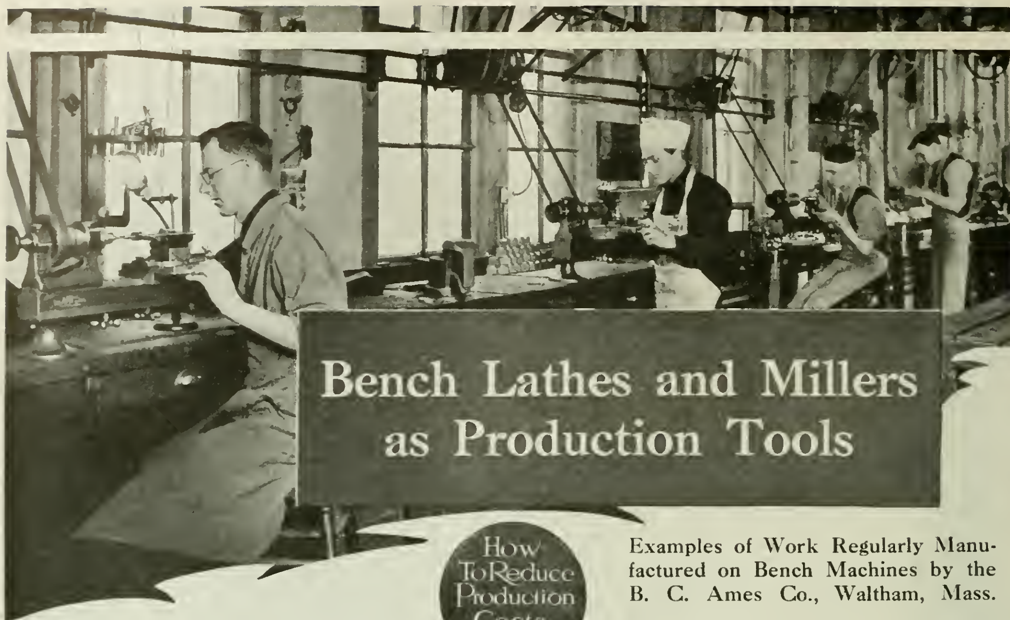
Selection of Motor

Within the last year, one of the largest motor manufacturers has put a motor on the market, which, when run at full load will attain a temperature rise of 50 degrees C., but no overload capacity is guaranteed. Compared with the old rating of a full load at a rise in temperature of 40 degrees C., it would seem that the new motors are over-rated about 15 per cent. When the machine tool catalogue calls for a 5-horsepower motor, will a motor having a rise in temperature of 40 degrees C., with a 25 per cent overload capacity be required, or will the motor with no overload capacity, but a permitted rise in temperature of 50 degrees C., prove satisfactory? When the catalogue reads "3 to 5 horsepower" the motor selected should be either a 5 horsepower, no overload, or a 3-horsepower motor having a rise in temperature of 40 degrees C.

In the majority of cases, too large a motor is used on machine tools, thus giving poor load conditions on the motor and resulting in low efficiency and unnecessary expense for unused power. Even in the steadiest of production work, there are always intervals in the cycle of operations when the motor is pulling only the friction load of the machine. This makes the average load on the motor considerably lower than would be expected, and should be borne in mind by those who write the specifications for machine tool catalogues. The requirements should be made to agree with the standard sizes, that is, the catalogues of machine tools should specify standard size motors or motors of sizes most easily obtained such as 1, $1\frac{1}{2}$, 2, 3, 5, $7\frac{1}{2}$, 10 and 15 horsepower, etc.

* * *

In a recent Commerce Report, it is mentioned that an American manufacturer who has been investigating the market for bolts and nuts in Norway states that German firms now almost completely control the Norwegian market in this field. It is stated that German firms are now quoting lower prices and filling orders in less time than domestic Norwegian factories.



Bench Lathes and Millers as Production Tools

How To Reduce Production Costs ?

Examples of Work Regularly Manufactured on Bench Machines by the B. C. Ames Co., Waltham, Mass.

BENCH machines are rarely considered as production equipment. In most cases they are regarded as precision tools, but are not regularly made use of where quantities of parts are to be made even though a high quality of the product is desired. There appears to be no reason, however, why certain classes of work should not be manufactured on a production basis with machine tools of the bench type. Although these machines are regarded as precision equipment, and are suitable for high-grade production work, when large quantities of high-grade work are to be made the hand screw machine or the floor type milling machine is generally selected for the work; but the bench machine is often just as suitable for general manufacturing purposes. There are also the factors of lower first cost, conservation of floor space, and general applicability of bench machines, which should receive consideration.

In order that machines of the types mentioned may be better appreciated as production tools, a number of operations regularly performed on bench lathes and milling machines by the B. C. Ames Co. in their factory at Waltham, Mass., have been here selected. These jobs are performed with Ames equipment, most of which is standard, and all of which can be readily applied to the machines. The Ames lathes and bench millers are made with standard size ways, so that the headstocks, tailstocks, index-heads, and other fitted members may be used interchangeably on these two machines. The spindle heights are also the same, and the collets used are identical.

Grinding Bearings in Collet Chucks

The spring collets used in the Ames machines are ground internally to form a bearing surface for the work to be chucked. This is one of the regular production jobs handled

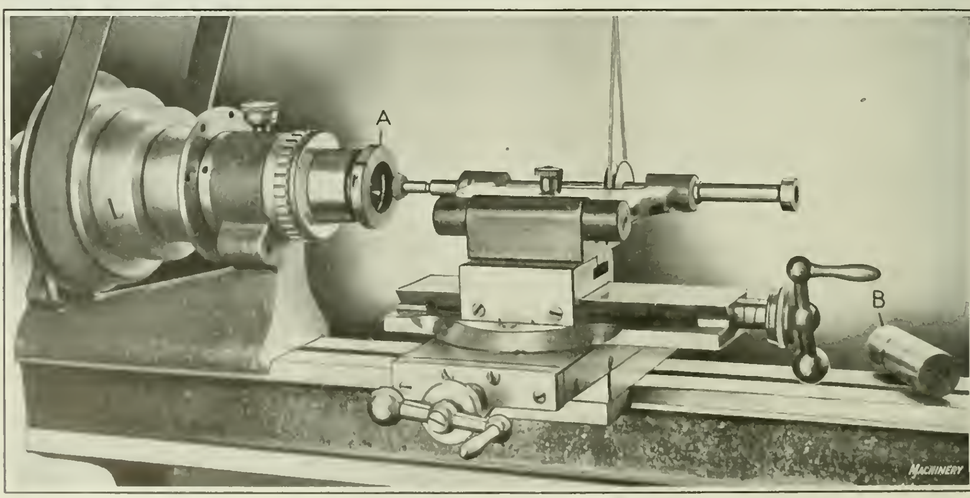


Fig. 1. Bench Lathe Set-up for grinding Internal Bearing Surfaces in Spring Collets

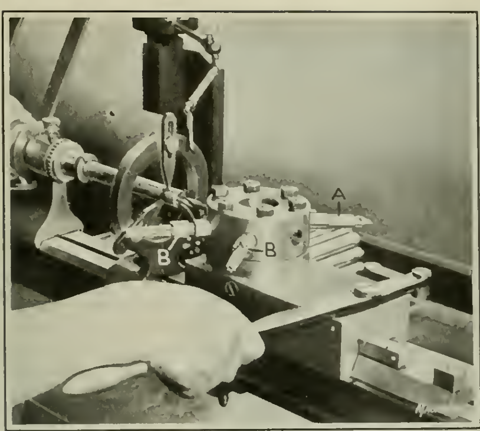

Fig. 2. Machining the Taper Hole in Tail-spindles on a Bench Lathe

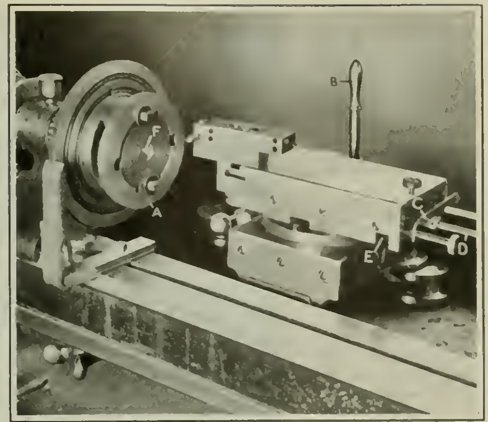

Fig. 3. Equipment used for graduating on a Bench Lathe

on a bench lathe, and the set-up used in the operation on a 1-inch collet is illustrated in Fig. 1. The traversing grinder spindle runs without oil in steel bushed bearings mounted on the compound slide rest of the lathe and driven by a round belt as shown. The grinding wheel used in this operation is a Norton alundum 36-60 K wheel and operates at a speed of 10,000 revolutions per minute. To prevent the collets from springing while being chucked, a grinding liner *A* is used. This is simply a collar which fits over the end of the collet and which has three spacing pieces to fill the slots in the collet and prevent contraction. The operator feeds the spindle to the proper radial depth with the cross-feed screw and then pushes the spindle in and out until the bearing surface is ground to the proper diameter and to a length of about one inch.

The machine spindle is driven at 1800 revolutions per minute, and this, in combination with the grinding wheel speed, brings the surface cutting speed up to approximately the recommended grinding speed of 5000 surface feet per minute. A "Go" and "Not Go" plug gage, shown at *B*, is used for inspecting the hole. Production for the 1-inch size of chuck is sixty pieces per day. Beyond the ground bearing surface machined in this operation, another grinding operation is performed subsequently which provides a clearance of from 0.006 to 0.008 inch extending through the chuck. Chucks of small size (less than ¼ inch) are ground on their internal bearing surfaces by using diamond laps. The smallest of these diamond laps is 0.005 inch in diameter, and the operation is performed by simply replacing the grinding wheel with a lap, which has a standard taper shank to fit the grinder spindle.

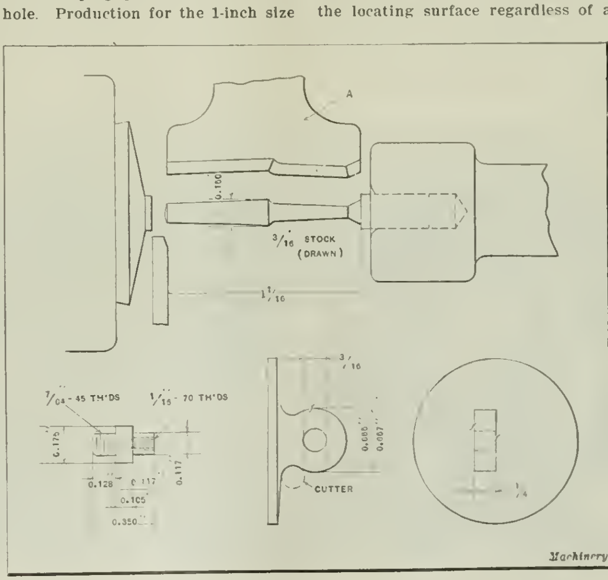

Fig. 4. (Above) Diagrammatic Tooling Lay-out for making Taper Points for Dial Gages: (Below) Two Examples of Work machined with Bench Equipment

Machining Morse Taper Hole in Lathe Tail-spindle

The operation shown in Fig. 2 is that of drilling and reaming a taper hole 2 3/16 inches deep in the end of a tail-spindle for a No. 3 Ames lathe. This work is perhaps a little heavier than is usually conceived of as suitable for a bench lathe, but this is a regular production job which is handled in good time with the set-up shown. The work is held in a steel step-chuck, the step being 3/16 inch deep. The opposite end of the work is supported by a three-jaw brass steadyrest having a foot to fit the lathe bed.

The first operation is spot-drilling with the centering tool *A*, after which the hole is drilled to the required depth, as determined by the regular turret-slide stop. Rough- and finish-reaming operations are next performed in order, with two taper reamers furnished with special stop-collars *B*. By this provision the depth of the tapered hole will always be correct, regardless of variations in the length of the work or in the method of chucking. By bringing the stop-collars up hard against the end of the work, this surface becomes the locating surface regardless of any other consideration. The hole has a standard No. 1 Morse taper, and the time required on this job is five minutes per piece, which includes chucking time. In chucking the work, it is necessary for the operator to use both hands, and to aid him in getting a firm grip on the work, the step pulley is locked by a pin to prevent rotation. These tail-spindles are made of cold-rolled steel, and are casehardened.

Graduating Base of Vise

Another bench lathe job regularly performed is that of graduating the base of milling machine vises, and for this work certain special equipment is needed, as shown in Fig. 3. A rack-and-pinion slide-rest, which is standard Ames equipment, is attached to a right-angle shoe which extends from the rear of the machine and which is located properly by the regular T-slot on the back of the lathe bed. An ordinary pointed drill-rod tool is used for graduating, this being attached in the simplest possible manner to a block carried on the slide-rest in the position shown in the illustration. The work to be graduated is shown at *A*, and is located by a pilot *F* over which the work is slipped. Holes in the work are made use of in attaching the castings to the driving plate on which they are located. The index-plate has 360 ratchet teeth and is held in position by a suitable spring finger. The side of the index-wheel also is graduated, so that the operator can tell at once when he must change the length of the graduation lines which he is cutting on the work; that is, every 5 or 10 degrees a longer line is scribed, and when these marks are reached, adjustment of the tool traverse is made accordingly.

Fig. 5. Drilling the Hole in a Small Stud preparatory to tapping

In cutting the short graduations, the operator simply moves the top slide longitudinally back and forth by means of handle *B*. The other hand is kept constantly on the spring finger with the thumb on the index-plate, so that with each withdrawal of the tool, the spring finger is sprung outward and the thumb used to advance the plate another notch. After a little practice this operation becomes automatic and by observing the graduations on the side of the index-plate, the operator can readily see when the longer lines are to be cut. At this point, he simply throws the latch *C* out of contact with the nut on screw *D*, which permits the top slide to advance on the next forward movement an additional distance equal to the difference in length between the long and short lines.

The tool-block is provided with an adjusting screw for bringing the cutting point of the tool into the same horizontal plane as the center of the work. In cases where the work does not overhang from the driving plate as it does in the present instance, the tool is increased in travel from the beginning of the cut rather than at the end, and when this practice is followed, a spacing block is used for a stop, which is removed from between the end of the stop-screw and surface *E* when cutting the longer graduations. These vise bases are made of cast-iron, and are graduated through 360 degrees in thirty minutes. The lines produced by this method of graduating are even and accurately spaced, and the work can be done much more quickly than by employing an index-head on the milling machine, and in a more satisfactory manner than by rolling the graduations with a knurling tool.

Machining Lever Studs for Dial Gages

Lever studs used on Ames dial gages are first turned and threaded and then faced on one end, center-drilled, and tapped with the equipment shown in Fig. 5. A detail of the lever stud which is made of cold-rolled steel, is shown in the lower left-hand corner of Fig. 4, from which the size of the work and the nature of the operations performed may be readily seen. The collet chuck in which the studs are held, to assure correct facing length, is furnished with an independent stop. The first operation is that of facing to length, locating the work by this stop and using the tool shown in the front tool-holder on the cross-slide. The end of the work is then centered with tool *A*, the spindle in which this tool is carried being laid in the half-open tailstock and fed into the work by the hand-lever *B*.

The next operation is drilling the hole with a No. 50 drill. This is the operation shown in process, and the illustration indicates how the hand-lever is operated to advance the tool-holder until stop-collar *C* is brought into contact with the rear face of the back bearing of the tailstock. The last

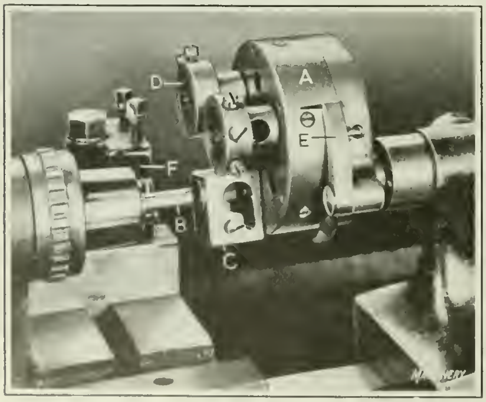

Fig. 6. Bench Lathe with Turret Head, used in making Fillister-head Machine Screws

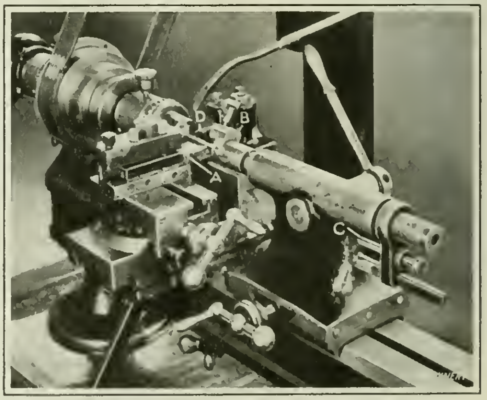

Fig. 7. View of the Bench Lathe Set-up used in making Taper Points for Dial Gages

operation consists of tapping the hole, the tap being shown at *D*. It will be seen from Fig. 4 that this is a 1/16–70 thread tap, and the hole is 0.117 inch deep. Each tool is provided with a stop-collar similar to the drill spindle, so that the depth of hole is accurately maintained from the end of the work after it has been faced, rather than from the collet stop against which it is located for facing to the proper over-all length. In the tapping operation, the operator holds the tap spindle in the half-open tailstock bearing, with one hand, and works the belt back and forth similar to the action of hand-tapping. These lever studs are machined as described at the rate of thirty per hour.

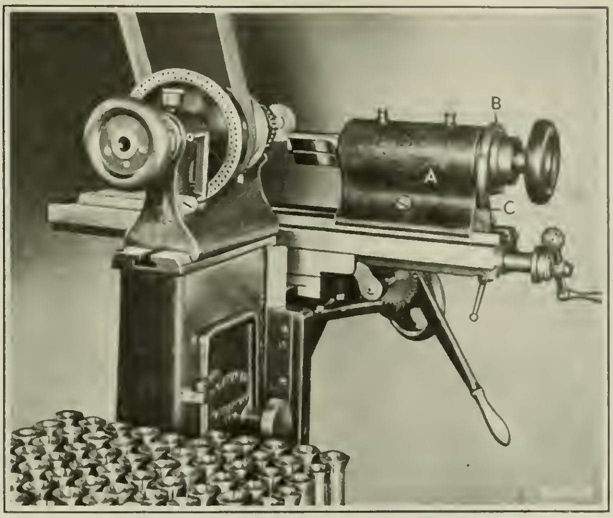

Fig. 8. Bench Milling Machine, and the Set-up used in slotting Spring Collets

Making Fillister-head Screws on a Bench Lathe

The production job, the set-up for which is shown in Fig. 6, is that of making fillister-head machine screws from cold-rolled steel. These screws are ¾ inch long and have a 3/16–32 thread. The tail-spindle which carries the turret-head *A* is located against a stop which bears on the rear end of the tailstock, thus definitely locating the tools relative to the work. The stock, which is shown projecting from the chuck at *B*, is then advanced through the lathe spindle, against a stop located on the face of the turret-head between the box-tool *C* and die-head *D*, in which position it is secured by the lever-chuck closer regularly provided on Ames bench lathes. In turning the stock to the correct diameter, the box-tool is provided with a separate stop on its inside wall in alignment with the stock, which governs the turned length. This stop is adjustable to accommodate various lengths of the same diameter stock. Rough- and finish-threading dies are next brought successively into operation by indexing the turret; this is accomplished by depressing latch *E* which, when the turret-head is in the operative position, is held by spring tension in the registry notches. The threading dies may be adjusted for wear by the screws shown on the outside of the holders. Finally, the work is cut off and the screw-heads chamfered by a tool carried in the rear tool-holder *F*. The production time for this job is three hundred screws per nine-hour day.

Making Taper Points for Dial Gages

Taper points for Ames dial gages are made with the bench lathe equipment illustrated in Fig. 7. A diagrammatic tooling lay-out of this job is also shown in the upper part of Fig. 4, which gives an idea of the size of the part and the relation of the tools used in producing it. The pins are 1 1/16 inches long and they are made from 3/16-inch drawn stock. It will be observed that in Fig. 7 the position of the forming tool and cutting-off tool is reversed from that shown in the diagram, but the method of setting the job up is flexible enough to permit either arrangement. The special forming tool *A* produces a 1-degree taper 9/16 inch long for the body, and a 1½-degree taper ½ inch long for the shank. The stock is fed against a stop *B* attached to the tail-spindle and this stop carries a spring pin having a knurled head. This pin bears against the stock after it has been brought into contact with the stop and acts as a steadyrest for the end of the work, which rests in a V-block directly beneath the stop, and is held in this position by the pressure exerted by the spring pin.

The adjustable stop for the tailstock, shown at *C*, is of similar construction to the one referred to in connection with Fig. 6, and is of vital importance in setting up the job. The tailstock is operated by a rack-and-pinion feed to bring it against this stop, and establish the location of the stop. The tail-spindle is relocated for each piece, which permits the stock to be fed through the spindle further than required for actually making the piece, so that with the end of the stock against stop *B*, the tailstock may be advanced, pushing the stock back, thus facilitating chucking to the correct length. The wide-faced, special forming tool *A* is secured in a rugged tool-holder, and the cut-off tool *D* is carried in a block at the rear of the cross-slide. Although there is nothing unusual about the set-up for this operation, the fact that these pins are produced in quantity, free from chatter marks and to size, with bench equipment at the rate of thirty-six per hour, is noteworthy.

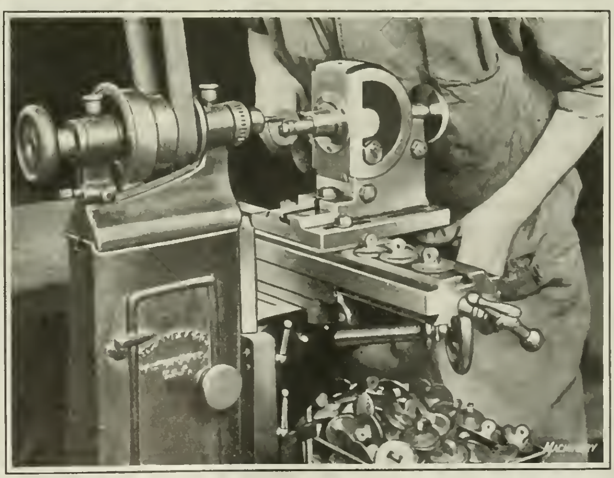

Fig. 9. Milling the Circular Lug on Ames Gage Back on a Bench Miller

Typical Bench Miller Work

A set-up which shows the value of the bench miller as a production tool is illustrated in Fig. 8, the job performed with this equipment consisting of slotting collet chucks. The milling machine is provided with an index-head *A* which has an index-plate *B* and a spring index-finger *C* for positioning the spindle of the head for every 120-degree revolution of the work. The draw-in tube screws into the collet to be slotted, similar to the construction of an ordinary draw-in chuck. The collet has a taper bearing in the spindle and is also located by a stop so that it cannot be drawn in so far as to cause the work to spring together and bind on the saw during the slotting operation. Thus, although the work is chucked on the end that is slotted, the tension is so regulated that the collets are held firmly but without binding on the slitting saw. Hand feed is used for traversing the table during the operation, the length of the table traverse being determined by a stop. It will be noticed that the nose of the spindle is slabbed on three sides to give clearance for the arbor, and to allow the saw to reach through the collet. A 1¾-inch saw, 0.027 inch thick, is used for this operation, and the production time is from fifteen to twenty-one collets per hour.

The hand milling operation shown in Fig. 9 is milling the circular lug on gage backs for Ames indicators. The detail of this part is shown in the lower right-hand corner of Fig. 4, the surface to be milled being indicated by the limit dimensions for the lug, the tolerance on the diameter being 0.002 inch. The operation is performed with an end-mill, which when new is 5/16 inch in diameter, and which is used until it has worn down 1/16 inch. These cutters are made of plain drill rod, and are manufactured in quantities, because the nature of the work causes frequent replacements. The work is clamped to the end of a spindle carried in the index-head, and is then swung around until the cutter fits in the curved surface which joins the lug and the flange of the work, as indicated by the dotted lines in Fig. 4. The index-head is attached to a right-angle shoe secured to the milling machine table, and after the table has been adjusted to position the work for starting the cut, the index-handle of the head is turned by hand, thus swinging the work around under the cutter until the cutter has reached the joining curved surface on the opposite side of the work. The end-mills are necessarily made long in order to reach by the flange of the work, and being slender, care must be exercised to prevent excessive breakage of the tools.

In making the work-arbor, an interesting construction is used. This consists of extending a long center stud through a hole in the arbor, this stud being driven by a pin extending through the arbor. The end of the stud is threaded and extends beyond the arbor, and on it the work is located by the central hole, and then secured in position with a nut. If the arbors were made solid with a projecting threaded slender end, the percentage of breakage of this threaded portion would be high and the expense of making the arbors great. The illustration shows the position of the end-mill at the beginning of the cut and the convenience with which the operator works in the performance of this operation. The end-mill is rotated at 1600 revolutions per minute, and the production is fifty gage backs an hour.

* * *

STEELS RECOMMENDED BY THE GEAR MANUFACTURERS' ASSOCIATION

At the fifth annual meeting of the American Gear Manufacturers' Association in Cincinnati, Ohio, the list of forged and rolled steels given in the accompanying table was recommended for use in the manufacture of gears. These steels were selected with the aim of eliminating, as far as possible, steels which overlap one another in physical properties. The steels are to be identified by the specification numbers employed by the Society of Automotive Engineers, although the properties of some of the steels differ slightly from those of the S. A. E. steels having identical numbers.

Steel 1020 is a straight carbon steel suitable for casehardening. Steel 1030 differs from the regular S. A. E. steel of this number in that the maximum phosphorus content is 0.050 instead 0.045 per cent. This steel is intended for use mainly in an untreated state against an iron or steel casting. When it is desired to harden it somewhat, this may be accomplished by heating it and quenching in water. Steel 1045 is to be known as S. A. E. 1045 special. It differs from the regular S. A. E. steel of this number in the manganese content, the percentage of this element specified being 0.30 to 0.50, instead of 0.50 to 0.80 per cent. This modification gives a steel more suitable for water-quenched gears. Steel 2315 is a standard 3.5 per cent casehardening nickel steel, while steel 2345 is a standard 3.5 per cent oil-hardening nickel steel, and the companion steel to 2315.

Steel 3115 is a chrome-nickel steel suitable for casehardening, both the chromium and nickel contents being low. Steel 3215 is a chrome-nickel steel, also suitable for casehardening, in which the chromium and nickel contents are medium, while steel 3245 is another medium chrome-nickel steel suitable for oil-hardening. Steel 3315 is a casehardening chrome-nickel steel in which the chromium and nickel contents are high. Very high physical qualities can be secured in this steel when it is correctly treated. Steel 3340 is an oil-hardening chrome-nickel steel in which the chromium and nickel contents are high. It is the companion steel to 3315, and like it, high physical properties may be secured by heat-treatment. Steel 6120 is a chrome-vanadium steel suitable for casehardening, while steel 6145 is an oil-hardening chrome-vanadium steel, and the companion to 6120.

How To Reduce Production Costs?

Efficient System of Hiring Men

Methods Adopted by a Large Manufacturing Plant for Insuring the Selection of the Applicants Best Suited for the Work

By RUSSELL J. WALDO

ONE of the principal factors affecting the cost of production is the human equation, and if industrial engineers expect to lower costs, only capable men who are reasonably certain to remain with a concern should be hired. Such employes are to be had if the man responsible for hiring them has any method whereby he can recognize them among other applicants. Satisfactory results along this line have been obtained by the Studebaker Corporation through the use of the methods outlined in the following, and it is believed that by careful application of the same methods, equally good results may be secured by other organizations.

When this system was instituted, a vast amount of work was imposed upon the employment department, owing to the fact that a new plant was being opened, which required a large number of new employes to be hired, in addition to those taken on to meet the ordinary demand. Therefore, it was necessary to have an employment department personnel which would seem a burden to many. This organization is represented diagrammatically in Fig. 1, the employment manager being in general charge of all phases of the work. The assistant manager interviewed all applicants and hired desirable ones. There were four write-up clerks, whose duties consisted of making complete records of all men hired. All of these clerks were usually busy on Mondays and Tuesdays on this work, but during the remaining days of the week when a less number was required for this purpose, some of them were assigned to other duties in connection with the employment department, such as research, completing records, and making out reports. This scheme made it possible to handle all the work of the employment department with a smaller number of employes than would otherwise have been necessary, and gave the write-up clerks a variety of work. The physician was in charge of the physical examination of applicants. The general duties of all other members of the staff of the employment department should be obvious from their titles which are given in the illustration Fig. 1.

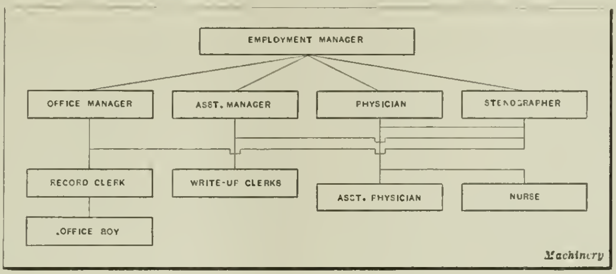

Fig. 1. Chart representing Organization of Employment Department

Plan of Operation

The floor plan of the employment department is illustrated in Fig. 2. An applicant enters door *A*, receives a numbered slip from a clerk seated at *B*, and then takes a seat in either of the waiting rooms *C*. A fence three feet high encloses both of these rooms on the entrance corridor sides. A seat large enough to accommodate four applicants is placed at *D* and this is kept constantly filled by those who are to be interviewed. The men in charge of the waiting rooms seat applicants upon this bench in the order in which they apply. The interviewer, or assistant employment manager, is located in room *E* where he carefully examines each applicant by a system to be described later, and then sends him through the rear door into corridor *F*.

Here a successful applicant waits his turn to have a complete record made by the write-up clerks in rooms *G*. The latter are large enough for a desk and two chairs, and still have sufficient space for moving about. When the record has been completed, the applicant passes into corridor *H* and

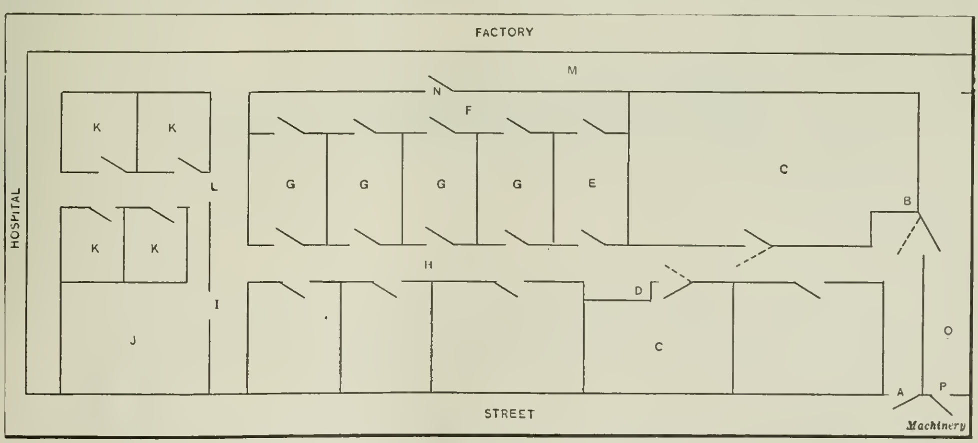

Fig. 2. Arrangement of Waiting Rooms, Offices, and Corridors in the Employment Department

through door *I* into the waiting room *J* of the physical examination department. These examinations are conducted in dressing rooms *K*. After being examined, the applicant passes through door *L* and into corridor *M*, from which he goes to the pay department to receive a clock number. While in the waiting room of the latter department, the new employe is instructed in the use of the time-clock, and his card is stamped.

Fig. 3. Requisition filled out by the Foreman of the Department requiring Additional Workmen

If an applicant is undesirable, he passes from corridor *F* through door *N*, up corridors *M* and *O* and out door *P* to the street. When an applicant is to report for work at a later day, he leaves the office in the same manner, and his record is made by a write-up clerk when he reports for duty. This scheme prevents a man from passing by the general waiting rooms of the employment department.

Forms Used by the Employment Department

When a person applies for a position by mail, a form is sent to him to be filled out, containing questions as to the age, height, and weight of the applicant, whether the applicant is married or single, whether he speaks the English language, what sort of position he desires, where he has been previously employed, and in what capacities. The application form, when returned, is filed according to the position asked for, until a place is available. The requisition used by a shop when additional help is needed, is shown in Fig. 3. This is made out in duplicate, the duplicate being retained by the labor superintendent, while the original is sent to the office manager of the employment department. If the latter is satisfied that an additional man or men are required by the requisitioning department, the form is forwarded to the office of the assistant employment manager where it is filed according to the requisitioning department until a man is assigned to the job. When this occurs, the requisition is sent to the write-up clerks with the man employed. Thus, it not only becomes a part of the record of the employe, but also, when the form is initialed by the interviewer in the upper right-hand corner, gives the write-up clerks the authority to make a record of the man being hired.

A daily record of all requisitions on file is kept on a sheet, so that it is possible to tell every position open by simply glancing at the record. As each man is hired a suitable indication is made on this record so that not more than one man will be employed for the same job. In this way the record serves to keep track of the number of men sent to each department a day. When new requisitions are received, suitable notations are made on the record before the requisition slips are filed.

The information on the daily record sheet is later transferred to a permanent record, which gives the total number of men sent to each department, according to the classes of work for which they were employed. This record includes only those who start to work immediately. A man instructed to return for work at a later date is not recorded until he actually begins working. Such a man is given a slip showing that he has been hired, the department number in which he is to work, and the rate of pay he is to receive. When he returns at the proper time, this slip takes the place of that which an applicant ordinarily receives upon entrance. Persons with employed slips have precedence in going through the routine of the employment department.

A record of each employe is made by the record clerk on the front and back of a large card on which all information obtained by the write-up clerks and from the examining physician is included. There is also plenty of space for recording changes of address and clock number, transfers about departments, wages received per day, etc. The employe is required to sign this card. A notice of factory employment, made in duplicate, accompanies this record. This notice is shown in Fig. 4. The original is used by the cooperative representative in presenting the new employe for physical examination, to the pay department, and to the foreman of the department for which the man was hired. The foreman notes the starting time thereon, and returns the card to the cooperative representative, who delivers it to the pay department where the name of the employe is entered on the payroll, after which it is forwarded to the time department. The duplicate is filed in the employment department as a permanent record.

A small yellow slip is used by the employment department when a man is to be transferred from one department to another. Fig. 5 shows the front of a card filled out by the foreman when a new man is sent to him. The reverse side, shown in Fig. 6, is filled out by the foreman when the man is transferred from the department, is laid off, or leaves of his own volition. When an employe is transferred to another foreman by the cooperative department, notice of the transfer is made on the form illustrated

Fig. 6. Reverse Side of Card in Fig. 5 on which Characteristics of Employe are noted

in Fig. 7. This form is also made in duplicate, the original being sent to the pay department for the issuance of a new clock number, then to the new foreman, who indicates the starting time thereon, after which it is taken by the representative of the cooperative department to the employment department. The duplicate is sent to the employment department, where it is retained until the receipt of the original, after which the original and duplicate are sent to the time and pay departments, respectively.

One of the most valuable records kept by the employment department is that of undesirable employes who have left or been discharged. This record is kept on small cards, filed by name in the office of the interviewer, and contains such information as the starting and leaving date, the reason for leaving, the department number, the foreman under which the employe worked, the rate of pay received, and whether the employe should be rehired or not. It is through the information on these cards that undesirable men are prevented from entering service a second time. Often a competent man without funds appears for employment, and to enable such a man to obtain immediate room and board, an order slip is given to him at the end of the first day. He signs this slip and turns it over to his boarding-house keeper, who presents it to the pay department and receives the amount of money indicated. This amount is subsequently deducted from the pay of the employe. This method has proved an aid to the acquisition of many a good man.

Examination of Employes

In the examination of an applicant, the greatest aid to the interviewer is the series of tests developed to check the actual ability of the applicant to do the task for which he applies. These tests were found necessary because of the costly mistakes made with the former method of briefly questioning an applicant, and they proved successful far beyond expectations. It is, of course, impossible to secure absolute perfection in work of this nature, yet the results have been most satisfactory. A test was made up for every class of work in the plant.

Owing to the labor shortage, it was necessary to determine with the greatest possible degree of accuracy, what each applicant was capable of doing, and to place him somewhere, even if he could not be used on the job for which he made application. To this end the tests were first made out to determine what an applicant was capable of doing. As these were used, revisions and additions were made until the tests served a fourfold purpose. First, they determined what the "floater" type was capable of doing or what he was interested in, so that he could be placed where his abilities, both natural and acquired, would be of the greatest value to himself and the firm. Second, they reduced the labor turnover, through a more careful placing of each applicant. Third, they placed an inexperienced applicant where he would find his natural abilities serving him to the greatest advantage. Fourth, they developed more responsible men.

The tests consisted of asking an applicant questions as to the operation of the type of machine he claimed to have had experience on, the manner in which various attachments are used, the way the machine should be set up for certain operations, the function of the different parts of the machine, and the names of some of the more important parts and units, as well as questions involving general mechanical knowledge in their answer. Photographs of the various types of machines were kept in the office of the interviewer for use in this connection. On some machines photographs were taken of disassembled units and parts for the same purpose. A set of qualifications was prepared for journeymen, to gage whether applicants were really proficient in their respective trades. Another list of questions dealt with the characteristics of the applicant, whether he spent any of his leisure time in studying to improve his abilities, and if not, how he did spend his evenings, etc.

These tests took a great deal of time to make out, verify, and revise, but as it was possible to pass upon at least double the number of applicants in the same time as before, and with greater accuracy, it proved to be an efficient means of employing men. No competent man has ever objected to such a test. On the other hand, he is eager to have the test made, feeling that he has a fair chance to prove his ability. It is the inexperienced man, realizing that he cannot convince the interviewer that he has the ability he claims to have, who objects to the examination.

Inspection of Involute Gear Hobs

Methods Used in Examining the Test Gears—Second of Two Articles

By CARL G. OLSON, Chief Engineer, Illinois Tool Works, Chicago, Ill.

TO transmit uniform rotary motion by gearing, the tooth curves of the gears must have definite theoretical forms, and in practice they must be made very nearly true to these forms. As the involute gear tooth system is the most flexible and the most convenient, it is being universally adopted; and hence we will limit our attention to the inspection of gears having involute teeth. The construction of the involute is well known, but to make this article complete, a reference to the theory will make the principle on which the testing machine operates clearer.

The Involute Test

The tooth curve as shown in Fig. 2 is traced by a point in a string unwinding from a cylinder; and in Fig. 3 an equal line is traced by a point in a tangent rolling on a cylinder without slipping. The fixture shown diagrammatically in Fig. 1, and in Figs. 4 and 5, is constructed on the foregoing theory. The base circle is here represented by a disk, and the tangent by one edge of a flat block on which is mounted an indicator terminating in a contactor point located in the plane of the tangent.

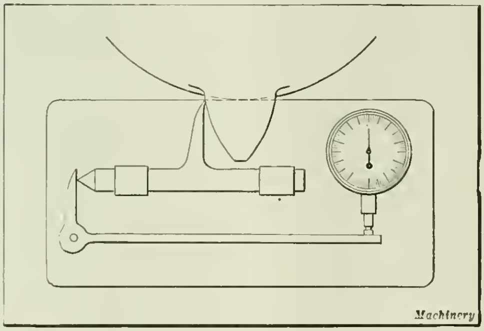

Fig. 1. Involute Testing Machine

The base disks must be of accurate diameters, and these are governed by the number of teeth, and by the pitch and the pressure angle of the gears. A formula for figuring these diameters is given in connection with the accompanying tables of base disk diameters for common sizes and pitches of gears. A groove in the center of the face of the disks is made to accommodate a wire, and it should be of a depth equal to one-half of the diameter of the wire that is used. The edge of the indicator block has a corresponding groove of the same depth as the groove in

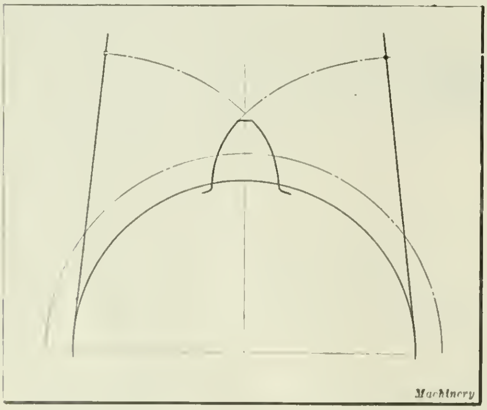

Fig 2. Involute Curve traced by a Point in a String while unwinding from a Cylinder

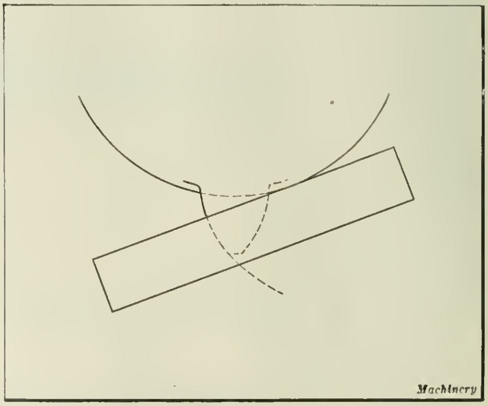

Fig. 3. Involute Curve traced by a Point in a Tangent rolling on a Cylinder

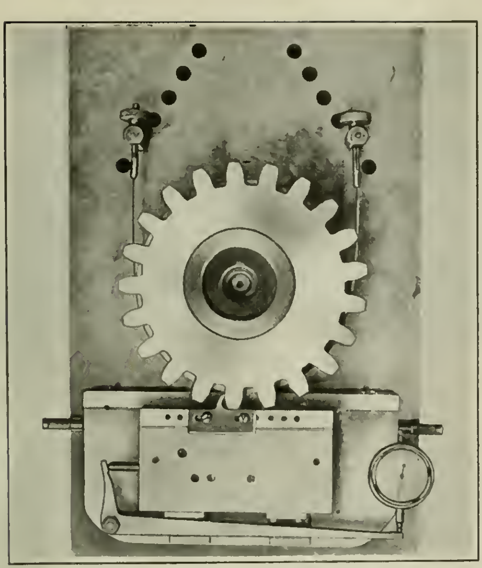

Fig. 4. Testing the Involute Tooth Form of a Spur Gear

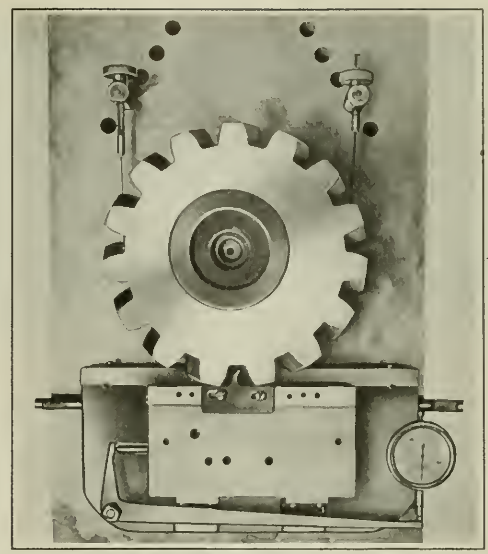

Fig. 5. Testing the Involute Tooth Form of a Helical Gear

the disks. This allows the tangent to roll directly on the base disk, and by having one half the wire in each member, no slipping takes place from the bending of the wire.

To make a test of a gear, the correct base disk is selected and placed on the stud in the table of the machine, after which a spacing collar and the gear to be tested are put in place. The wire bands are then adjusted and tightened. The gear is turned until the face of one tooth acts on the contactor, turning the indicator pointer about one half revolution, when the gear and base disk are locked together with a hand-nut on the stud. The block is rocked on the base disk, allowing the contactor to follow the involute tooth face, while the deflection of the indicator is noted.

If the involute is perfectly true, there will be no deflection of the indicator pointer, but such perfection is hard to obtain. In practice, it has been found that a variation of a fraction of a thousandth inch is not noticeable in the running of the gears.

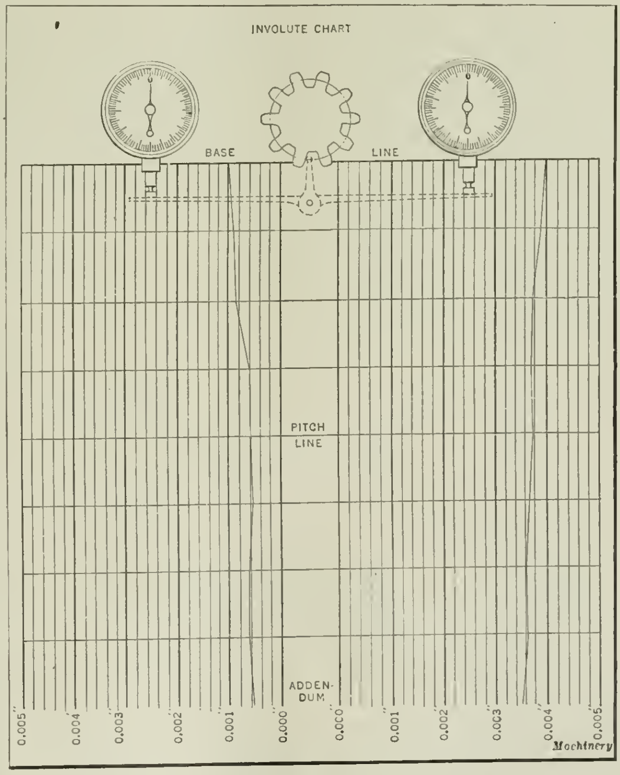

Fig. 6. Chart for recording Results of Involute Gear Tests made on Machine shown in Figs. 4 and 5

The deflection may be recorded in a diagram of the form shown in Fig. 6. The main divisions formed by the vertical lines indicate 0.001 inch, and the horizontal spacing divides the tooth face into eight main divisions headed by the base line, from which the curve is started downward to the pitch line and the addendum line. The base line and the pitch line should be indicated on the gear, but the other lines may be approximated for all practical purposes.

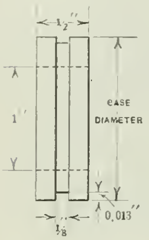
The Jump Test

One of the commercial methods of testing gears is the so-called "jump test," which consists of placing the gears on a gear-testing machine, provided with suitable studs, one of which is mounted in a sliding part acted upon by a spring that tends to force the gears together. An indicator is affixed to the machine in such a manner that it will show the movement of the sliding part and stud when the gears are gently rolled by hand, measuring the "jump" as each pair of teeth meshes. This apparatus is shown in the heading illustration. The maximum tolerance of jump in commercial gears should not exceed 0.010 inch divided by the diametral pitch of the gears.

Dependence cannot be placed upon the jump test for gears that have backlash, because the thin teeth will not roll tightly at the proper center distance, and a closer center distance will not generally show the true condition. To detect the run-out or the eccentricity of the pitch lines, the gears are turned through a complete revolution, but this test does not refer to the correctness of the hob with which the teeth were cut. However, it shows if the gears were

TABLE 1. BASE CIRCLE DISK DIAMETERS

For Testing the Involute Curve on the Testing Machine



The base diameter is equal to the pitch diameter multiplied by the cosine of the pressure angle.

Formula: $BD = PD \times \cos PA$

The depth of the groove is equal to one half of the diameter of the band or wire used on the testing machine.

Machinery

carefully hobbed. The gear-testing machine should be provided with means for accurately measuring the center distance of the gears and means for locking the studs while making roll tests and when checking the backlash.

The Roll Test

When placed on the studs of this machine and adjusted to the proper center distance, the gears should roll without interference and without any noticeable interruption when passing from tooth to tooth, when they are gently rolled by hand with the tooth faces pressed together while rolling. The bearing or rolling contact is carefully noted. To make the bearing show up plainly, the surfaces of the gear teeth may be coated with a thin film of red lead and oil.

The ideal bearing is uniform over the greater part of the face of the teeth, blending gradually out at a point slightly inside the addendum circle. This blending is called the "approach curve" and should be very slight in the case of gears that are not to be heat-treated after hobbing; but in gears that will be subjected to a process of heat-treatment, and, therefore, to a possible slight distortion, this curve should be greater to allow more flexibility in the assembling of gear trains. It has been found that by making liberal approach curves in the tooth profiles of heat-treated gears, rejections due to noisy running have been greatly reduced.

DRESSING WHEELS FOR CONCAVE AND CONVEX GRINDING

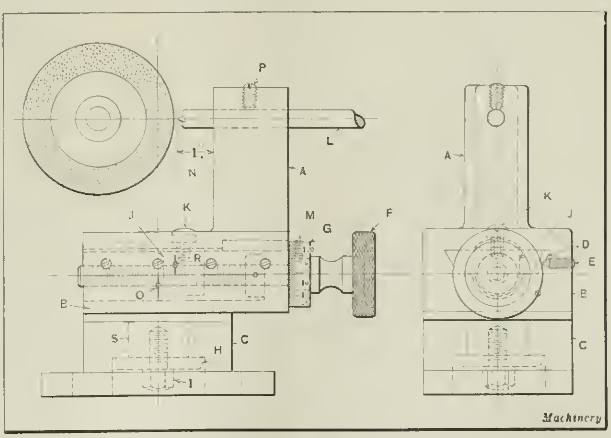
The attachment shown in the accompanying illustration was designed by the writer for use on a universal grinding machine. With it the periphery of the grinding wheel can be given either a concave or a convex form, of any radius within the range of the attachment. This device eliminates the necessity of dressing the wheels with a hand-dresser to conform to a radius gage. The principal parts of the attachment are the diamond-point wheel-dresser holder *A*, which is held to the angular dovetail of saddle *B* by means of gib *D* and screws *E*. Saddle *B* is, in turn, attached to base *C* by means of cap-screw *I* located in the shank *S* of part *B*. Shank *S* acts as a pivot around which part *B* swivels.

Holder *A* can be adjusted on saddle *B* by means of a knurled-head screw *F*, which fits into nut *J* attached to *B* by cap-screw *K*. Screw *F* has an 8-pitch thread, and is provided with a dial *G* having 125 division lines, each representing a movement of the holder *A* of 0.001 inch. Dial *G* is a loose fit on screw *F*, but can be held firmly to it by tightening screw *M*. This attachment has a range for truing wheels up to 6 inches in diameter, and can be used to give the periphery of a wheel either a concave or a convex surface of any radius up to $1\frac{3}{4}$ inches. The device has been tried out in practice, and has given satisfactory results.

In dressing a grinding wheel to a given radius, the device is mounted on the grinding machine table and a diamond-point wheel-dresser inserted in holder *A*. This holder is advanced through the hole until the diamond point projects one inch from the face of the holder, as indicated by the dimension at *N*. Screw *P* is next tightened and dimension *N* checked with a gage. The knee of the grinding machine is then raised until the diamond point is in line with the center of the grinding wheel spindle. The knurled-head screw *F* is then turned until line *R* on the holder *A* coincides with line *O* on the saddle *B*.

This adjustment brings the diamond point directly over the center lines of pivot *S*. Dial *G* is then adjusted until the two zero lines coincide, after which screw *M* is tightened to hold the dial in place. Adjusting screw *F* is then turned until the reading of the dial shows that the device is properly set to true the wheel to the required radius. The wheel is trued by swinging the holder *A* about pivot *S*, the machine being adjusted, of course, to bring the diamond truing point into proper contact with the periphery of the wheel.

Conneaut, Ohio F. A. Gross



Attachment for dressing Concave and Convex Form-grinding Wheels

---

FASTENING PAPER TO DRAWING-BOARD

In making large lay-out drawings that require considerable time to finish, the use of thumb-tacks for fastening the paper to the board is unsatisfactory, especially if the lay-out is to be traced, because the paper is sure to stretch and form ridges between the tacks. A good way to keep the paper flat and avoid the annoyance caused by the triangles or drafting machine coming in contact with the thumb-tacks, is to mount the paper on the board in the following manner: Cut the paper, either a heavy grade of detail paper or "Whatman's Hot Pressed" about 4 inches longer each way than the finished tracing, and use a drawing-board the same size or a little larger than the lay-out paper. After the paper is cut, turn up the four sides about 2 inches from the edge without cutting the corners, and remove any dirt or grease that may have accumulated on the part of the board which is to be covered by this 2-inch margin.

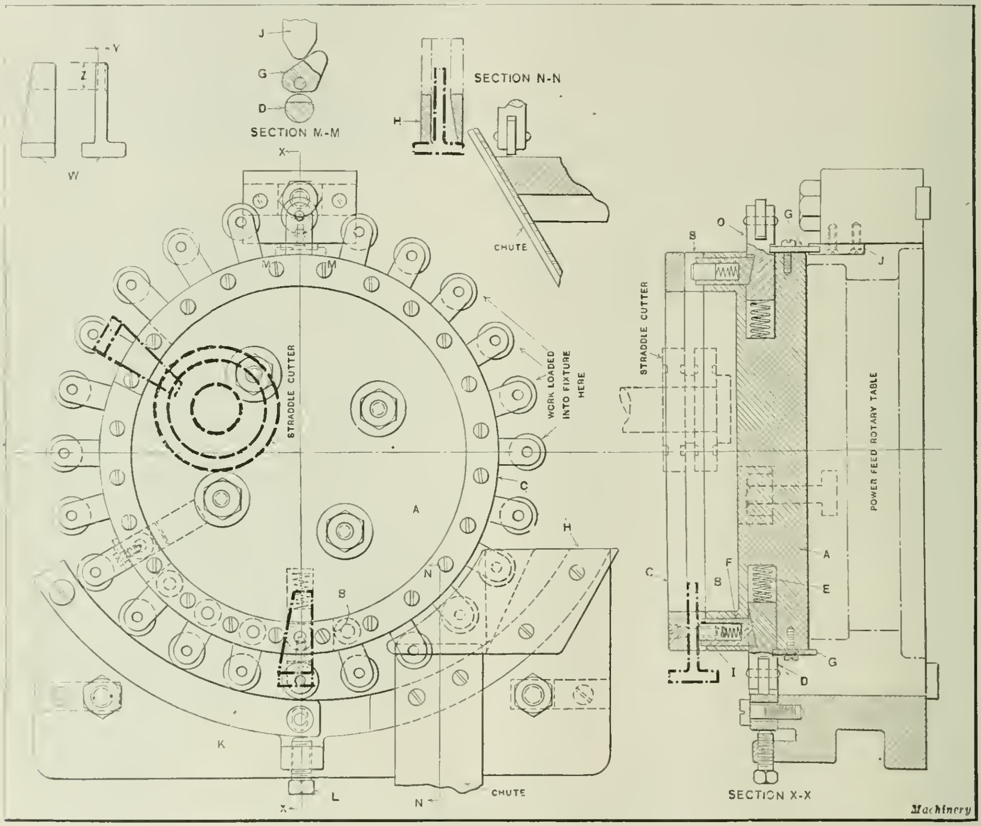
On the inside of this turned-up portion apply a coating of some good library or photographic paste, thinned out with water to about the consistency of liquid glue. Wet the side of the paper on which the paste has been applied with a sponge inside the border of paste. Then place the wet side of the paper on the board and press the upper edge down. Then gently pull the paper out as flat as possible and press the other three edges down smooth. When the paste has taken a good hold on the board, wet the upper face of the paper. The water should not be applied to the portion of the paper directly over the pasted margin; the ridge formed by turning up the edge of the paper for pasting will serve as a guide. Now press down the edges several times with some hard, smooth object, such as the back of a pocket knife, to remove any air bubbles which may be left in the pasted surface.

If the surface of the paper begins to dry in spots, wet the portions that are drying too rapidly so that the entire surface will become dry about the same time. When the paper is thoroughly dry, it will be flat and ready for use. If it is necessary to preserve the lay-out after it has been taken from the board, the drawing should not extend over the pasted border. The writer has found it advisable to stretch the paper down before the end of the day's work so that no time will be lost waiting for the paper to dry. After the lay-out has been traced, cut the paper inside the pasted margin and remove the paper left on the board by rubbing with emery cloth or sandpaper.

Philadelphia, Pa. WALTER A. TEGLER

There are a number of holes drilled radially in base *A*, to receive springs *E* and plungers *D*. Clamp *F*, riding on a bevel on plunger *D*, clamps the work against ring *C* by the pressure of spring *E*. The spring in clamp *F* releases it from the work when the plunger *D* is forced in. Stop *G*, engaging in a slot in the under side of plunger *D*, holds spring *E* in check, keeping clamp *F* released as shown.

Unloading is accomplished by the ejector *H*. As the fixture is revolved, the head of the work hooks into the ejector, which draws it out until it is entirely clear of the clamp, whereupon it overbalances and falls into a chute, which delivers it to a receptacle provided for that purpose. In manipulating this fixture, the operator loads the work into the fixture as the parts are ejected. The auxiliary spring-actuated plunger *I* holds the work in position until clamped. As the fixture rotates, trip-pin *J* trips stop *G* and releases



Milling Fixture with Automatic Clamping and Ejecting Devices

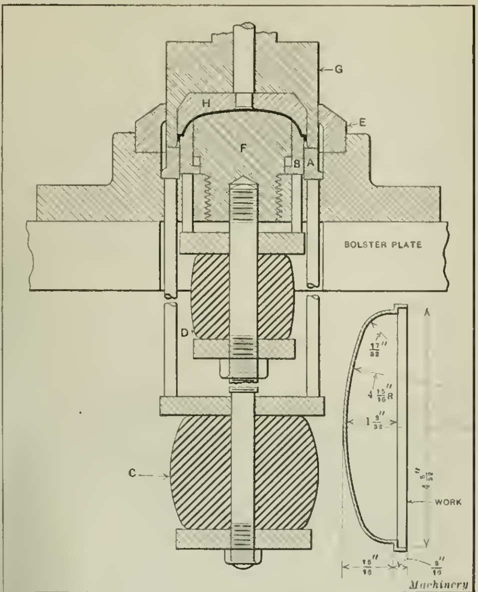
MILLING FIXTURE FOR CONTINUOUS CIRCULAR MILLING

A continuous circular milling fixture for use on a vertical milling machine is shown in the accompanying illustration. This fixture was designed for straddle-milling the ends of aluminum castings such as shown at *W*. The end of the work was required to be machined to a thickness *Y*. As a large number of these parts are used, the fixture was designed for rapid production. The whole fixture comprises the fixture proper, the clamping and releasing members, and the work-ejecting device. The fixture proper is bolted to a standard power-feed rotary milling table. To base *A*, is screwed and doweled the steel ring *C* and spacing blocks *B*. The latter serve also as gage-blocks to locate the work on the tapered side.

plunger *D* which clamps the work while it is carried past the cutter. In unclamping, plungers *D* (which have rollers mounted on them to minimize friction) are forced in by cam *K* until the slots on the bottoms of the plungers allow stops *G* to return to their normal positions, thus holding the plungers in check after they have cleared the cam.

The clamping pressure can be regulated by using a small or a large bevel on plunger *D*. The set-screw *L* is used for adjusting cam *K* after the fixture has been set up. The cutter should be set in a fixed position, a little beyond the point at which trip *J* releases plunger *D*. The dimension *Z* on the work was not required to be held to close limits of accuracy in this particular case, but when necessary, special provision can be made for locating the work radially with greater accuracy.

Brooklyn, N. Y. LESTER FERENCI



Punch and Die Construction permitting the Completion in One Operation of Parts generally produced by Two Dies

DIE WITH TWO DRAWING RINGS

Two distinct drawing operations on power presses are commonly employed in the production of parts which can be just as satisfactorily drawn in one operation by means of a punch and die construction similar to that shown in the accompanying illustration. This punch and die is used for drawing oil-can breasts to the shape and dimensions shown in the lower right-hand corner. The development of a die for producing this part in one operation was difficult because of the shoulder near the open end and the thinness of the metal from which the part is drawn, this metal being cold-rolled stock, 0.024 inch in thickness. The blank diameter is 5 3/32 inches. The special feature of this die is the provision of two drawing rings, one inside the other, against which upward pressures are exerted by means of two separate rubber buffers.

The illustration shows the relation between the punch and the moving members of the die at the completion of a downward stroke of the press ram. Prior to a descent of the punch, drawing rings *A* and *B* are in raised positions due to the pressure exerted by rubber buffers *C* and *D*, respectively. The pressure of each buffer is transmitted to the bottom of its respective drawing ring through the medium of a plate and two round rods. When ring *A* is in the raised position, its upper surface coincides with that of the blanking ring *E*. The raised position of ring *B* is such that the top of the ring does not project beyond the highest point of center plug *F*.

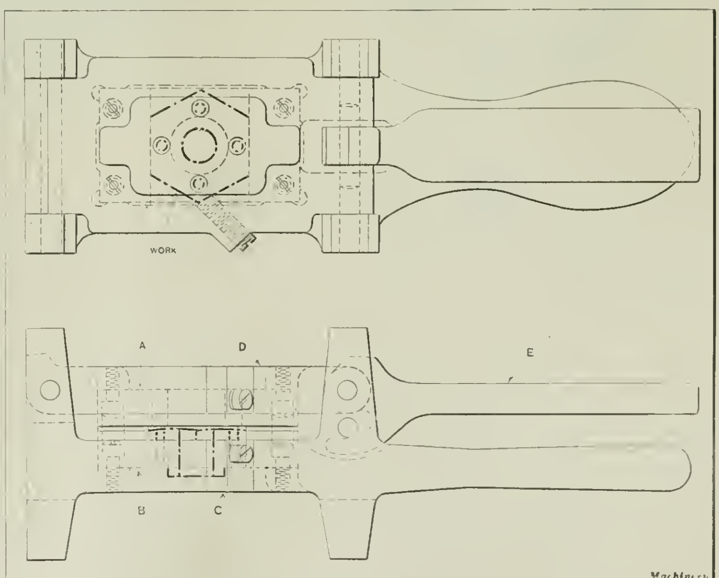
The strip of metal from which a part is to be drawn is laid on the upper edge of ring *E*, and blanked to size as punch *G* enters this ring, pressure being exerted against the blank by drawing ring *A* in the manner previously described. The blank and ring *A* are pushed into the die as the punch continues to descend, while ring *B* remains stationary for a moment due to the pressure of buffer *D*. The result is that the edge of the blank is turned down around ring *B*. This ring is pushed downward after section *H* of the punch comes in contact with the blank, the latter being stretched on plug *F* and ring *B*, and the shoulder being formed. By stretching the metal in this manner all wrinkles are eliminated on the drawn part, so that subsequent spinning or restriking is unnecessary.

The completed part is forced from the die on the upward stroke of the press ram by rings *A* and *B* as they resume their normal positions. In case the part adheres to the ascending punch it is ejected from this member by section *H* which, in addition to its function of shaping the shell, also serves as a knock-out pad. If the die for making this part was of the common design, drawing ring *B* would be integral with plug *F* and so it would be practically impossible to draw a shell without wrinkles. The top edge of ring *B* is rounded, so that the blank is not cut through when it is forced upon the ring.

Toledo, Ohio — J. Bingham

INTERCHANGEABLE-PLATE JIG FOR SMALL PARTS

In shops where a large variety of small parts must be drilled and a jig used for the operation in each case, obviously a considerable investment is involved for the jigs alone, and if it were possible to employ the same jig in a number of cases by simply substituting one or two members to suit the work, drill jig costs might be greatly reduced. With this end in view, the jig shown in the accompanying illustrations was designed. This jig has an upper plate *A* and a lower plate *B*, each of which is replaceable to suit a



Drill Jig designed to accommodate a Large Variety of Work, being provided with Interchangeable Plates to suit Each Part large number of parts of different shapes. In the illustration the plates are those employed in drilling and tapping four holes through the hexagonal head of a small part, the work being located by means of a recess in the lower plate.

Both plates may be provided with bushings so that operations can be performed from both sides of the work. In many cases, the holes are drilled from one side, and then tapped, countersunk, or counterbored from the other. Bushings may often be eliminated by hardening the plates. The latter are located along one side and one end by accurately machined surfaces on the jig body *C* and leaf *D*, against which the plates are forced by means of two screws. With this arrangement, it is unnecessary to fit the plates in the jig. It will be seen that the plates are attached to the leaf and body, respectively, by means of four fillister-head machine screws. The holes for these screws are located from a jig so that the plates for the various pieces of work will be interchangeable. The body and leaf are steel castings, and the work is clamped in the plates by means of cam-lever *E*. This jig may be made in a number of sizes.

Cleveland, Ohio A. J. Cayouette

BORING-BARS FOR DOUBLE-END CUTTERS

The two types of boring-bars here shown were designed as a result of the demand for boring-bars which would hold double-end cutters, and give the maximum length of service when used with a milling or boring machine or in connection with boring fixtures, for the production of duplicate machine parts requiring a high degree of accuracy. The writer has found these boring-bars to be superior to those frequently used, which have a machine steel or soft tool steel bar for holding the hardened cutter. With boring-bars of the latter type it is often found that, after a very few cuts and changes of cutters have been made, the driving of the taper wedge—usually employed to hold the cutters in place—as well as the thrust on the cutters due to the cutting action tends to peen the bars under the angular or flat centering shoulders, thus making the cutters loose in the bar and impairing the accuracy of the tool to such an extent that new bars or cutters are required.

Machinery

Boring-bars of improved construction, such as shown in Table 1, are intended for boring blind holes, where the bar is supported by a follow-up bushing behind the cutter. The cutter is made with a centering shoulder on each side. These shoulders are turned on centers so that they will fit the inside bores of the two hardened and ground collars. The collar on the inner side is made a tight fit on the bar, and the outer collar is made a good slip fit to facilitate the changing of cutters. The combination of cutter and collars is clamped tight by means of the nut on the threaded end. The outside diameter of the cutter can be ground to size when held on centers or while in position in the bar.

Machinery

In a boring-bar of the construction indicated in the illustration shown in connection with Table 2, where the bar is supported on both sides of the cutter in a fixture and driven by a universal joint arrangement, it is desirable that the diameter *H* be made as large as is consistent with good practice. In this construction two hardened and ground collars are used and the cutter is centralized by the usual flat shoulder supported on the flats of the inside collar which is tight on the bar. The cutter diameter is ground to size in a suitable fixture or while in position in the bar. Boring-bars that are made in accordance with the dimensions given in the accompanying tables have been found very satisfactory, their additional first cost being more than compensated for by their greater accuracy, dependability, and length of life.

Waterbury, Conn. Albert H. Gaess

HARDINGE OIL BURNER FOR INDUSTRIAL PLANTS

Hardinge Bros., Inc., Berteau and Ravenswood Aves., Chicago, Ill., have developed a new type of oil burner known as the Hardinge oil burning machine. This equipment is constructed to burn all kinds of fuel oil, from the heavy low-grade Mexican product to the better grade of kerosene. Some of the important features incorporated in this oil burning machine are the provision of an atomizer and agitator, which treat the oil before burning; a revolving needle in the oil-feed valve which feeds the oil in small regular quantities; a pressure chamber which eliminates air and water bubbles; an air regulator which regulates the air mixture; an automatic stop which stops the machine and prevents flooding if the fire accidentally goes out; a convenient method of cleaning the burner; and an oiling system for the atomizer spindle. These features make it possible to burn ordinary fuel oil economically without objectionable noise, odor, or dirt.

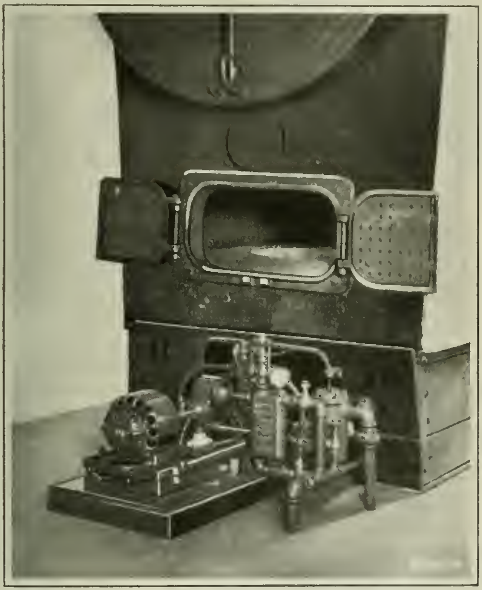

Fig. 1. Hardinge Oil Burner applied to Boiler

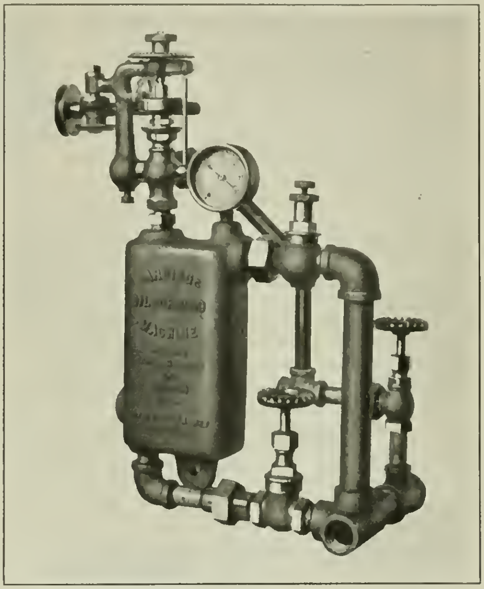

Fig. 2. Valve Control Unit of Hardinge Oil Burner

The machine can be adapted to heating systems of small residences as well as to the heating of boilers in large industrial plants, and is equally applicable whether the problem is one of heating or of generating steam for motive power. The burner is always under control and has a wide range of adjustment. For instance, in the case of an installation in the heating system of a small residence, it is possible to turn the flame down so low that only one half a gallon of fuel oil will be consumed per hour. A good idea of the relative size and location of the oil burning machine as applied to the heating of a boiler may be obtained by referring to Fig. 1. In Fig. 2 is shown a close-up view of the control unit by means of which the fire is controlled.

Operation of Burner

The oil is drawn from the supply tank (which is usually placed under the floor) up through the strainer by a pump driven by an electric motor, as shown in Fig. 1, which also serves to drive the rotating members of the burners. From the pump the oil is forced into a chamber where it is kept under pressure by the pump. It next passes upward through a revolving needle valve seat which regulates the quantity of oil to be burned. From this point it follows the pipe line up to the openings of a short standpipe. It then flows downward through the bottom of the revolving cup of an atomizer where it is thrown off through the oil-tube by centrifugal force. This rotating oil-pipe is held in a bearing located under the burner. An agitator at the bottom of the cup keeps the oil constantly emulsified.

Dirt, water, and other substances are separated from the oil during its passage upward through the cup, according to their specific gravities. The oil next passes over the atomizer into the firebox. The dirt, water, and other substances that are heavier than the oil constantly pass off under the oil and are consumed. This constant treatment of the oil eliminates all possibility of dirt accumulating in the pipe system.

The only place where any dirt can collect is on the convex curve of the atomizer bell, and this is cleaned by the simple process of drawing a small steel poker over the bell surface while the machine is in operation. A small size burner need not be cleaned oftener than once in two weeks, while a commercial burner may require cleaning once a week. The cleaning operation can be done in less than a minute while the fire is burning. As the oil leaves the bell-shaped atomizer it is thrown by centrifugal force into the firebox.

ELECTRIC ARC WELDING WITH CARBON ELECTRODES

In the first paragraph of the article on electric arc welding, appearing on page 1051, July MACHINERY, it is stated that the weld obtained by ordinary electric arc welding with carbon electrodes is so hard that it cannot be machined. This statement is erroneous. Carbon arc welding has been done in many steel foundries with a great degree of success, and, if the welding is properly done, little or no difficulty is encountered from the hardness of the weld.

* * *

Of the machine tools exported from Germany in 1920, 20 per cent went to Holland, 15 per cent to Switzerland, and 15 per cent to France.

The Metal-working Industries

THERE has been little change in conditions in the metal-working industries, but what has developed has been for the better. A greater demand for small tools, accessories, and grinding wheels is reported; the pig iron output shows an increase after nine months of steady decline—a rather certain and accurate indication of improving business in the metal-working field. The railroads are reporting decidedly better net earnings than in the past, and there is a tone of confidence in business in general that should not be overlooked. The credit situation has improved, and bankers, business men, and manufacturers alike agree that the lowest point of the depression has been passed and that improvements have taken place in many directions.

The Machine Tool and Small Tool Industry

In the machine tool field this improvement has as yet been but little felt, because there will be no appreciable buying of machine tools until the industries are working at greater capacity; but that many of the plants in the machine shop field have started to work is indicated by the demand for taps, reamers, milling cutters and drills, which has increased considerably during the past month. Some of the small tool plants are doing a business equivalent to from 25 to 35 per cent of capacity, and one shop reports doing a monthly business equal to the average monthly business for 1916. The manufacturers of grinding wheels report a similar condition—the demand having improved—and while orders are still small they are numerous. Business in hacksaws is reported to be quite satisfactory. In the machine tool field also, somewhat better conditions are reported by several dealers. The buying in general is done by small shops taking the cheaper types of machine tools. Sales of machinery for repair shops and garages have been unusually good, considering conditions. The second-hand market is quite active, particularly in the New England states. The foreign market for machine tools shows little or no improvement, although there has been a greater number of inquiries during recent weeks.

The most serious aspect of the situation is doubtless the large stocks on hand in the machine tool and the small tool fields. It will take considerable time to reduce these stocks to normal, and in many instances the stock manufactured from high-priced raw materials and with labor at peak rates will have to be sold at considerable reductions, in some cases involving distinct losses.

According to the monthly review of the Federal Reserve Bank, the situation in the molding machine line, foundry supplies and hoisting machinery shows improvement, even though slight. The lowest point of the depression in these lines appears to have been passed.

Prices of Materials

Pig iron, being the basic raw material, represents, both as regards production and price, an index to the situation in the entire machine shop field. The price of pig iron seems now to have been stabilized at from $19 to $21 per ton, at base points, for different grades. A year ago these prices were from $46.50 to $50 a ton. The pre-war price was from $14 to $15 a ton. Steel billets previous to the war averaged about $25 a ton, and are now $29 a ton. Prices of structural steel and bar steel have been reduced in the past year and now compare with pre-war prices the same as pig iron and steel billets. But tool steel is still quoted at only 15 per cent below the peak price, and manufacturers of small tools are complaining about this, as it makes it impossible for them to reduce the prices of their products in proportion to the reductions taking place in other fields. The railroads also suffer from high prices of steel rails. Previous to the war the price was $28 per ton, but it is now $47, notwithstanding the fact that steel billets are only 16 per cent above the pre-war price. Lower rail prices aid the railways, and anything that aids the railways would aid, directly or indirectly, all the industries of the country.

The Automobile Industry

The production of the Ford factories broke all previous records during the month of August with a total output of 117,696 cars and trucks. The automobile industry continues to hold its own in spite of the prophecies to the contrary earlier in the year. The Studebakers production for August was also a record for that concern—8642 cars. The business of the Reo Co. for the same month has been surpassed only three times since the company's organization. All the automobile companies cannot report as favorable conditions, but on the whole the situation is much better than was expected during the earlier months of the year.

Reports from the automobile truck industry vary. One prominent manufacturer states that his orders for the month of July showed an increase over the corresponding month last year, which is the most encouraging report in this field since the beginning of the depression; but another manufacturer finds the truck business practically stagnant. Some of the 75,000 trucks which the Government sold last year in foreign countries were bought by speculators and have been returned to this country for marketing. This has increased the difficulties of both manufacturers and dealers.

The rubber industry has shown a steady improvement during the last few months, and many plants have almost reached capacity production. The industry in general is estimated to be running at approximately 80 per cent capacity, the peak having been reached about August 1, with a slight falling off since then.

The tractor and agricultural machinery business is still suffering from a severe depression, as farmers are repairing old rather than buying new equipment. The farm implement business is estimated at between 50 and 60 per cent of the business a year ago with large stocks on hand. Prices have not been materially reduced.

General Business Conditions

There are many indications of increasing industrial activity. The demand for coal is better, and there is an increase in the inquiries for iron and steel. Copper, after a serious decline in price, has advanced somewhat, and building materials are in greater demand. Bradstreet's reports are distinctly encouraging, showing an expansion of the jobbing trade and a great improvement in textiles, as compared with the earlier months of the year. The woolen industry, which in January was running at only 30 per cent capacity, averaged 80 to 90 per cent on July 1, with still further improvement reported since then. Some of the New England woolen mills are reporting day and night shifts. The improvement in the railroad situation is perhaps the most noteworthy. The deficit from which the roads suffered earlier in the year has been turned into a substantial surplus, so much so that the net revenue now almost equals the average for the three years ending June 30, 1917, which is considered the most prosperous period in American railroad history. This showing is all the more remarkable as the high freight rates have diverted much transcontinental traffic to the Panama Canal route.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application.

Lees-Bradner Gear-tooth Grinding Machine

For use in the production of hardened gears to insure accuracy of profile and spacing of teeth and an equal degree of precision as regards the concentricity of the bore with the pitch circle, the Lees-Bradner Co., Cleveland, Ohio, has developed a No. 10 gear-tooth grinding machine. In using this equipment, it is unnecessary to exercise special care in cutting the teeth or boring the hole. After the blank has been turned and bored and the teeth cut, the gears are hardened. Then the bore is rough- and finish-ground and the preliminary and final grinding operations are performed on the teeth. Owing to the fact that the bore is ground first, all grinding operations on the teeth are controlled from the bore and the teeth are thus ground true and concentric with the bore. Before entering into the details of the construction, attention is directed to Fig. 1 which shows the machine from the front, and to Fig. 2 which illustrates one end. The machine is adapted for grinding involute-tooth spur gears having pressure angles of from 14½ to 24 degrees, of any diametral pitch from 12 to 3, and of any pitch diameter from 2 to 12 inches. A 30-inch grinding wheel is employed, the wheel being mounted on a stationary column, and the work traversed past it by a slide having a reciprocating action. The work is given combined rotary and sliding motions in order to obtain the desired tooth profile as ground by the wheel

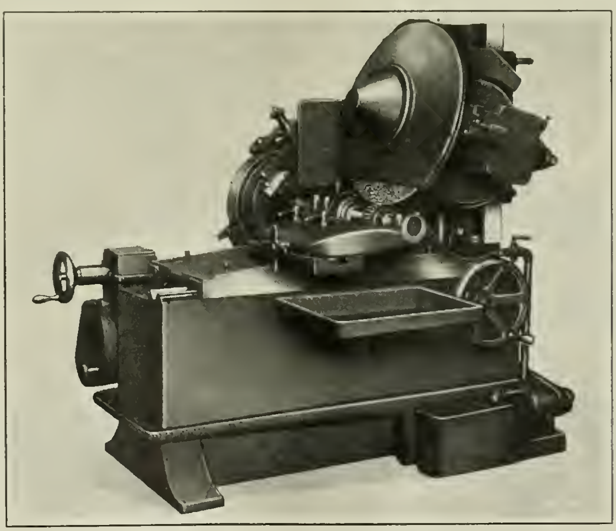

Fig. 1. Gear-tooth Grinding Machine developed by the Lees-Bradner Co.

face. A circular segment is used in conjunction with steel tapes or bands to obtain this combined sliding and rolling action. The segment can be modified in various ways to obtain any desired change in the tooth profile.

Truing and Driving the Grinding Wheel

A diamond which is lever and screw-controlled is used to true the face of the grinding wheel. The diamond is mounted in a ball socket container which can be swiveled to any angle, thereby permitting the diamond face to be used on all its edges. This container is locked into the arm, which is both power- and hand-controlled so that either a fast spiral cut or a slow continuous cut may be taken on the wheel face. The dresser is carried by the main swivel-head casting, which always locates the diamond point in one plane, and the adjustment is made endwise of the wheel when taking a dressing cut. The truing device is used in conjunction with the wheel-spindle micrometer feed.

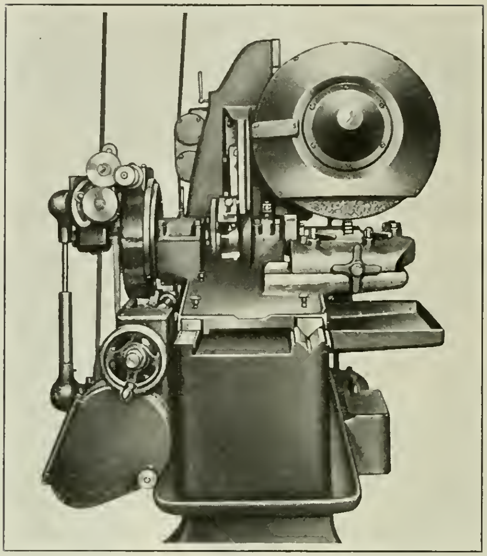

Fig. 2. End View of Gear-tooth Grinding Machine

An endless belt drives the wheel-spindle, this belt being guided by two idler pulleys at the rear of the machine and carried in a bracket having a sliding adjustment on the column to suit any diameter of gear being ground. The machine is driven by a single belt from a lineshaft, but a motor drive may be substituted when desired. Indexing of the work is accomplished by means of hardened and ground plates secured to the work-spindle and completely enclosed. These plates are made by the Warner & Swasey Co. who has a very accurate machine for work of this kind. The indexing is automatic and takes place at one end of the slide reciprocation. The wheel is set to the proper angle by means of a worm and segment on the swivel-head. A pump and connections supply coolant to the point of contact between the grinding wheel and the work. The latter can be held between centers or on a mandrel having a tapered shank to fit the work-spindle and supported at the outer end by the tailstock as shown in Fig. 3. In this illustration *D* indicates the mandrel, and *E* the work.

Means of Obtaining Generating Motion

On this machine power is not applied directly to the work-slide, but to a sleeve in which the work-spindle rotates while indexing. When the machine is grinding, the sleeve and spindle rotate together as one unit. The sleeve carries the segment to which one end of each tape is fastened. The other end is secured to a bracket on the column; accordingly, when the sleeve is rotated first in one direction and then in the reverse direction, the tapes wind and unwind on the segment, and, through their pulling action on the bracket, cause the work-slide to reciprocate. This arrangement is shown in Fig. 4. A uniform torque load is transmitted to the work-spindle by a worm and worm-wheel, the primary function of which is to rotate the sleeve in the reverse directions. There is also a uniform load on the tapes, due to the fact that the frictional resistance of the work-slide on the ways is kept constant by gravity alone. The relation of the grinding wheel face to a gear tooth is illustrated in Fig. 5. The plane face of the grinding wheel has a continuity of action with the gear tooth being ground.

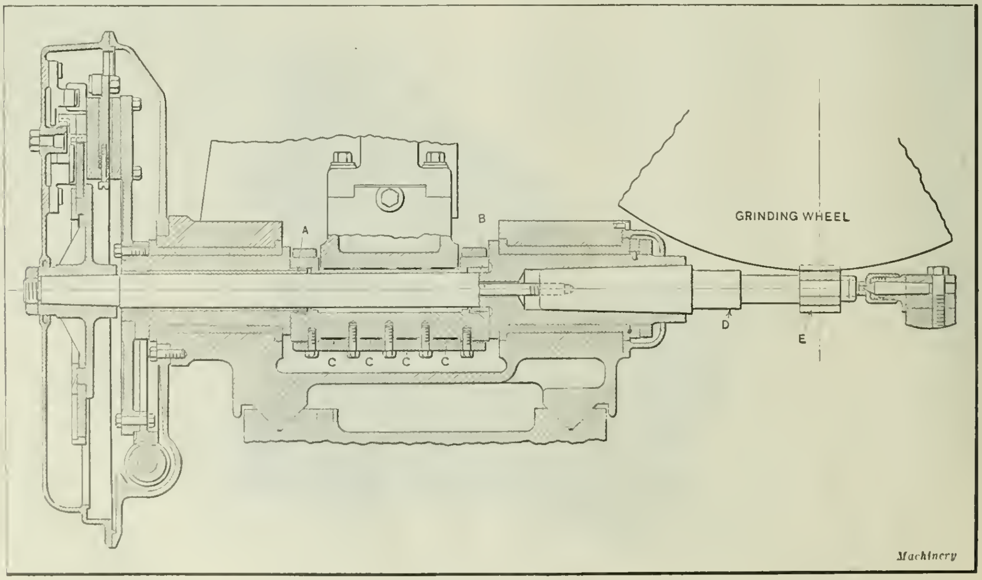

Fig. 3. Longitudinal Sectional View of Work-spindle

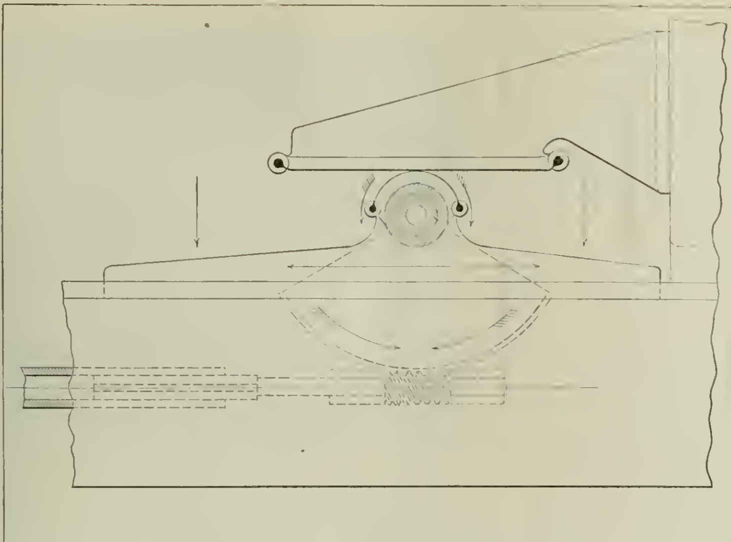

Fig. 4. Segment and Tape Principle of operating Work-slide

Fig. 5. Position of Wheel

How the Tapes and Segment are Mounted

The flat surface *A*, Fig. 3, of the grinding sleeve is utilized not only to drive the segment, but also to locate it in the correct relation to the spindle axis. There is also a support for the other end of the segment. This support is mounted so that it can rotate on the work-spindle, and has a flat locating surface *B*. Surfaces *A* and *B* are used as initial locating points for the radii of the segments, and should any modification of a radius be required, it is made by inserting or taking out metal shims at these points. The tapes are indicated by the letters *C*. They are all the same length and are placed in position loosely, both on the tape-bar and the segment. At the time of tightening up, an independent end adjustment of the tape-bar is used to move the tapes endwise, and in this way rotate the segment to its vertical position for the original set-up. A zero mark is placed on the bar and on the sleeve to facilitate obtaining this position.

The tight and loose pulley drive is so located that the driving belt can be used at any angle without interfering with the operation of the machine. The main shaft drives the gearing in a reverse feed-box in which speed-change gears are used to obtain the number of strokes per minute required of the work-slide. The length of the slide travel is regulated by a trip-dog located inside the gear-case. A starting and stopping lever controls the slide travel, and this is operated from the front of the machine. Hand adjustment of the slide is secured by means of a handwheel. A belt-shift lever is provided for the tight and loose pulleys, for starting and stopping the machine.

A section through the wheel-spindle is shown in Fig. 6, in which *F* indicates the spindle, and *G* the grinding wheel. Pulley *H* at the center of the spindle furnishes the drive. A micrometer adjustment is obtained by means of the worm and worm-wheel mechanism *J* which actuates a screw fastened to the sleeve in which the spindle is mounted. It will be seen that the spindle is mounted in ball and bronze bearings. End thrust of the spindle is taken by a raised shoulder *K* on the spindle, this shoulder being interposed between two ball bearings that are adjusted by cap-screws on the outer side of the flanged end cap The taking up of the end thrust bearing at this point eliminates any displacement through heat acting on a long bearing and creating either play or tightness.

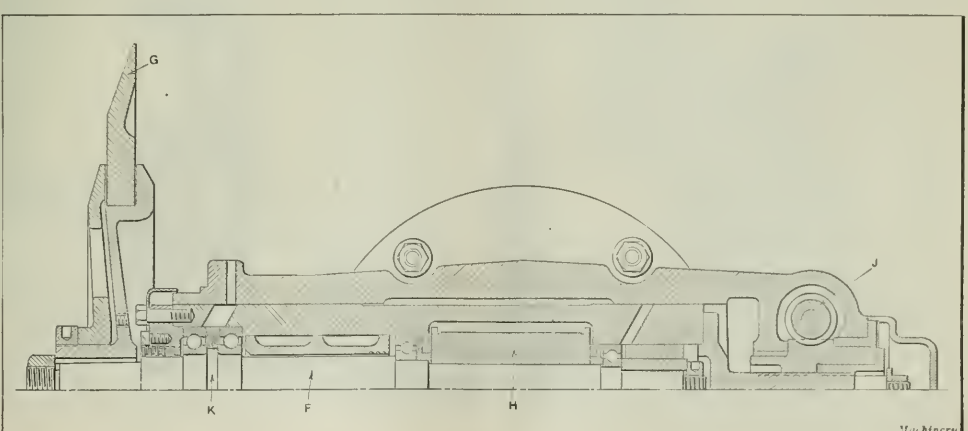

Fig. 6. Longitudinal Sectional View of Grinding Wheel Spindle

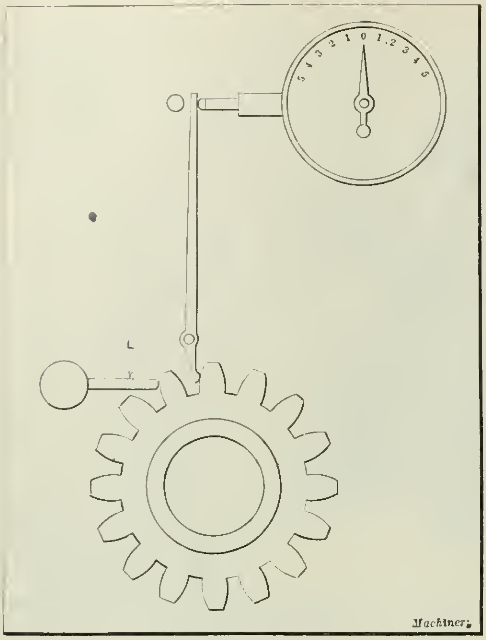

Fig. 7. Device used in testing Spacing of Gear Teeth

Operating the Machine

In operating the machine, the procedure is as follows: A segment corresponding to the pitch diameter of the gear to be ground is located on the work-spindle. The grinding wheel is set to the pressure angle of the tooth to be ground, and the wheel-head is raised to the proper height for the wheel to cover the working depth of the tooth. The wheel is then dressed. Two positive stop-pins located in a circular T-slot are used in conjunction with a positive stop to locate the wheel in the starting and finishing positions, and an intermediate spring stop is used in taking the roughing cut. The starting stop is usually set for the grinding of 0.004 inch from the gear teeth. The work is then locked on the arbor with a tooth in contact with the wheel. When the machine is started, the roughing cut is first taken, the grinding wheel being located by the spring stop to cut 0.003 inch from each tooth. Then the micrometer adjustment feeds 0.001 inch to the finishing stop, in this way removing the 0.004 inch allowed on the teeth for grinding. This movement brings the wheel back into the generating plane and into the position in which it was dressed. The wheel is generally redressed after the grinding of every two gears, and about 0.0004 inch is removed from its face. The dressing is accomplished by an independent feed to the micrometer, so that the starting and finishing stops need not be disturbed.

Modifying the Ground Tooth Form and Testing the Spacing of Gear Teeth

Thus far it has been assumed that perfect tooth profiles are required, but it is a matter of general knowledge that gears are not always used in machines having perfect alignment and accurate center distances, and which are free from other inaccuracies. Consequently the gears may need to be modified, or in other words, the profile changed to suit conditions. As previously explained, the modification of the profile is made by raising the segments by means of shims.

The method of measuring gear teeth for indexing is done by means of the device illustrated in Fig. 7 in which the gear is placed on a stud and a tooth turned against a positive stop *L*. The indicator is set to zero, after which the gear is indicated tooth by tooth, and if the reading remains at zero each time, the gear is perfect. Angular errors are recorded plus or minus by the indicator in increments of 0.0001 inch.

PAWLING & HARNISCHFEGER BORING, DRILLING AND MILLING MACHINES

A new line of horizontal boring, drilling and milling machines, of which the No. 4-F machine shown in Fig. 1 is the smallest size, has been developed by the Pawling & Harnischfeger Co., 38th and National Aves., Milwaukee, Wis. These machines are especially designed for heavy milling and large boring operations, and can be used either as single-purpose machines or for general machine shop work. Among the features of the design are narrow guiding surfaces, take-up for all sliding parts, centralized control, and interchangeability of externally and internally driven faceplates. The back-gears are close to the spindle, and all driving shafts run at a high speed. Automatic stops are provided for the saddle and column of electrically driven machines. The column may be moved transversely on guides on the base by means of a screw. It may be traversed either forward or backward, by hand, power-feed or rapid traverse. The motor for driving the machine is located at the left-hand side of the column. The runway for the column is of a deep box section and is heavily ribbed.

The spindle saddle contains the drive for the spindle, the feeding mechanism, and the feed distributing mechanism. The main spindle sleeve bushing is made of phosphor-bronze, and is scraped to a slight taper so that wear of the sleeve may be readily compensated for. The saddle is guided on the column by a narrow guide located at the front. The feed-screw is located at the center of this guide. The saddle is counterbalanced by a weight inside the column, and is raised or lowered by a worm-wheel nut actuated by a screw. The raising or lowering of the saddle may be accomplished by hand, power-feed, or quick traverse.

The spindle is made from a high-carbon hammered alloy steel forging, and is ground to a sliding fit in the driving sleeve. Power is applied at the front end of the spindle while it is fed from the rear end through a rack and pinion.

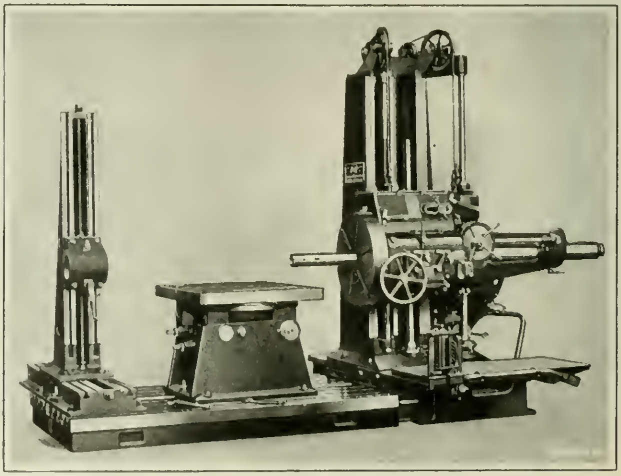

Fig. 1. Boring, Drilling, and Milling Machine built by the Pawling & Harnischfeger Co.

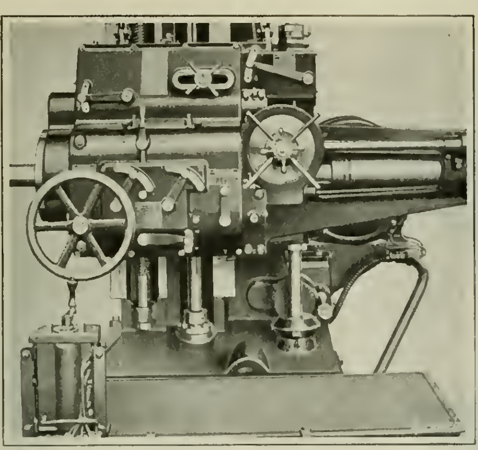

Fig. 2. Close-up View showing the Operating Levers arranged on the Saddle within a 42-inch Circle

The front end has a No. 6 Morse taper socket, and contains the necessary slots for driving milling cutters and boring-bars. The drive is transmitted to the spindle either through a small faceplate with a wide-face, coarse-pitch gear or a larger faceplate with an internal gear of coarse pitch and wide face. These faceplates have slots and tapped holes to provide for the attachment of milling cutters and facing heads. The feed of the spindle on this machine is 36 inches; the minimum height of the spindle from a 9-inch bedplate, 25½ inches; and the maximum height, 73½ inches.

The machine may be driven by a 10-horsepower constant- or variable-speed motor or by belt. The machine is double-back-geared and, through the operation of three levers, eighteen reversible spindle speeds in geometrical progression, ranging from 5½ to 200 revolutions per minute, can be secured. The boring and drilling feeds to the spindle are eight in number, reversible, and range from 0.0076 to 0.45 inch per revolution of the spindle. There are also eight reversible milling feeds to the column and the saddle, ranging from 0.009 to 0.54 inch per revolution of the spindle. The saddle and column have a rapid power traverse of 60 inches per minute.

All operating levers and handwheels are within easy reach of the operator and are conveniently arranged for the various operations. All levers are interlocking so that the engagement of two conflicting speeds or feeds at the same time is impossible. The work bed is provided with planed T-slots running parallel to the direction in which the spindle traverses. A planed squaring strip for aligning work is provided on three sides of the bed. The latter can be made to any desired size. The outer support, unless otherwise specified, has vertical and transverse movements of 48 inches. Graduated verniers reading to 0.001 inch are furnished for the main column and saddle and the outer support and saddle. A screw chasing attachment for cutting threads varying from 2 to 16 per inch and to any length within the capacity of the machine, can be furnished. A universal tilting and revolving table or a plain revolving table with movement by hand or power can also be furnished. The No. 4-F machine without bedplate, outer support, tables or electrical equipment, weighs about 17,000 pounds.

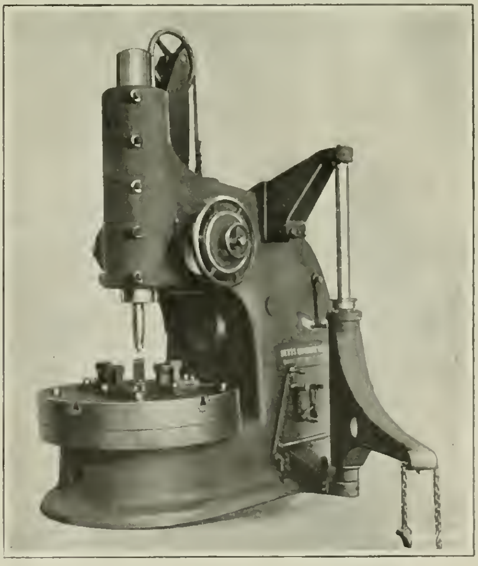
POLLARD WORK-BENCH

A small work-bench designed for use in garages and by mechanics at home is now being placed on the market by Pollard Bros., 4034-4036 N. Tripp Ave., Chicago, Ill. The top is made of selected heavy Norway pine. The legs are constructed of 1¼-inch angle-irons, each pair of legs being joined by three cross-braces welded together The legs are punched for fastening to the floor. Two 3-inch flat steel bars bolted to the legs act as stringers, and eliminate any side or end sway. A large drawer, independent of the top and sliding on angle cross-braces welded to the legs, is furnished. A semi-steel machinist's vise with 3-inch tool-steel jaws having a 4-inch opening, is mounted on the bench. The bench top is 33 inches above the floor, 44 inches long, and 16 inches wide. The drawer is 23½ inches wide, 15½ inches from front to back, and 5 inches deep. A recess at the rear of the top will hold tools, nuts, bolts, etc. The weight of the bench complete, equipped with a vise, is 65 pounds. The wooden portions are shellacked, and all metal parts are painted black.

BETTS CAR-WHEEL BORING MACHINE

A 52-inch car-wheel boring and facing machine has been added to the line of heavy railway machines manufactured by the Betts Machine Co., 400 Blossom Road, Rochester, N. Y. This machine is intended to cover the requirements of both manufacturing and repair shops. The bed and frame are one massive casting, and the entire machine is designed to withstand high stresses. Special attention has been given to simplicity of operation. The machine may be driven by a single pulley or by being direct-connected to a constant- or variable-speed motor. The necessary speed changes to given faceplate revolutions of 10.2, 13.9, 20.4 and 30.7 per minute are obtained by means of hardened sliding steel gears running in oil. The two short levers seen on the frame in the accompanying illustration are used for obtaining the four speed changes. These levers are interlocked so that no two sets of gears can be placed in mesh at the same time.

The table revolves on a wide bearing and has a large spindle running in a bronze-bushed bearing. This spindle is provided with a locking collar at the lower end to prevent it from lifting. The table is equipped with a five-jaw chuck that is both universal and independent, and is readily adjustable for wheels of any size within the range of the machine. Five stations are provided for operating this chuck so that one of them will be convenient to the operator, regardless of where the table is stopped. The long lever seen



Railway Car-wheel Boring Machine built by the Betts Machine Co.

just to the right of the table is used for operating a friction clutch and brake, whereby the machine may be started and stopped instantly.

Six automatic boring and facing feeds are obtained by means of a two-step cone pulley and sliding steel gears so arranged that the feeds can be changed instantly from roughing to finishing. The boring ram has an easy hand adjustment that is facilitated by a counterweight within the machine. When so desired, the machine can be equipped with a facing ram on which the facing head is supported close to the cut. This ram is of such construction that it can be slid out of the way when chucking wheels of large diameter. The machine is regularly equipped with a quick-acting air-operated crane for loading and unloading the car-wheels. This crane can also be arranged to be driven by an individual motor or by belt. All control levers and the hand adjustment of the boring ram are within easy reach of the operator from one position.

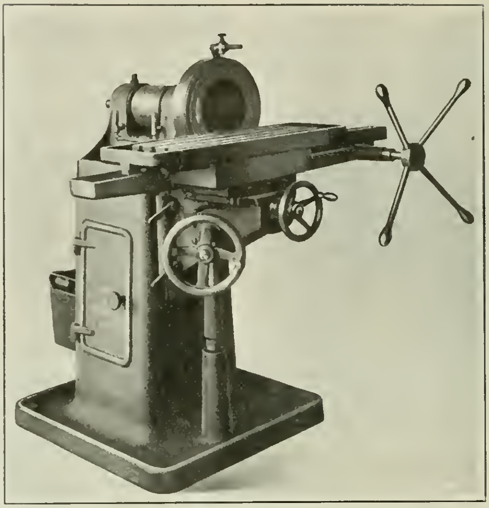


Fig. 1. Knee-type Ring-wheel Grinding Machine brought out by the Graham Mfg. Co.

GRAHAM RING-WHEEL GRINDING MACHINE

The knee-type ring-wheel grinding machine illustrated in Fig. 1 was recently developed by the Graham Mfg. Co., 71 Willard Ave., Providence, R. I. The abrasive wheel has an outside diameter of 12 inches and a hole 7 inches in diameter, so that the face is 2½ inches wide. The thickness of the wheel when new is 3 inches, and it can be worn to a thickness of about ½ inch. The wheel is held in place by a pressed-steel holder, manufactured by the same concern, which was described in May, 1909, MACHINERY. The construction of this holder can be seen by reference to Fig. 2, which shows a sectional view of the wheel-head. The ring-wheel is clamped in this holder by means of a cone-shaped ring that is drawn into an internal tapered surface in the body. An adjustable flange which screws on the hub of the holder is employed to advance the wheel as the latter becomes worn, and it is an easy matter to remove a worn ring.

After the wheel is in place it can be easily trued up and the cutting face reduced to any desired width. A holder for commercial truing devices is supplied, which is fastened to the table. The machine may be driven by a belt from a countershaft as provided for on the machine illustrated, or it may be driven by a motor, mounted on a bracket at the back of the machine and attached to the rear end of the wheel-spindle by means of a flexible coupling. The machine may also be driven by belt from a motor mounted on a bracket on the right-hand side of the column, or one placed inside the column and belted upward. A fifth driving method is by means of a motor built into the head.

The column has cast ledges on the inside to provide for shelves; however, the space may be used for a starting box. Water is supplied to the work by means of a No. 2 B. & S. centrifugal pump, fastened to a tank at the rear of the machine, the water being applied to the work through a nozzle fastened to universal pipe joints. The head is cast separately and is provided with bushings for holding the outer races of the Timken roller bearings with which the spindle is equipped. In order to reduce end play to a minimum, the rear bushing is a close sliding fit in the head and is pushed by means of a coil spring, in the proper direction to automatically take up all end motion and wear. Further adjustment is attained by means of a castellated nut and cotter-pin. The spindle is made of tool steel and is provided at the front end with a collar shrunk on and machined to

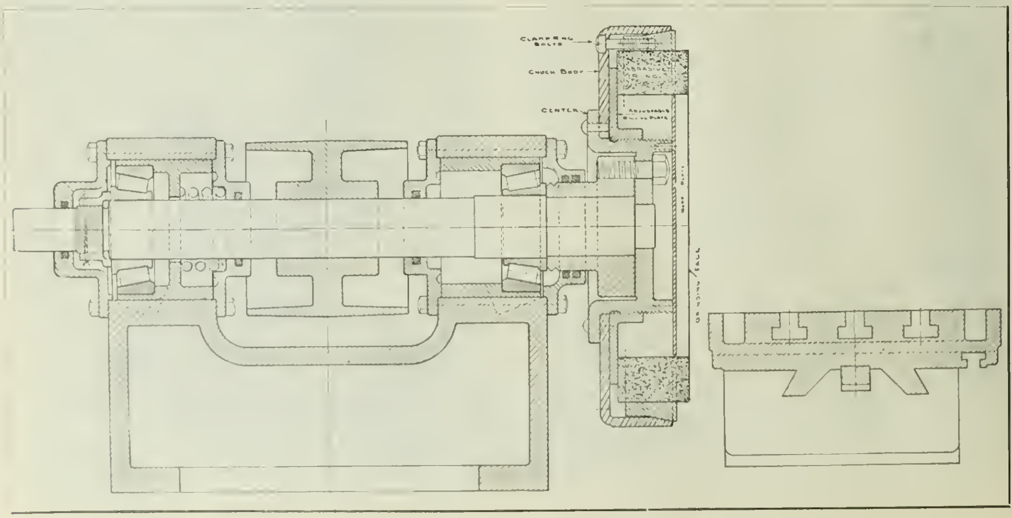

Fig. 2. Sectional View through Wheel-head of Ring-wheel Grinding Machine

accommodate the ring-wheel holder. Felt-packed dust collars protect all running parts on the head, and glass oilers indicate the amount of lubricant in the bearings.

The knee is of box construction, and is adjusted by an elevating handwheel set at an angle. A water trough is machined and fitted to the knee. The table block rests on the knee and is gibbed. It is fitted with an adjustable nut for the cross-feed shaft. This nut may be indexed in increments of 0.001 inch and serves to regulate the depth of cut. The table is fed past the wheel by means of a pinion and rack operated by the spider wheel at the right end. The top surface of the table has standard T-slots in it. Sufficient water guards are furnished to prevent the operator from becoming splashed. These guards were removed at the time the photograph reproduced in Fig. 1 was taken, in order that the construction of the machine could be more readily observed. Some of the specifications of this grinding machine are as follows: Height from floor to center of spindle, 42 inches; working surface of table, 24 by 10 inches; maximum travel of table, 16 inches; vertical movement of table, 7 inches; speed of machine, when driven by standard motor, 1780 revolutions per minute; and weight of machine, approximately 2000 pounds.

MONARCH SMALL-SIZE ENGINE LATHES

A line of engine lathes of 9- and 11-inch swing, made in bed lengths of from 2½ to 5 feet, has been brought out by the Monarch Machine Tool Co., 209 Oak St., Sidney, Ohio. These machines are sold under the trade name of "Monarch Junior." A 9-inch lathe provided with bench legs is shown in Fig. 1, while Fig. 2 illustrates an 11-inch machine equipped with a chip pan and floor legs. The headstock of these machines is of the solid full-webbed bowl type, and the spindle is made from crucible steel, accurately ground and having a 1 1/16-inch hole running through its entire length. The spindle is driven through a three-step cone pulley and single back-gears. The latter are locked in and out of position by a ball and spring plunger.

The base of the tailstock is graduated to enable accurate settings for taper-turning, and is so arranged that it can be considerably overhung on the bed to give greater distances between centers. Either a full-quick or semi-quick change-gear box can be furnished. With the former, fifty-four changes of threads and feeds are obtainable. The feed and lead-screw reverses are secured through a lever on the headstock. Reversing is done instantly, while the lathe is running. The countershaft is equipped with Edgemont friction clutches and cast-iron hangers provided with ring-oiled bearings.

The compound rest is gibbed throughout, and has large bearing surfaces. The toolpost is provided with a "Mac-It" non-breakable screw. The lead-screw is tested on a Hartness screw-thread comparator. The carriage is drilled and tapped to receive a taper attachment, chasing dial, or chasing stop. The upper knurled handwheel on the apron has three positions; when thrown to the left-hand position, the longitudinal feed is engaged, when placed in the right-hand position, the cross-feed is engaged, and when placed in the neutral position, the half-nut is engaged. The lower knurled handwheel controls the mechanism that operates both the power cross-feed and the longitudinal feed. The regular equipment furnished includes a double-friction countershaft, faceplate, dog plate, center-rest, follow-rest, centers, compound rest, and wrenches. A taper attachment, draw-in attachment, and other accessories can be applied by a customer without any machine work or fitting.

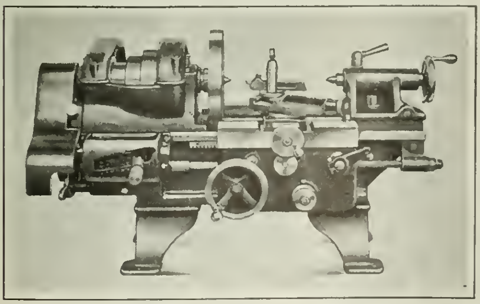

Fig. 1. Small Engine Lathe built by the Monarch Machine Tool Co.

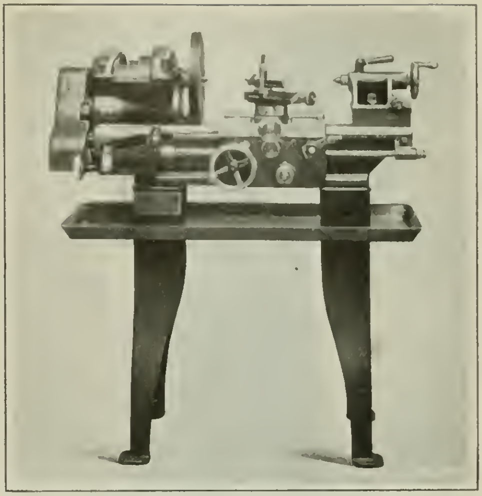

Fig. 2. "Monarch Junior" Lathe provided with Floor Legs and Chip Pan

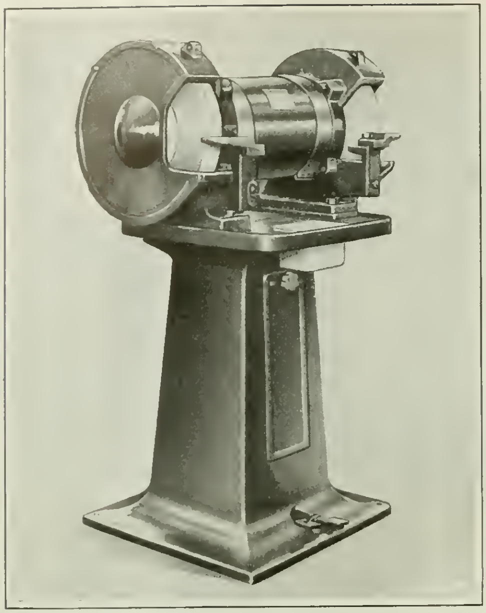
VAN DORN HEAVY-DUTY GRINDING MACHINE

The heavy-duty ball-bearing grinding machine here illustrated has just been introduced to the trade by the Van Dorn Electric Tool Co., Cleveland, Ohio. It is equipped with two grinding wheels, 14 inches in diameter, and 2½ inches face width. These wheels are mounted directly on the ends of a 1¼-inch motor shaft, and they are quickly changed by removing four bolts and the end flanges. Provision is made on the wheel guards for connection with exhaust ducts when desired, and a lug on each guard permits an eye-shield to be attached. The tool-rest can be conveniently located by horizontal and vertical adjustments. An aluminum water pot is located in the proper position to be reached by a short movement of the arm. This pot may be readily lifted out of place.

The motor was designed especially for this machine, and its rating is 4 horsepower for normal continuous operation, and 7 horsepower for a momentary overload. The standard motors operate on three-phase, 60-cycle alternating current with either 220 or 440 volts, but special windings such as two-phase 60-cycles, or three-phase 50-cycles, with either of the given voltages, are made to special order. The speed of the 60-cycle motors is 1200 revolutions per minute, and that of the 50-cycle motor, 1500 revolutions per minute. The motor is completely enclosed by a dustproof housing which is smaller in diameter than the grinding wheels, so that there is ample space for the operator's hands to move without coming in contact with the machine. Interference when grinding long pieces is also obviated.

Ventilation under all normal conditions is furnished by a fan within the motor, but under conditions of excessive dust a supply of fresh air may be piped to the intake of the housing. The motor shaft is set in large ball bearings rigidly

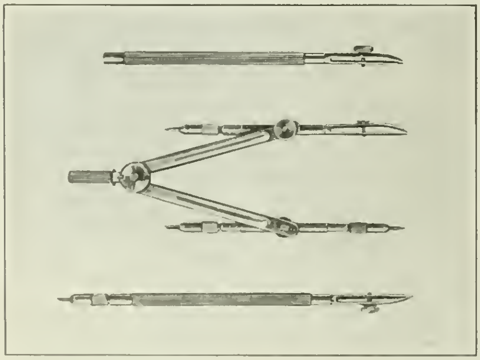


Heavy-duty Ball-bearing Grinding Machine built by the Van Dorn Electric Tool Co.

supported by the housing. Lubrication is accomplished by inserting a grease-gun nozzle in grease ports located directly above the bearings. The pedestal serves as a cabinet for the switch, fuses and connections. The cable conduit enters through a hole at the back, and no wires or electrical appliances are exposed anywhere on the machine. The machine is started and stopped by a pedal switch located at the base of the pedestal. The spindle center is 39 inches above the floor, and the grinding wheels are set 25 inches apart. The machine weighs approximately 700 pounds.

"CYMA" DRAWING INSTRUMENTS

The drawing instruments illustrated are being sold by Edgar Bourquin, 1347 Main St., Waltham, Mass., under the trade name of "Cyma." The ruling pen at the top of the illustration is of the standard type, while that at the bottom is provided with a lead end. The instrument at the center is a combination divider and pen and lead compasses. Either the pen, lead, or divider points may be brought into position for use by swinging the lower legs of the instrument which are pivoted at the center. The legs are clamped in position by tightening a nut at the fulcrum. The divider points may be used for scribing on metal. This combination compass and divider is intended for use as a pocket instrument by draftsmen, machinists, patternmakers, etc.

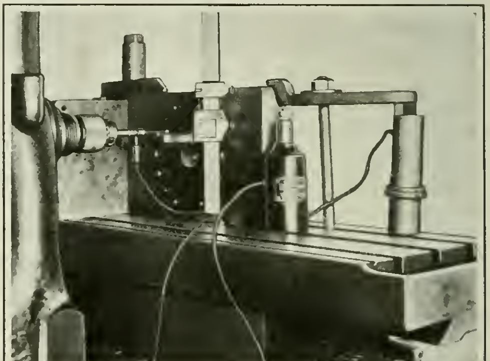


"Cyma" Drawing Instruments

HANSEN "ELECTROCATOR"

An instrument known as the "Electrocator," intended for use in ascertaining the alignment of machine members and in the locating of surfaces or centers for the accurate machining of parts, has been developed by the S. M. Hansen Co., 601 Washington St., Lynn, Mass. The Bely Sales Co. of the same address is the sales agent. When this instrument is used, the previous lay-out of centers is unnecessary, and the use of plugs and buttons is entirely dispensed with. The illustration shows the "Electrocator" being used for locating the center of a hole to be machined in a part mounted on the table of a milling machine.

The ball pointer is held in a chuck inserted in the spindle of the machine, and a vernier height gage is set to the distance that the center of the hole is to be located above the table, allowance, of course, being made for one-half the diameter of the ball end on the pointer. This pointer is connected to an electric light on the member of the instrument shown on the table, which, in turn, is connected to a light socket. When the gaging surface of the vernier gage is constantly in contact with the ball point as the spindle revolves, the light remains lit.

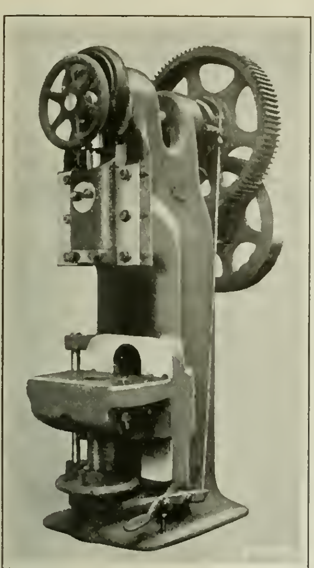


"Electrocator" made by the S. M. Hansen Co., being used on a Milling Machine

The concentricity of round pieces can be readily determined, as the light will go on and off according to the amount that a piece is out of round. The instrument may also be used for testing the alignment of the tables and knees of machine tools and the alignment of a lathe bed with its spindle. The ball pointer can be held in a chuck or clamped to the side of an arbor or boring-bar.

FERRACUTE ADJUSTABLE-BED PUNCHING PRESS

A punching press designed for work requiring a long stroke and an unusual height between the bed and the ram is shown in the accompanying illustration. This machine is built by the Ferracute Machine Co., Bridgeton, N. J., and is equipped with a bed that is adjustable vertically. As the bed and frame are separate castings, it is essential that their connection be strong and rigid, and this condition is obtained by attaching the bed to the frame by heavy steel bolts, and supporting the bed on a steel adjusting screw 4 inches in diameter.

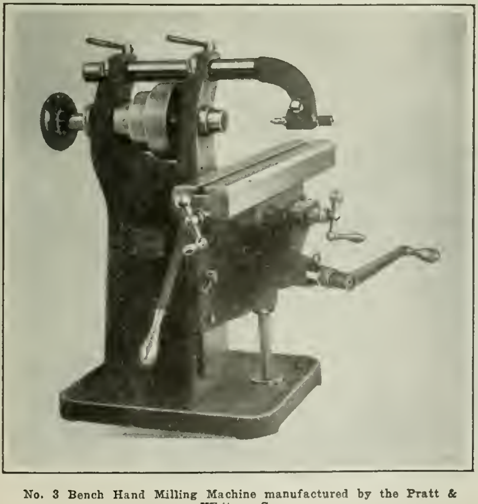


Adjustable-bed Punching Press built by the Ferracute Machine Co.

A projection at the back of the bed fits a planed vertical guide in the frame, and keeps the top of the bed parallel with the bottom surface of the ram at all times. The press may also be used for horning operations by inserting a horn in a 9½-inch hole in the frame. The bed is hinged on a vertical rod at the left-hand side of the machine which enables it to be swung out of the way when the machine is used for horning. The ram has a maximum adjustment of 3 inches, and the bed 9 inches. The distance between the bed and the ram, when the former is adjusted to its lower position and the ram is at the top of its stroke and its highest adjustment, is 30 inches. The ram stroke is 8 inches. The press exerts a pressure of 70 tons, and weighs approximately 13,200 pounds.

PRATT & WHITNEY BENCH HAND MILLING MACHINE

An addition to the line of machine tools built by the Pratt & Whitney Co., Hartford, Conn., is the No. 3 bench hand milling machine here illustrated. The spindle and draw-back on this machine is identical to that provided on the No. 3 bench lathe manufactured by the same concern, and therefore all the spindle attachments of the bench lathe interchange on the milling machine. The table of the latter is of a design suitable for the mounting of attachments and it accommodates the headstock and tailstock of the bench lathe. All screws on the machine are equipped with micrometer dials graduated to 0.001 inch.

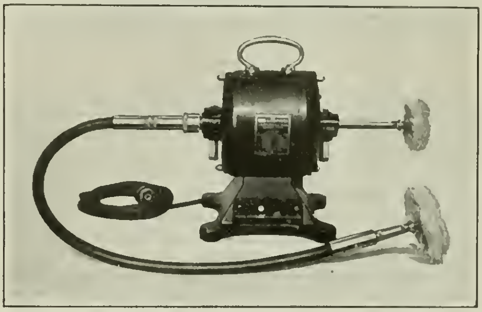


No. 3 Bench Hand Milling Machine manufactured by the Pratt & Whitney Co.

The spindle is made of tool steel, is hardened and ground, and has a conical front end. The front spindle bearing has a double taper, and is also made of tool steel and hardened and ground. A "Non-Gran" bronze bearing is provided at the rear of the spindle. Both bearings are adjustable for wear. The spindle is driven through a three-step cone pulley, which provides speeds ranging from 153 to 1510 revolutions per minute. The special equipment which can be furnished for this machine includes a swivel vise graduated in degrees, an index quill center, a tailstock, arbors for saws, a right-angle adapter, and a vertical milling attachment. The latter is mounted over the spindle nose and is driven by a plug placed in a draw-in collet.

JANETTE PORTABLE BUFFING MACHINE

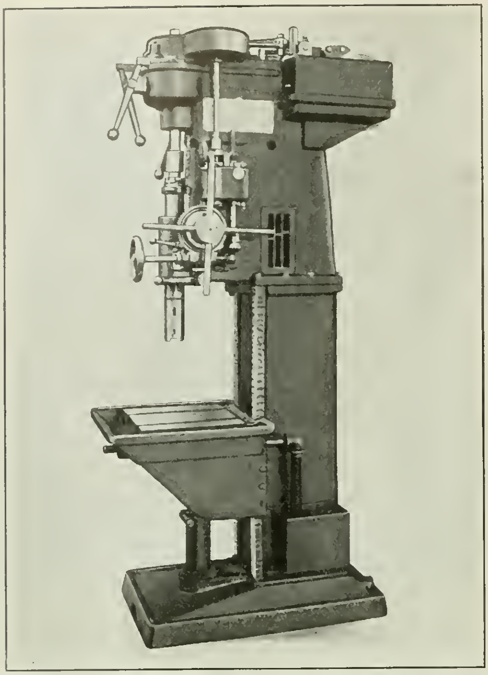
For use in the performance of buffing operations in cases where it is most convenient to take the machine to the work, the Janette Mfg. Co., 556 W. Monroe St., Chicago, Ill., has developed the portable equipment shown in the accompanying illustration. It will be seen that this machine is furnished with two wheels. One of these is mounted at the end of an extension of the armature spindle, and the other is driven by a flexible shaft. This combination assures maximum convenience in handling a wide range of work. The motor is furnished with a 10-foot connection and plug to screw into a lamp socket. The motor develops ¼ horsepower at 3500 revolutions per minute, has a push-button control, and may be supplied for alternating or direct current. With suitable modifications this machine could be adapted for other operations besides buffing.



Two-wheel Portable Buffing Machine introduced by the Janette Mfg. Co.

BAKER DRILLING MACHINES

Baker Bros., Toledo, Ohio, have added the No. 121 single-purpose and the No. 121 quick-change drilling machines to their line of products. These machines are adapted for driving drills ranging from ⅜ to 1½ inches in diameter, and in the general lines of construction are somewhat similar to the No. 217 single-purpose and the No. 314 flexible machines manufactured by the same concern. There are, however, a number of changes and improvements of design, the more important of which will be mentioned in the subsequent description. The No. 121 quick-change machine is shown in the accompanying illustration. The single-purpose machine is similar to this, but the feed-box is provided minus the feed-change gears, shafts, etc. A single-purpose machine can be converted into a quick-change type by the provision of the necessary shafts and gears, which are interchangeable so that they can be assembled without fitting.



No. 121 Quick-change Drilling Machine built by Baker Bros.

Slip change-gears are furnished in addition to the sliding gears to increase the range of speeds, so as to assure the efficient operation of all sizes of drills. This provision also facilitates the efficient use of different sizes of taps. It will be seen that a cabinet is provided in the column to receive these slip change-gears. The introduction of slip change-gears also provides different feeds from those formerly supplied, and so a different dial is provided to correspond with each set of slip change-gears. Attention is called to the convenient arrangement of all operating levers, which are not only centralized, but also located to enable the hands of the operator to move continuously from the highest position downward in shifting levers manipulated with either his right or left hand.

Another feature of the improved design is the casting of the bearing brackets for the tight and loose pulleys integral with the machine column, the pulleys being located directly behind the column. This arrangement is important when it is desired to set machines in gangs, as it brings the control levers on all machines within easy reach of the operator and saves floor space. Simultaneously with the throwing of the belt on the loose pulley, a cam-actuated brake is applied to the tight pulley to bring the machine to a stop quickly. A piston on the spindle rises into a cylinder as the counterbalanced spindle rises rapidly to the starting point after the feed has been tripped. By this means the spindle is quickly returned without occasioning any shock as it reaches the top of its upward movement.

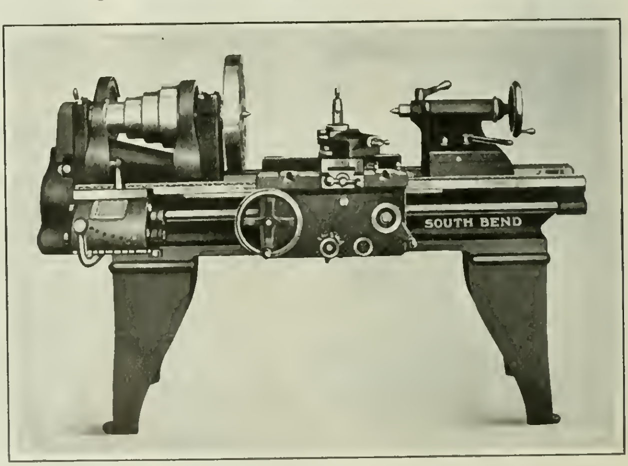
Included in the table-elevating mechanism is a sleeve nut that slides in an auxiliary column. In adjusting the position of the table, the bolt which clamps this sleeve is loosened; then by clamping the table to the main column of the machine and turning the table-elevating crank, the sleeve may be raised or lowered. By tightening the sleeve-clamping bolts and loosening the table-clamping screws, the table is ready to be moved to any desired height. Attention is finally called to the fact that the speed change-gear box is made as a unit which may be readily removed from the column. Ball and roller bearings are provided for the shafts in the speed-box.

ALCORN-BLOCKOUSE HEAT-TREATING FURNACE

An automatic continuous heat-treating furnace of a conveyor type, which is equipped with a combination conveyor for such articles as crankshafts, camshafts, and rear axle shafts, and for miscellaneous small pieces, such as gears, has been produced by Alcorn, Blockouse & Co., 1418 Walnut St., Philadelphia, Pa. The motion of the conveyor is always vertical, so that there is no longitudinal motion in the furnace. The important advantages are a uniform heating of the pieces being treated and the elimination of skilled labor. An increase in fuel efficiency and a decrease in repair and upkeep costs are also claimed. The uniformity of treatment and the reduction in fuel costs are due to the fact that the pieces are suspended above the furnace hearth and, except with flat pieces, are continuously revolved or turned over during the entire treatment. This eliminates spots due to contact with the hearth. The length of treatment is automatically controlled by a variable-speed motor, and the temperature is controlled by Leeds & Northrup control instruments having a temperature recorder. The furnace can be heated by electricity, gas, oil, coal, or any other kind of fuel which will produce the necessary heat.

SOUTH BEND QUICK-CHANGE-GEAR LATHE

The quick-change-gear lathe shown in the accompanying illustration has recently been added to the line of lathes manufactured by the South Bend Lathe Works, 420 Madison St., South Bend, Ind. It is made in eight sizes ranging from 9 to 24 inches swing, and may be provided with either a straight or gap bed. The quick-change gear-box is the same as that provided on Flather lathes, and has forty-eight changes of feeds and threads. These changes are also available for the cross-feed. All gears in the gear-box are made of steel forgings. The index-plate shows the holes in which to insert the plunger for the different changes, and the crank-lever above the box operates an inside clutch.



Quick-change-gear Lathe built by the South Bend Lathe Works

The bed has three vees and one flat way for guiding the headstock, tailstock, and carriage. The headstock is equipped with an improved reverse and a hollow spindle made of special steel and accurately ground. The tailstock is offset to allow the compound rest to be swiveled parallel to the bed, and is provided with a set-over to enable the turning of tapered parts. The tailstock center is self-ejecting. The carriage is provided with T-slots for clamping work to be milled or bored. Both the automatic cross-feed and the automatic longitudinal feed of the carriage are operated from the front of the apron, and but one feed can be engaged at a time. Both feeds are driven by a splined screw and worm so that it is only necessary to use the lead-screw thread when thread cutting.

The compound rest is graduated to 180 degrees, and the cross-feed screw has a micrometer graduated collar reading to 0.001 inch. The regular equipment includes large and small faceplates, graduated compound rest, follow-rest (not included on 9- and 11-inch lathes), adjustable stop for thread cutting, semi-machined chuck-back, gear guards, wrenches, and double-friction countershaft.

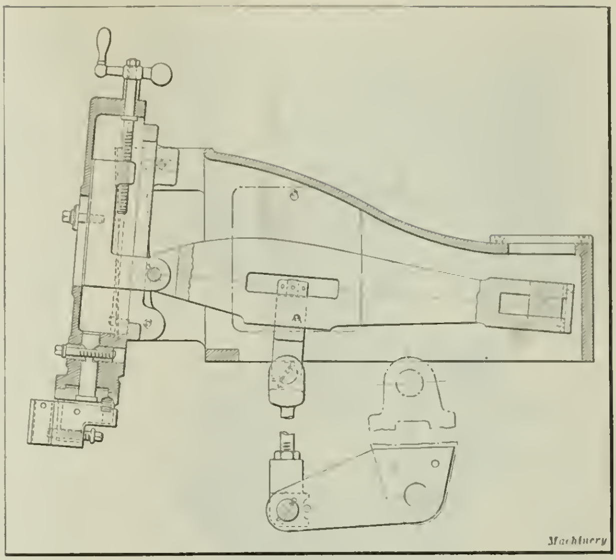


Fig. 2. Details of Vertical Shaper Attachment developed by L. E. Rhodes

RHODES VERTICAL SHAPER ATTACHMENT

To enable operations usually performed on shapers of the vertical type to be done on horizontal shapers, L. E. Rhodes, 51 Oak St., Hartford, Conn., has developed a vertical attachment that can be quickly applied to any of the standard types of crank shapers. This attachment is shown in the accompanying illustrations. The housing which contains the vertical ram and its necessary mechanical parts is made to fit in the ways occupied by the regular horizontal ram. This housing can be adjusted to the desired position with reference to the work, and held in that position by the regular gibs.

The installation of the attachment is a simple matter; practically all that is necessary is to remove the driving arm and attach two steel leg plates which remain on the machine permanently, screw in a connecting-rod, and insert a pin. This attachment is also provided with a rotary work-table equipped with standard index-plates.

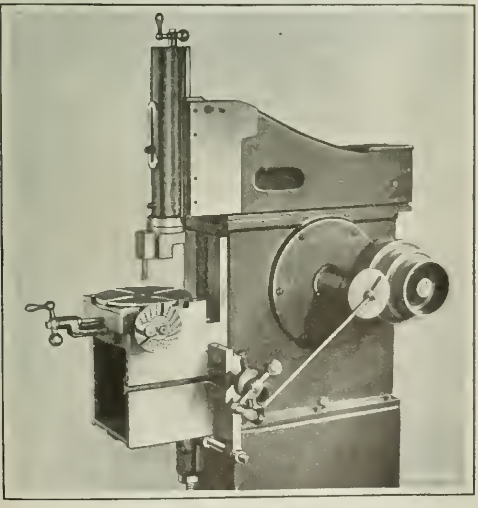

Fig. 1. Shaper equipped with Rhodes Vertical Attachment

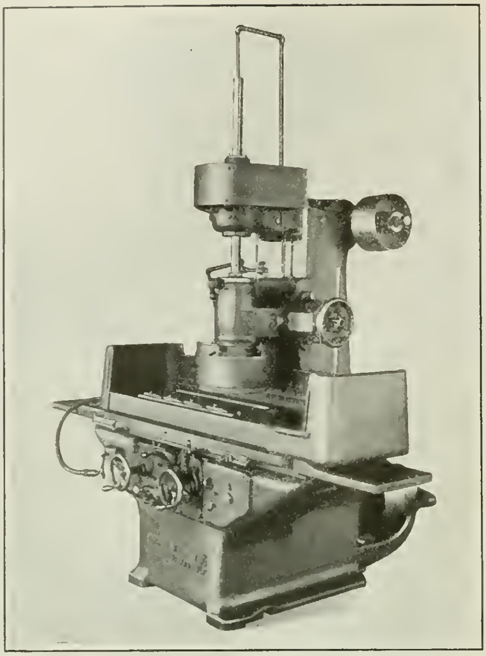
PRATT & WHITNEY VERTICAL SURFACE GRINDING MACHINE

The 14-inch vertical surface grinding machine of the movable platen type built by the Pratt & Whitney Co., Hartford, Conn., has had a number of new features incorporated in its design. The ball bearing mounting of the spindle has been completely redesigned, the weight of the wheel unit now being carried on springs set against the upper bearings. This arrangement provides an automatic compensation for wear. The upper section of the mounting is lubricated by oil dripping from regulation oilers through the bearing, and falling into whirling cups which throw it back into the bearing by centrifugal force. In the lower section oil is poured into a large reservoir from which it flows into the upper bearing and runs along the spindle to the lower bearing. The grinding wheel faceplate acts as a retainer, and ribs in this plate continually throw the oil up into the bearing.

The table drive has been strengthened by the use of hardened shafts, gears, and clutches, and is amply lubricated from sight-feed oilers on the front of the case. The entire drive-shaft unit is easily removed through the provision of split bearings. Hand operation of the table has been simplified by the use of a sliding gear on the handwheel shaft in place of a clutch. Smoother reversing of the table is accomplished by means of a dwell in the pinion drive which permits the table to come to a stop before reversal takes place. This eliminates shock and protects the clutch mechanism. The idlers over which the main driving belt runs have been equipped with roller bearings which are lubricated by large grease cups in the ends of the stationary shaft, and the spindle driving pulley is surrounded by a heavy sheet-metal guard.

A series of baffle plates are cast integral with the tank, and these plates are provided with openings alternately at the top and bottom. The solution flows over and under these plates in such a manner that a clean solution is obtained in the last compartment from which it is drawn off by the pump. The motor drive has been improved by mak-

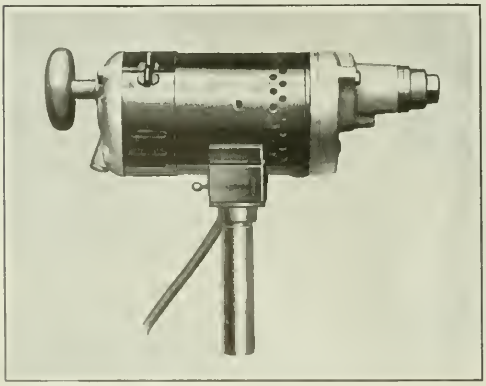


Improved 14-inch Vertical Surface Grinding Machine built by the Pratt & Whitney Co.

ing the motor base adjustable so that the driving belt may be correctly adjusted relative to the steps of the driving cone. The drive for the rotary tilting chuck is now equipped with a flexible coupling, which facilitates the mounting of the unit and the aligning of the driving shaft.

PORTABLE ELECTRIC DRILL

The Electro-Magnetic Tool Co., 2902 Carroll Ave., Chicago, Ill., has recently placed on the market a ½-inch portable electric drill. This tool has been designed to fill the requirements of garages, service stations, small machine shops, etc. A simple inexpensive stand is also made to convert the tool into a small drilling machine and so increase its usefulness. The gears are made of a high-grade steel and are hardened and ground. The spindle shaft is equipped with ball thrust bearings. The tool is controlled by a positive switch. All electrical connections are made in the switch box, the cover of which is removable to permit the reconnecting or changing of lead cords without opening the tool. The commutator may be inspected and the brushes removed by taking off a cover plate.

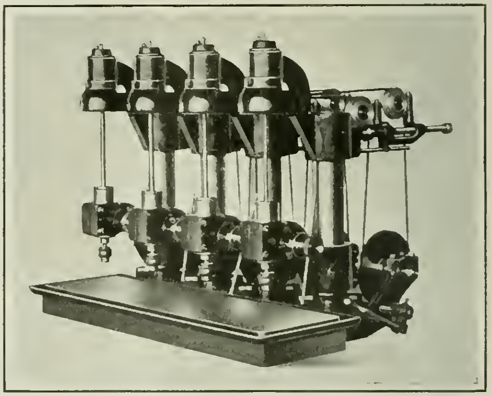


Portable Electric Drill made by the Electro-Magnetic Tool Co.

HENRY & WRIGHT BENCH MULTIPLE-SPINDLE DRILLING MACHINE

A recent development of the Henry & Wright Mfg. Co., 760 Windsor St., Hartford, Conn., is the No. 0 bench multiple-spindle drilling machine illustrated. This machine is equipped with ball bearings and has a two-step pulley in each spindle drive and on the rear driving shaft. These pulleys give four speeds, of which the maximum is 12,000 revolutions per minute, and drive a 13/64-inch drill to the full capacity. The tension on the belt driving each spindle is governed by a spring that can be quickly adjusted to give the proper tension for the size of drill being used.

The lower arm has a vertical adjustment on the column of 6¾ inches, and this, together with a feed of 2½ inches, gives a maximum height of 7⅞ inches from the table to the nose of the chuck. A quick return of each spindle is secured by means of an adjustable flat coil spring connected to the pinion which operates the rack. This spring also prevents the tool breaking when the drilling of a part is completed. The machine is equipped with tight and loose pulleys and a belt shifter. Special attention is given to the alignment of all parts so that high speeds can be maintained. Each spindle is ⅜ inch in diameter, and is provided with a chuck having a capacity up to 13/64 inch. The center distance of the spindles is 7 inches and the distance from the center of each spindle to the edge of its corresponding column is 5¼ inches. The machine occupies a floor space of 26¼ by 33 inches, has a height of 22¾ inches, and weighs about 345 pounds.



No. 0 Bench Multiple-spindle Drilling Machine manufactured by the Henry & Wright Mfg. Co.

WESTINGHOUSE SAFETY MOTOR-STARTING SWITCHES

Motor-starting switches Types WK-30 and WK-55 have been added to the line of electrical equipment manufactured by the Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. These switches are of the quick make-and-break knife type, and are completely enclosed, being operated by an exterior handle. The WK-30 switch protects the motor from overloads, both when starting and when running, because it is equipped with thermal cut-outs that open the circuit on dangerous sustained overloads but do not operate under harmless momentary overloads. The cut-outs resemble cartridge fuses, but are not interchangeable with fuses, so that the latter cannot be substituted by error. They operate by fusing a special washer which can be quickly replaced at a negligible cost.

On both switches all parts are enclosed so an operator cannot touch live contacts. The door to the cut-outs or fuses is interlocked with a switch that cannot be opened unless the switch is in the "off" position, when all accessible current-carrying parts are dead. If desired, the door can be padlocked to prevent access by unauthorized persons. It is also possible to lock the handle in the "off" position by three separate padlocks for the protection of those working on machinery controlled by the switch.

MELDRUM-GABRIELSON ADJUSTABLE LIMIT SNAP GAGES

Improved type "Syracuse" adjustable limit snap gages are now being manufactured by the Meldrum-Gabrielson Corporation, Syracuse, N. Y. Style A is shown in Figs. 1 and 2. The measuring pins on these gages may be adjusted to suit conditions, and then sealed over with wax to prevent tampering. The adjusting of the pins to the desired limits is a simple operation. The locking screw *A*, Fig. 2, is first loosened, and the measuring pin set by moving the split adjusting screw *B* either in or out as necessary. By then tightening the locking screw, the split adjusting screw is locked securely in place due to the action of the tapered head of the locking screw. The screw head is then covered over with sealing wax.

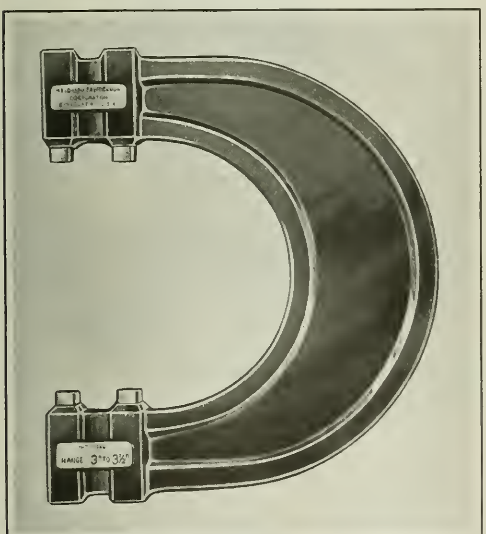


Fig. 1. Style A Adjustable Limit Snap Gage made by the Meldrum-Gabrielson Corporation

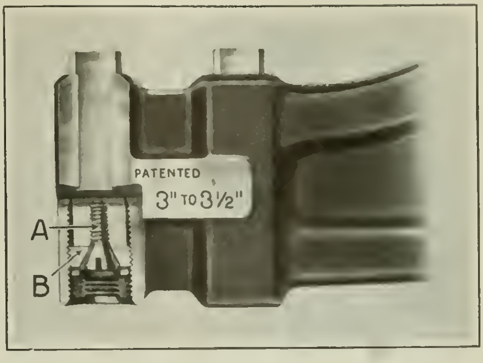

Fig. 2. View showing Arrangement for adjusting and locking Measuring Pins

The gage is provided with square pins, and patents are held on all other styles except round. The pins are made of tool steel, and are hardened and accurately ground to a tight fit. One advantage of a square pin is that it obviates any possibility of a pin turning in its hole. This shape also presents a straight edge to the work. The amount of adjustment possible is sufficient to permit several regrindings and lappings. The frame is made of gray iron, and is reheated to relieve all strains and to season the metal. It is finished in black enamel, baked on.

A gage similar to the one described, but which is provided with rectangular pins for measuring against shoulders is also manufactured. This type is known as Style B. It eliminates the danger of work passing inspection which has an enlarged diameter adjacent to a shoulder. A third type, provided with three pins and intended for use in the closer inspection of parts, is known as Style C. The outer pins of this gage are set to the "Go" dimension, the middle ones to the nominal size, and the inner ones to the "Not Go" dimension. These gages are made in twenty-four sizes, of which the smallest has a capacity of from 0 to ¼ inch, and the largest from 11 to 12 inches.

MARQUETTE EVEN-PRESSURE SPRING CUSHION

In drawing metal shells in dies, it is desirable to have an unvarying pressure during the entire stroke of the press, and in order to produce this uniform pressure, the Marquette Tool & Mfg. Co., 319-331 W. Ohio St., Chicago, Ill., has developed the spring cushion illustrated in Figs. 1 and 2. It is stated that with this device sufficient pressure is obtained at the beginning of the draw to eliminate the wrinkling of the metal and unnecessary wear on the dies. This pressure is maintained evenly at every point of the drawing operation, which avoids the straining of the metal to the breaking point toward the end of the stroke. By eliminating increased pressure at the bottom of the stroke, backlash of the press is avoided.

The cushion is attached to the press by means of a single bolt, which screws into the bolster plate or the die in the same manner that rubber bumpers or coil springs are fastened. No special drilling of the press or bolster is required, and the cushion will fit any ordinary drawing die. When the punch descends on the blank, die pins resting on a plate which, in turn, rests on spring housing *A*, Fig. 2.

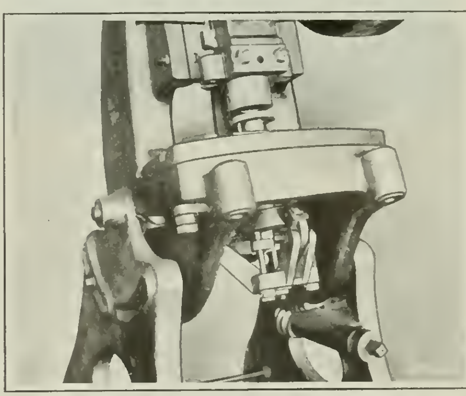

Fig. 1. Even-pressure Spring Cushion made by the Marquette Tool & Mfg. Co.

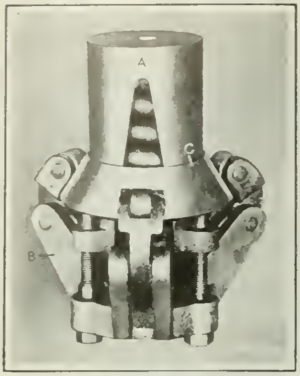

Fig. 2. Detail View of Spring Cushion

force the latter down, compressing the spring against a washer. This washer is carried by the lower ends of equalizing levers *B*. As the spring housing descends, it carries with it adjusting screws which allow the equalizing cam *C* to descend by yielding to the pressure of the rollers at the upper end of the equalizing levers. The angular surface of the cam permits the equalizing levers to swivel about their journals and the spring washer to descend, thereby causing, on a long drawing operation, only a slight compression of the spring. On a 1½-inch draw the compression amounts to only ⅝ inch. The angular surface of the equalizing cam, together with the change in the leverage of the equalizing levers as they swing about their journals during the down stroke of the press, compensates for the increase in the spring pressure made by its slight compression. During the return stroke the same movements take place in reversed order.

NORTON PISTON-GRINDING ATTACHMENT

The Nortou Co., Worcester, Mass., has recently brought out a universal piston-grinding attachment which is to be supplied as regular equipment with this company's auto-part regrinding machine. This attachment facilitates the setting up of a machine for pistons of different makes. It can be used on pistons from 2¾ inches in diameter up to tractor pistons 7½ inches in diameter. The fixture can be set up in less than two minutes.

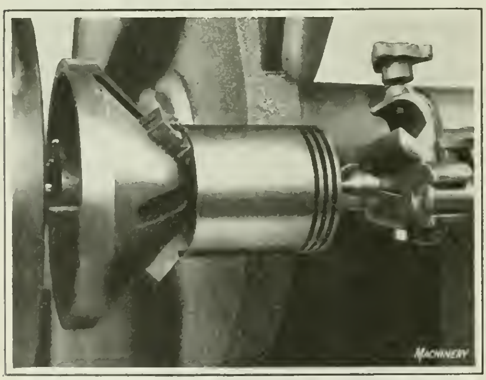

Fig. 1. Piston-grinding Attachment developed by the Norton Co.

In Fig. 1 the fixture is shown in place on a machine. From this illustration it will be seen that it consists essentially of a dead center upon which revolves a cone-shaped member in which three dovetail slots are cut. In each of these slots is mounted a slidable member of hardened tool steel, the upper surface of which is ground to a conical shape. This surface is parallel to the bottom of the slot in the cone, so that the movement of the jaw is along an element of the cone. In each of these jaws is turned a transverse groove, as shown in Fig. 2, which permits the corner of the wheel to travel beyond the end of the piston without interference. The jaws are also slotted longitudinally and locked in place by a taper-pointed screw.

As the surfaces upon which the piston rests are elements of the cone, an accurate setting of the jaws is unnecessary. They are merely set by eye to bring the clearance grooves into their proper positions. The cast-iron cone revolves upon the end of the dead center on a conical bearing, and is driven by the regular drive pin extending from the faceplate of the machine into a cored slot. The piston, in turn, is driven by means of a spline made of a small piece of sheet steel screwed to the side of one of the jaws, as shown in Fig. 2. A shallow slot is filed in the skirt of the piston to engage this spline. In case the maker of a piston does not recommend slotting the skirt, a special driver can be furnished which is adjustable for all sizes of pistons.

The bearing of the cone on the dead center is tapered, and wear is taken up by adjusting a split threaded collar, immediately in back of the cast-iron piece. The slidable jaws can be readily dressed in case of wear by setting the fixture in the adjustable center-grinding attachment which is furnished with the grinding machine. Ample oiling facilities are provided by means of drilled holes leading from the back of the center to the inside of the bearing. The attachment is known as Style No. 509.

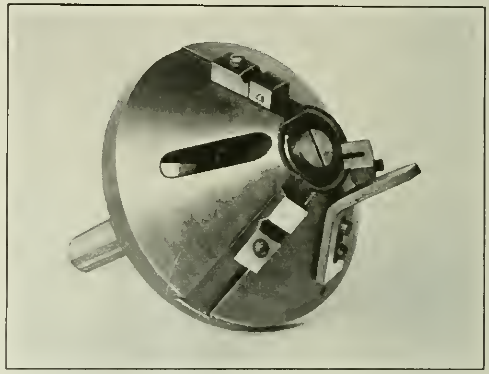

Fig. 2. Close View of Norton Piston-grinding Attachment

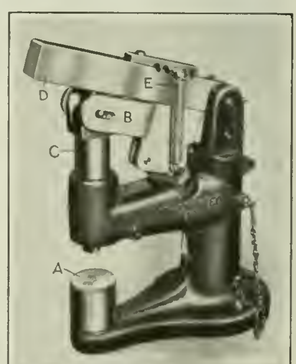
GILES TRIP-HAMMER STAKING MACHINE

A machine designed for staking or riveting cupped or drilled rivets, studs, screws, pins, etc., in the assembly of small parts, is now being manufactured by the H. C. Giles Corporation, 303 Cox Bldg., Rochester, N. Y. The machine is particularly adapted for jobs where uniformity of the product is required and where distortion of the work is not permissible. It is operated by foot through a treadle-rod that extends through the bench on which the machine is mounted. This rod is not shown in the illustration.

After placing the rivet or stud, and the parts to be assembled, on the staking block *A*, spindle arm *B*, and consequently spindle *C*, is brought down-



Staking Machine built by the H. C. Giles Corporation ward by operating the treadle, until a certain tension is obtained on a spring pad within the spindle and projecting from the lower end of the latter. When this tension has been secured, a latch in hammer *D*, which has been previously engaged with a stationary dog in arm *B* in such a manner that the hammer and arm are separated, is released. As this occurs, the hammer is pulled downward by two springs *E* which connect the hammer and arm *B*, and strikes a blow upon a pin projecting slightly from the top of the spindle. This pin, in turn, drives the staking set at the lower end of the spindle. A spring in the base of the machine raises the spindle after each blow.

JACKSON VERTICAL-SPINDLE MILLING MACHINES

The accompanying illustrations show improved types of vertical-spindle milling machines built by the Jackson Machine Tool Co., Jackson, Mich., for manufacturing and die-sinking purposes. The machine shown in Fig. 1 is known as the No. 6-A, and has power feeds. A machine known as the No. 5-A is similar to the No. 6-A machine except that the feeds are by hand, the table surface is smaller, and some of the traverses are less. The machines are very much the same as the Nos. 5 and 6 Jackson die-sinkers, but they are not equipped with a cherrying attachment.

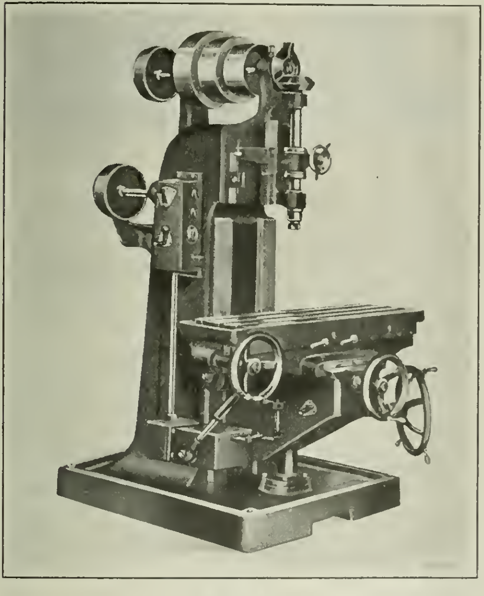


Fig. 1. No. 6-A Vertical Milling Machine built by the Jackson Machine Tool Co.

To facilitate operation, the spindle has a vertical movement, manipulated by hand through a mechanism permitting both hand feed and rapid traverse. Near the lower end of the spindle is a vertical sliding housing, which carries both the lower main spindle bearing and the thrust bearing and is operated for a slow feed by the handwheel shown at the right. The rapid traverse is obtained through a four-spoke pilot wheel located near the handwheel. The slow feed is quickly engaged or disengaged by a slight turn of a small knurled handwheel, and when the slow feed is disengaged, the rapid traverse is free to operate. The spindle and housing are counterbalanced by a weight inside the column, which is slightly greater than the weight of the spindle and attached parts, in order that all lost motion between the cutting tool and the handwheel may be taken up. A micrometer stop is provided for determining the depth of cut and the vertical position of the spindle. The spindle housing may be clamped in position for a longitudinal or a transverse cut when the proper depth is once obtained.

Fig. 2 shows the No. 10-A milling machine. Another machine known as the No. 10-B is similar to the No. 10-A, except that the latter has a table and cross-rail feed ranging from 0.001 to 0.015 inch per revolution of the spindle while the No. 10-B machine has a range of feeds from 5/16 inch to 16 inches per minute, regardless of the spindle speed. These milling machines are practically the same as the No. 10 die-sinker, the only difference being that they are provided with a head containing a heavy vertical milling spindle, whereas the die-sinker is equipped with a head containing a vertical spindle and a cherrying mechanism. Inside the milling machine head is a back-gear arrangement, whereby thirteen changes of spindle speeds ranging from 8½ to 310 revolutions per minute are obtained. A pull-pin lever on the head provides means for quickly shifting from direct to back-gear. All other speeds are secured through the change-gear box on the left-hand side of the base near the driving pulley.

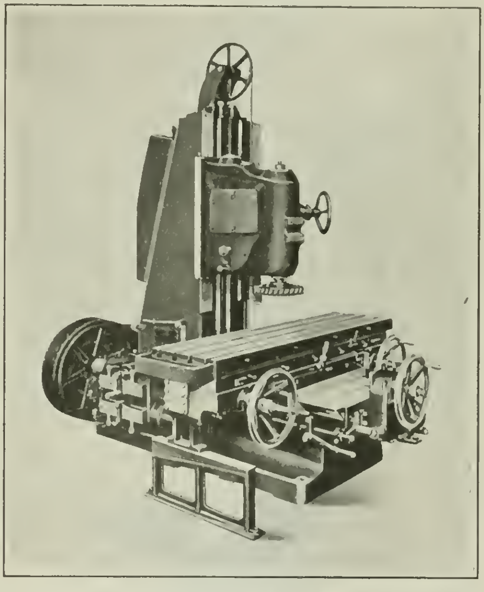

Fig. 2. No. 10-A Jackson Vertical Milling Machine designed for Production and Die-sinking

The lower end of the spindle has an integral flange 6½ inches in diameter and having a ¾-inch keyway running across the face and two holes for securing and driving large cutter-heads. It also has a hole 13/16 inch in diameter running its entire length for a draw-in bolt, and a No. 13 Brown & Sharpe taper hole at the bottom. All feed changes are controlled at the feed-change box on the right-hand side of the base near the rear end. A circular table 36 inches in diameter may be provided for circular and continuous milling. This table may be used as an attachment on the milling machine table, so that it may be removed when not in use, or it may have its bearing on a specially designed cross-rail. Standard sizes of cutters are made for these machines, the cutters being 4, 6, 8, 10, 12 and 14 inches in diameter. All cutters are made from standard stock and may be used with any cutter-head. The larger heads have backing rings for more securely holding the cutters.

PRATT & WHITNEY DIE-SINKING MACHINES

Several new points in design have been incorporated in the die-sinking machines made by the Pratt & Whitney Company of Hartford, Conn., to make their operation more convenient and their maintenance easier. The driving spindle has been provided with a positive pin lock in four positions, so that the chuck or collet can be tightened without holding the driving belt. The spindle pulley has a new system of oil-grooving opposite to the direction of rotation, so that oil is continually carried upward, thus insuring complete lubrication. A floating babbitt washer takes the thrust on the spindle. The main driving cone has been fitted with a hollow spindle having communicating oil-holes that deliver oil to a series of felt-packed grooves which conserve the lubricant and guarantee an ample supply.

Leather wipers held in cast-iron caps attached to the knee protect the ways from chips and dirt. The vise capacity has been increased to accommodate larger work, and the vise has been strengthened in proportion to its greater capacity. A telescopic elevating screw is furnished in place of the old type of straight screw. The elevating wheel shaft is equipped with a thrust bearing for ease of operation. The outboard bearings for the knee and vise slides have been strengthened, and the slides are grooved and protected with covered oilers.

A cherrying attachment recently developed for use on the die-sinking machines is illustrated in Fig. 2. This attachment is pivoted in a bracket attached to the side of the column. When in the working position, the swinging arm of the attachment is doweled and clamped to a boss at the lower machine-spindle bearing. The application of the cherrying attachment does not interfere with the regular functions of the machine. When in the working position, the regular feeds are available for governing the cut, and in the non-working position the spindle is released for ordinary operations. The adjustment to either position can be readily made.

The backs of the cutter teeth are utilized for driving the cutters. These are made in the form of gear teeth and mesh with a spur pinion. Two pinions of different pitch are furnished to permit a variation in tooth space on small and large cutters. Bevel gears transmit power to the cutter pinion, and the end of the machine spindle is threaded to receive the driving gear. The mating driven gear is held on the pinion-shaft by a friction which may be readily adjusted to suit conditions. This friction acts as a safety to prevent injury to cutters which might result from excessive feed or faulty manipulation.

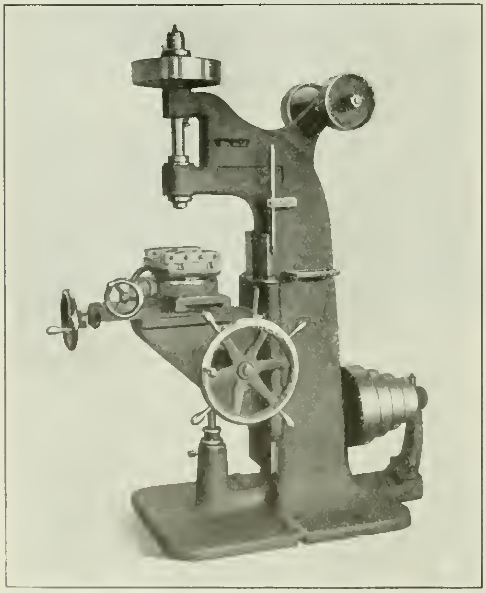

Fig. 1. Improved Die-sinking Machine brought out by the Pratt & Whitney Co.

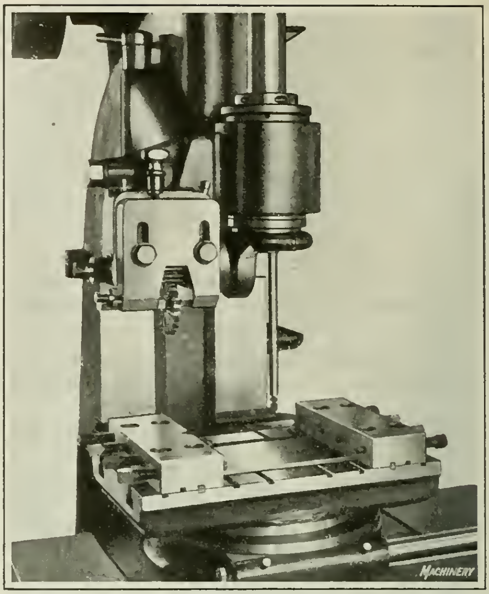

Fig. 2. Cherrying Attachment developed for Use on Die-sinking Machines

Cutters from 1 to 6 inches in diameter can be accommodated, the cutter-slide being provided with an adjustment to compensate for the various sizes. The smaller size cutters are mounted on conical centers, while the larger sizes are provided with a comparatively small hole for which cylindrical centers are utilized. The method of mounting the cutters on centers is such that half the cutter diameter can be used. This cherrying attachment is intended for finishing operations only, and before its use the impression should be roughed approximately to shape. Stock cutters have a 7-degree angle plus a shrinkage allowance of 3/16 inch per foot. The cutters are made from carbon and high-speed steels.

BICKFORD-SWITZER TAP GRINDER

A self-contained tap grinder, equipped with a 1/4-horsepower motor, for either direct or alternating current, has recently been developed by the Bickford-Switzer Co., 50 Norwood St., Greenfield, Mass. This machine is mounted on a column and weighs about 300 pounds. A good idea of its general construction may be obtained by reference to Fig. 1, while the diagram Fig. 2 shows the difference between a tap sharpened by ordinary methods and one sharpened by the new machine. The full lines show the shape of the thread after sharpening in the regular way, while the curved dotted line shows where the point of the tooth at *A* is removed when the tap is ground on the new tap grinder. In many respects the machine is similar to the drill grinder described in March MACHINERY. It is designed to sharpen any style of tap having any number of lands or flutes from two to six, inclusive, by grinding an eccentric relief on the top of the cutting lands. The machine is made to handle hand taps up to 1½ inches in diameter, tapper or machine

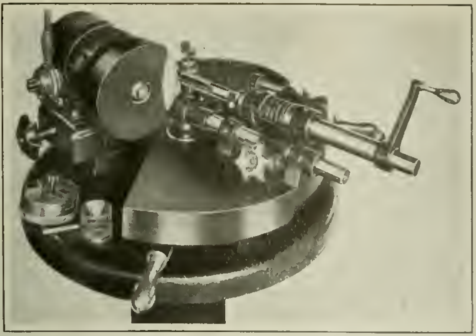

Fig. 1. Tap Grinder developed by the Bickford-Switzer Co.

nut taps up to $1\frac{1}{4}$ inches in diameter, and pipe taps up to 2 inches in diameter.

A feature of the machine is that it grinds the different lands of the tap separately and in consecutive order. A cam on the work-carrying spindle rides against a positive shoe, and causes the tap to approach, and recede from the wheel as it is revolved on its own centers. The squared end of the tap is driven by a bell center of the ordinary type, while the point end is supported by a male or female center as required. These two centers are mounted on a plate which can be revolved, or swung away from the grinding wheel to give sufficient space for inserting the shank of any long tap that it may be necessary to hold in the chuck.

The different cams employed to actuate the relief mechanism are machined on a single shell, mounted on the work-spindle in such a way that the cams do not revolve when the spindle is turned in a backward direction, but will start forward from any position when the spindle is turned forward. This arrangement facilitates the work of setting the tap so that its cutting lands will be in the proper position relative to the cam. In order to do this, it is only necessary to turn the tap backward until the contact point of the wheel is in a position between two lands of the tap and then turn the tap forward. The head which carries the main spindle can be clamped in the desired position on the rocker shaft. A flat spring which acts on the head serves to keep the particular cam in use in contact with its shoe, and a small cam-shaped collar is provided for the purpose of forcing the shoe in contact with the cam.

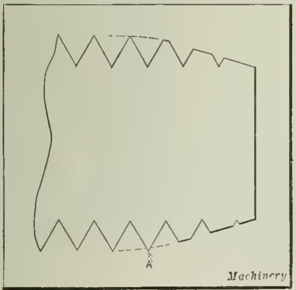

Fig. 2. Outline of Ground Tap

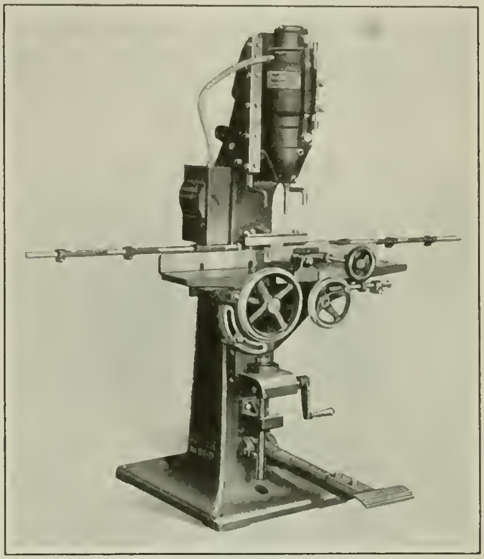
The machine can be used to sharpen countersinks and chucking reamers as well as taps, if they do not have more than six flutes. A lever located at the left is employed to feed the work forward into a position opposite the wheel, at which point another lever at the right of the first is used to set the work to the desired angle. The wheel is fed in as the work is revolved by means of a crank. A special feature incorporated in the machine provides for changing the angle of the work as it passes the wheel, so that a rounded contour is produced where the angle of the bevel near the end of the tap approaches the parallel sides. This feature prolongs the life of a tap and eliminates the necessity of using a hone to take off the sharp corners left on chucking reamers when the latter are ground by the usual methods.

OLIVER VERTICAL HOLLOW-CHISEL MORTISER

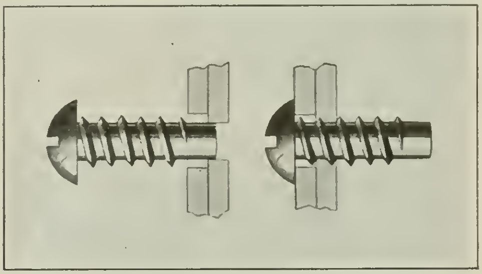
The illustration shows a vertical hollow-chisel mortiser on which the driving motor is built into the mortising head or ram. The motor operates on either two- or three-phase, 60-cycle current and at a speed of 3600 revolutions per minute. The machine is a product of the Oliver Machinery Co., Grand Rapids, Mich. The housing for the motor and head is in one piece, and the rotor of the motor is mounted directly on the machine spindle, which runs in high-grade ball bearings. The motor is connected by means of a flexible Greenfield conduit to a safety enclosed starting switch with fuses. This construction eliminates a countershaft, pulleys, and belts, and so saves floor space. The machine is equipped with a compound table having a handwheel rack- and pinion-feed and a clamp for the work. It is provided with the usual bushings, wrenches, etc.



Motor-driven Hollow-chisel Mortiser built by the Oliver Machinery Co.

PARKER SELF-TAPPING SCREW

A novel design of screw which requires no tapping of the hole in which it is inserted is shown in the accompanying illustration. This screw is manufactured by the Parker Supply Co., Inc., 785 E. 135th St., New York City, and will cut its own thread in die- or sand-cast parts of gray iron and softer metals, without the thread being injured. The screw has a V-thread of fairly coarse pitch and a cylindrical

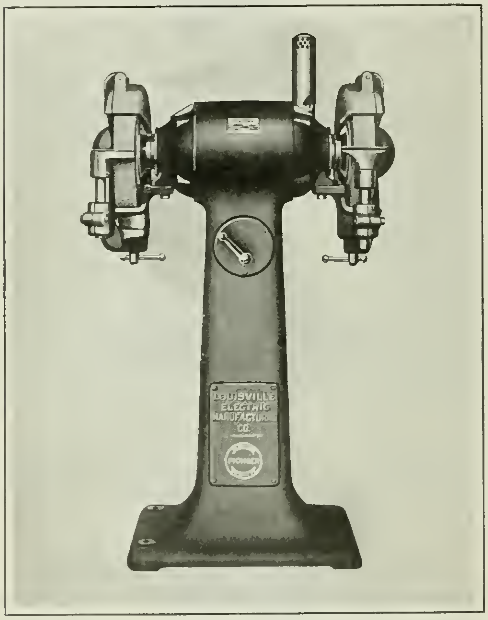


Self-tapping Screw made by the Parker Supply Co., Inc.

pilot which steadies the thread while it seats itself in the metal. In using this screw, a hole is first drilled in the piece which would ordinarily be tapped, a few thousandths of an inch larger than the pilot, and the piece to be assembled is drilled sufficiently large to provide clearance for the threads of the screw. The pilot is inserted in the hole, and with a few turns of a screwdriver, the screw is driven in place. The entire screw is hardened and heat-treated so that the thread cuts into metal similarly to a tap.

LOUISVILLE ELECTRIC GRINDING MACHINE

The Louisville Electric Mfg. Co., Louisville, Ky., has recently placed on the market the two-horsepower electric grinding machine here illustrated. It has improved ventilation, with an air intake so located that clean air is drawn through the motor. The machine can be operated continuously without exceeding temperature limits, and for intermittent duty the motor will operate safely with the air intake closed. The machine is provided with ball bearings,

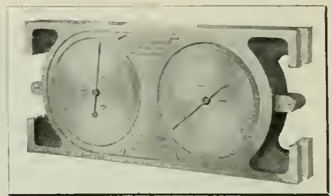


Electric Floor Grinding Machine brought out by the Louisville Electric Mfg. Co.

completely enclosed in housings. The safety hoods are made of steel and have a hinged side wall to enable wheels to be readily changed. The rests are adjustable. The motor-starting switch is enclosed in the column, and a water pot is attached to the latter. The machine is intended to be driven by either direct or alternating current. The height from the floor to the center of the spindle is 38 inches, and the wheels are 12 by 2 by 1 inch. The weight of the machine is approximately 400 pounds.

YOUNG-FISCHER "INCLINOMETER"

An instrument known as the "Inclinometer," which is intended to take the place of a plumb, level, sine-bar, and protractor in mechanical laboratories, machine shops, etc., has been developed by the Young-Fischer Inclinometer Co., Milwaukee, Wis., and is shown in the illustration accompanying this description. The instrument may be used on vertical, horizontal, and angular surfaces. It consists of an accurately machined metal case having two dials on the front face, one of which indicates angles in degrees and the other in minutes. The hand on the degree dial is fixed to the end of a small shaft on which is also attached a heavy pendulum, the result being that the hand indicates directly the number of degrees that the base of the instrument is off a true level. The minute hand is moved by a gear train that multiplies the motion of the pendulum so as to move the minute hand sixty places around the dial while the degree hand moves a distance representing one degree on its dial. A complete revolution of the minute hand represents an angular variation of 10 degrees.

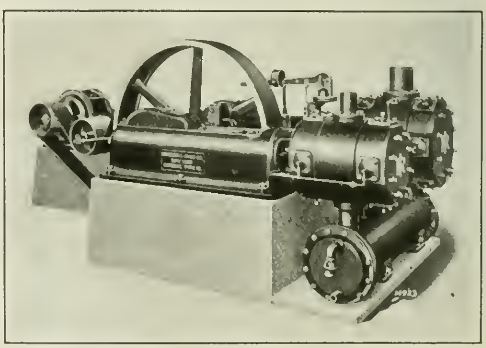


"Inclinometer" made by the Young-Fischer Inclinometer Co.

Inaccuracies due to bearing friction are overcome by mounting the bearings in rings which are concentric with the shafts and which are connected with arms or levers extending outside the case. The levers are provided with knurled handles, and in using the instrument the operator moves these handles up and down a few times, allowing the levers to strike against the ends of slotted holes in the case. The combination of the hammer effect and the oscillating movement of the bearings around the shaft eliminates retardation due to bearing friction.

INGERSOLL-RAND BELT-DRIVEN AIR COMPRESSORS

The Ingersoll-Rand Co., 11 Broadway, New York City, has announced a new line of belt-driven air compressors known as the "Imperial" Type XCB. These compressors are provided with Ingersoll-Rand plate valves for both the air intake and the discharge, and a five-step clearance control for regulating the output of the compressor. The plate valves are kept in alignment throughout their operation without wearing guides. The clearance control has been used with success on the larger direct-connected electric motor-driven compressors of this company's manufacture. This control provides a method of securing efficient operation at partial loads, as it automatically loads or unloads the compressor in five successive steps, as governed by the reduction or addition of clearance space in the air cylinders, which, of course, affects the volume of air taken in and compressed. The compressor will operate at full, three-quarter, one-half, one-quarter, and no load. At any one step the reduction in



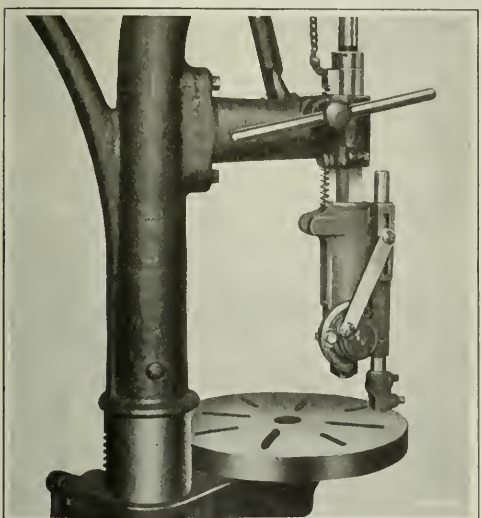
"Imperial" Type XCB Air Compressor developed by the Ingersoll-Rand Co.

input power required is in proportion to the reduction in the output capacity.

The compressors can be furnished in a single-stage style for low pressures and a two-stage style for higher discharge pressures. On a two-stage compressor clearance space in the proper proportion is added simultaneously for both the high and low cylinders, thus giving a constant rate of compression. An added feature of the control is the provision of a stop which will prevent the compressor from being operated at a load higher than desired. The piston displacement capacity for a 100-pound discharge pressure ranges from 610 to 1505 cubic feet of free air per minute. A short-belt driving attachment with a floating idler can be furnished for driving the compressor. This method of drive saves floor space and length of belt, and permits a greater arc of belt contact.

UTILITY FILING ATTACHMENT

A filing attachment designed to be employed with any make of drilling machine has been developed by the Utility Tool & Mfg. Co., 2717 Lafayette Ave., St. Louis, Mo., and is shown in the accompanying illustration. This device is

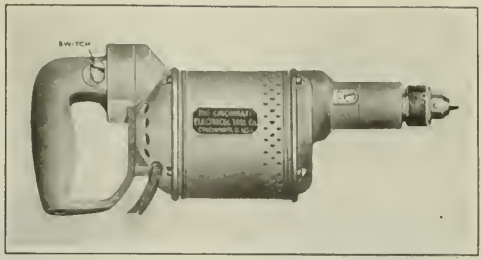


Filing Attachment for Drilling Machines, which is made by the Utility Tool & Mfg. Co.

suitable for either heavy-duty or small die work, and will accommodate any shape of file and any length up to 16 inches. The table of the drilling machine may be moved to any position, and the filing machine can be readily adjusted to any degree from 1 to 90. All gears are made of steel and are hardened and ground. In case of overstrain, a small cold-rolled pin in the shank becomes sheared, which stops the operation of the device. This pin can be easily replaced.

CINCINNATI PORTABLE DRILL

A light-weight portable electric drill of 3/16-inch capacity, provided with a pistol grip, is the latest addition to the line of tools manufactured by the Cincinnati Electrical Tool Co., 1501-1505 Freeman Ave., Cincinnati, Ohio. This drill is suitable for drilling steel, brass, aluminum, and sheet metal. and is especially intended for use in the manufacture of automobile bodies, window frames, etc. The drill is equipped with a universal motor for use on direct or alternating current of the same voltage. The motor housing, end caps,



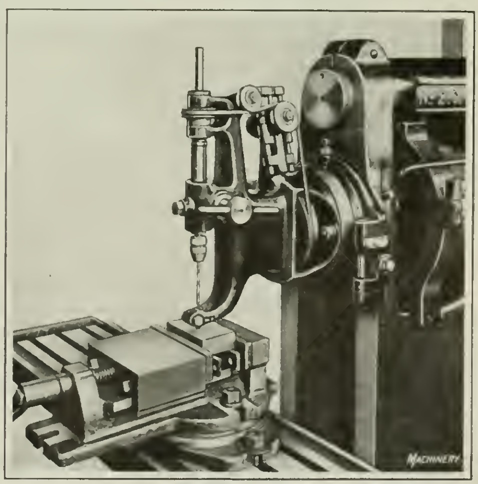
Portable Electric Drill brought out by the Cincinnati Electrical Tool Co.

and handle are made of aluminum, and the armature and gear studs are mounted on ball bearings. The switch is of the Cincinnati special quick make-and-break type, with an overload allowance of 50 per cent. It is entirely enclosed in the handle, and operated by a trigger conveniently located in that member.

KRAG SPOTTING AND ROUTING ATTACHMENT

A spotting and routing attachment designed to be mounted on milling machines for use in the accurate lay-out and drilling of holes up to and including 3/16 inch in diameter in dies, jigs, templets, master plates, etc., is here illustrated. This attachment is distributed under the trade name of "K-N" by E. L. Krag & Co., 50 W. Randolph St., Chicago, Ill. It is manufactured by Franz K. Krag, Chicago, Ill. The locating of holes by means of buttons is entirely unnecessary when this attachment is used. The attachment is securely mounted on a milling machine by means of a swinging clamp, requiring only one locking screw. It is placed in alignment permanently by means of a locating screw in the base, which is locked in place after having been adjusted.

The driving arbor for the attachment is inserted in the spindle of the milling machine, and is provided with a spring dog that engages automatically when the machine is started. The spindle of the attachment is driven by means of a round belt that is always kept at a uniform tension through the provision of a compensating spring idler, mounted in such a manner that the belt is always in alignment. The speeds of the attachment spindle and the machine spindle are in the ratio of 7 to 1. The spindle housing and the bracket which holds the guide bushings are cast



Krag Spotting and Routing Attachment

in one piece to assure alignment at all times. The spindle sleeve can be locked firmly in any desired position when using the attachment for routing by means of a friction plug. Five guide bushings, 1/16, 3/32, 1/8, 5/32, and 3/16 inch in diameter, are supplied, and these are made of a high-grade tool steel. The attachment is graduated to 360 degrees, and may be quickly adjusted to any desired angle. It is supplied for all standard makes of milling machines.

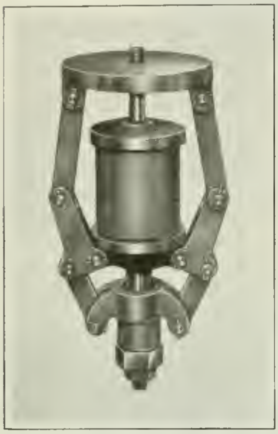


Fig. 1. Press Attachment made by the E. W. Bliss Co.

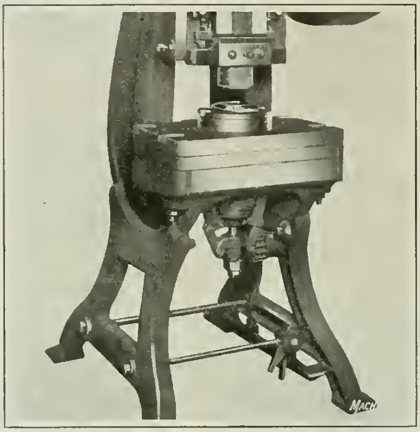

Fig. 2. Press equipped with Spring-pressure Attachment shown in Fig. 1

BLISS PRESS ATTACHMENT

The toggle-joint spring-pressure attachment here shown has been developed for use with combination dies, particularly when lithographed metal is being handled. This attachment is a product of the E. W. Bliss Co., Brooklyn, N. Y., and is intended for use with machines built by this concern. The attachment insures a uniform drawing pressure on the blank, and so increases the efficiency of the dies by minimizing the strain on the metal and reducing wrinkles and the breakage and wear of dies. The application of the toggle mechanism reduces the total rubber or spring compression. The reduced compression enables the economical manufacture of deep shells and a reduction in the number of operations required in cases where reducing operations follow the first blanking and drawing operation.

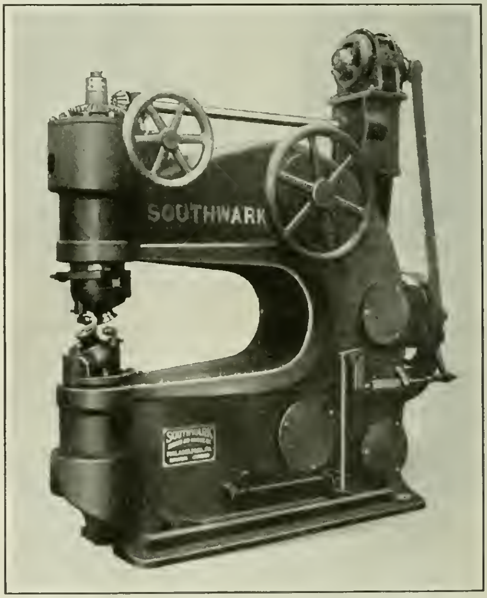
Some of the classes of work usually performed by double-action dies can be accomplished with combination and reducing dies when the presses are equipped with this attachment. The attachment is regularly built in four sizes and the depth of draw obtainable on the various sizes is as follows: No. 18 press, 1 1/4 inches; No. 19 press, 1 1/2 inches; No. 20 press, 2 inches; and No. 21 press, 2 1/2 inches. In order to have the maximum draws given, presses must have the same stroke and die space necessary with the old-style attachment. No change in the press equipment is necessary for the installation of this device.

SOUTHWARK-GRAY TURRET ROTARY SHEAR

A product of the Southwark Foundry & Machine Co., Philadelphia, Pa., known as Gray's turret rotary shear was described in MACHINERY for June, 1920. The principles of design and operation embodied in this machine have been incorporated in three new sizes of rotary shears recently developed by this company. These machines are adapted for cutting any shape of opening in sheet metal without cutting in from the edge and without turning the sheet, this method of cutting sheets and plates being made possible by mounting the rotary cutter on a turret which can be moved to any angle through a full circle while the cutting action is in process.

On the new No. 0 shear, which is the smallest of the four sizes, only the lower cutter is driven. This machine is designed primarily as a hand-driven machine, although power can be applied. On all sizes larger than the No. 0 machine both cutters are power-driven. The special feature of the largest or No. 3 machine, which is here illustrated, is the mounting of both the upper and lower cutters on adjustable turrets. This machine has a capacity for cutting any thickness of plate up to 3/8 inch. Both the upper and lower cutters are set at an angle, and they keep the same relative positions at any degree of the circle to which they may be turned. Handwheels for revolving the turrets are provided on both sides of the machine, so that the operator can control the machine from either side. The cutting speed of this machine is 10 feet per minute, and the throat depth 36 inches. Only 3 horsepower is required for driving.

The No. 2 machine has a capacity for cutting sheet metal of any thickness up to No. 8 gage, with a cutting speed of 10 feet per minute. The throat depth of this machine is 30 inches. The No. 1 machine will cut sheet metal up to No. 14 gage, and has a throat depth of 30 inches. The smallest or No. 0 machine will cut up to No. 16 gage, and has a throat depth of 18 inches. Special machines of larger sizes can be built to shear plates up to 1 inch in thickness. The lighter models of the turret rotary shear are employed

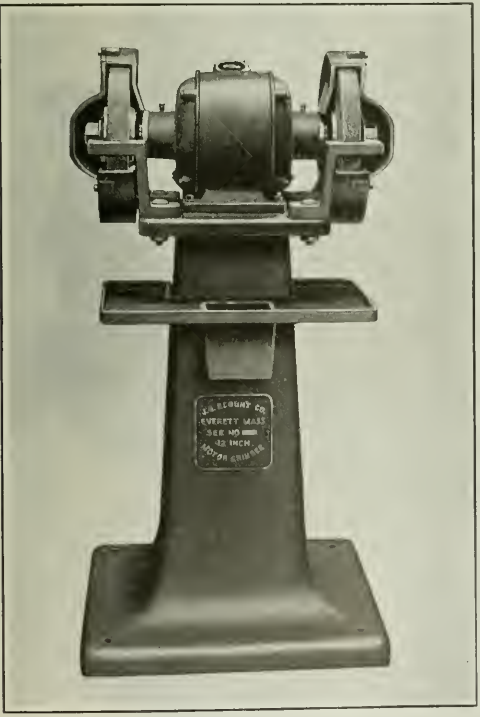


No. 3 Double-turret Rotary Shear built by the Southwark Foundry & Machine Co.

to cut such parts for automobiles as aprons, pans, tanks, mud guards, flanges, fenders, radiators, etc. In general sheet-metal work they are employed to cut elbows, tees, hoods, oil-pans, parts for ventilator systems, etc. The heavier models are employed to shear plates used in building ships, locomotives, boilers, etc., and in structural and ornamental iron work.

BLOUNT MOTOR-DRIVEN GRINDING MACHINES

A new line of grinding machines driven by alternating-current motors has recently been brought out by the J. G. Blount Co., Everett, Mass. The machines are built in ½-, 1- and 2-horsepower sizes. The ½-horsepower machine has 8- by 1-inch grinding wheels; the 1-horsepower machine, 10- by 1½-inch wheels; and the 2-horsepower, 12- by 1½-inch wheels. The illustration shows the 2-horsepower machine. These grinding machines are equipped with S K F ball bearings contained in dustproof mountings. The bearings are a light drive fit on the shaft, and are secured by lock-nuts. The spindles are made of a high-carbon steel, and are ground to size. The wheel flanges are machined all over, and the inner flanges are pressed to the shoulder of the spindle. The tool tray and water pot are bolted to the collar. They are separate and detachable. The tool-rests are in one piece and adjustable. Each machine is equipped with one coarse and one fine grinding wheel unless otherwise specified. The machines are driven by Westinghouse motors equipped with starting switches of the textile snap type.

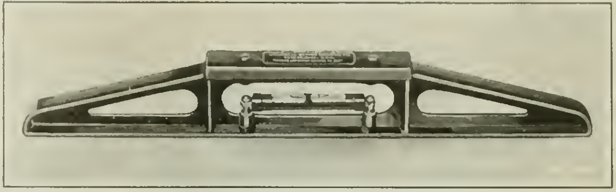


Two-horsepower Motor-driven Grinding Machine brought out by the J. G. Blount Co.

UNIVERSAL MACHINE-ALIGNING LEVEL

The Universal Boring Machine Co., Hudson, Mass., has just placed on the market a precision machine-aligning level. The frame is an iron casting of truss construction, and is of sufficient strength to eliminate strains. The leveling surface is 27 inches long. The vial is made of the best Jena glass, specially ground. It is set in a brass japanned case mounted on two lacquered brass studs which enable adjustments to be made. After being adjusted, the vial is locked in position by two nuts working against each other. The bubble in the vial has a guaranteed sensitiveness of 5 seconds of arc per graduation, this being equivalent to twenty-nine hundred-thousandths inch per foot. The manner of mounting the vial insures protection from breakage.

The level casting is insulated from the palm of the hand by means of a handle of non-conductive material and so distortion from this source is eliminated. In its manufacture, the casting is planed and drilled and then thoroughly seasoned. Subsequently, the base is hand-scraped and tested, after which it is allowed to rest for another period and is again tested. The vial is finally adjusted. The instrument is supplied in a felt-lined mahogany case, equipped with a brass handle to enable it to be conveniently carried from place to place. The level is 27 inches long and weighs about 9¾ pounds.



Machine-aligning Level placed on the Market by the Universal Boring Machine Co.

NEW MACHINERY AND TOOLS NOTES

Connecting-rod Machine: Sawyer-Weber Tool Mfg. Co., Los Angeles, Cal. A machine, the bed of which consists of a faceplate on which may be located clamps, V-blocks, boring tools, and other equipment such as required in babbitting connecting-rod bearings, straightening the rod, and boring the bearing to size.

Spring Tool-holder: Willard Tool Co., Inc., 105 E. Main St., Stratford, Conn. A spring tool-holder of the gooseneck type made of drop-forged steel and hardened to a spring temper. This holder is made in several styles and sizes, and is so designed that the tool will yield or recede in a practically straight line from the work, without causing chatter marks or breakage when taking a heavy cut.

Pneumatic Grinder: Onsrud Machine Works, Inc., 3908 Palmer St., Chicago, Ill. A high-speed grinder operated by compressed air at a pressure of 70 to 100 pounds per square inch. The complete unit weighs only 5½ pounds and is intended for small grinding wheels. Provision is made for attaching the unit to standard machine tools, but it can also be held in the hand and operated as a portable grinder.

Hardness Testing Machine: Riehle Bros. Testing Machine Co., 1424 N. 9th St., Philadelphia, Pa. A combination Brinell and scleroscope hardness-testing machine, designed primarily for the use of the Association of Manufacturers of Chilled Car Wheels in making a study of the hardness and comparative wearing and breaking qualities of chilled wheels. With this machine it is possible to employ both the Brinell and scleroscope tests on the same spot.

Electric Grinder: Forbes & Myers, 178 Union St., Worcester, Mass. A small grinder adapted for repair shop and garage work, whuch is supplied in either the bench or stand type. Model No. 42 is driven by a ¼-horsepower motor and is equipped with two 6- by ½-inch wheels. Model No. 62 is driven by a ½-horsepower motor and is equipped with two 6- by 1-inch wheels. The grinding wheels are mounted at each end of the motor housing. Straight-, round- or bevel-faced wheels can be supplied as desired.

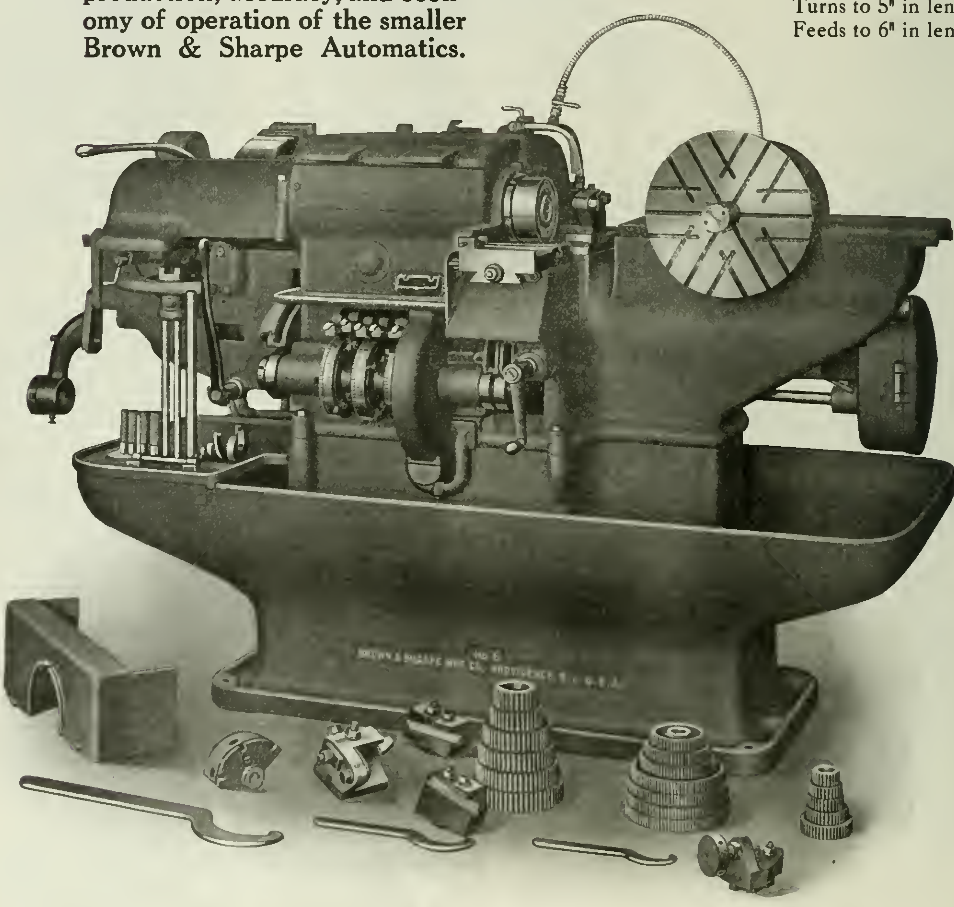
for heavy work—

BROWN &

No. 6 AUTOMATIC

With the characteristic high production, accuracy, and economy of operation of the smaller Brown & Sharpe Automatics.

Takes work to 2" dia.
(light work to 2⅜" dia.)
Turns to 5" in length
Feeds to 6" in length



PARKER-HOLLADAY POSTER SERVICE

An art poster service, for use in manufacturing plants, has been developed by the Parker-Holladay Co., 230 E. Ohio St., Chicago, Ill., which is intended to assist business men in educating their employes to think and act along constructive lines and to aid them in their advancement to more responsible positions. The service consists primarily of a series of posters, 28 by 42 inches in size, which are put up in frames and changed every week. Each poster deals with some common cause of failure for men to advance in their work and suggests methods of overcoming the trouble. The posters are printed in four colors to give them the maximum "attention value."

There are fifty-eight posters in the complete series. An oak frame is furnished for the set, which is hinged in the front, and the posters are perforated to slip over pins in the frame. An important feature of this arrangement is that the posters can be quickly put up and changed, and the same set can be used several times. In conjunction with the posters a leather-covered loose-leaf binder containing complete instructions for the application of this system is delivered to the man in charge of such work in the factory.

Pages are provided for what are known as "result charts" on which there are spaces for entering, in condensed form, the substance of reports sent in by the various foremen, indicating the results obtained by the posters in their departments. Such information is of definite value in using the posters a second time. For instance, suppose it is found that the labor turnover in a factory is excessive. If poster No. 17, entitled "Who's the Loser?" (reproduced in Fig. 1) had been used several months previously, and showed definite results in correcting this difficulty, the management would be justified in using this poster again with the expectation that it would overcome the trouble a second time.

For the use of foremen in making out their reports on the results obtained from successive posters put up in the factory, a special form of result chart is furnished, with spaces for entering the name of the poster, whether employes were interested, what comments were overheard, etc. The notations from these weekly result charts are summarized and entered on the permanent record sheets.

In using these posters, it is believed to be of the utmost importance to display the right poster at the right time. For instance, a poster pertaining to industrial accidents is likely to prove more effective if displayed when the thought of an accident is fresh in the minds of the workers in a factory. To obtain maximum results, it is essential for the foremen, superintendent, and other officials to show personal interest in each poster. By so doing, they will draw out remarks and discussions from the workers which will help in maintaining an accurate record of results. Illustrations are used, so that even though there may be many employes who do not read English, the subject matter of the posters will still be understood by the illustrations.

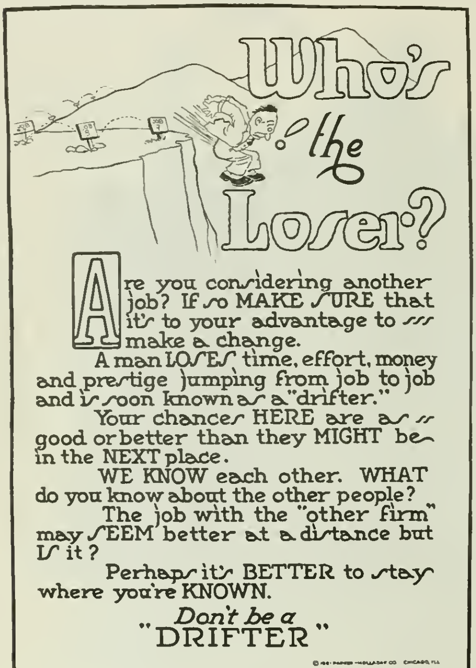


Fig. 1. Poster intended for Display in Manufacturing Plants in Cases where the Labor Turnover is Excessive

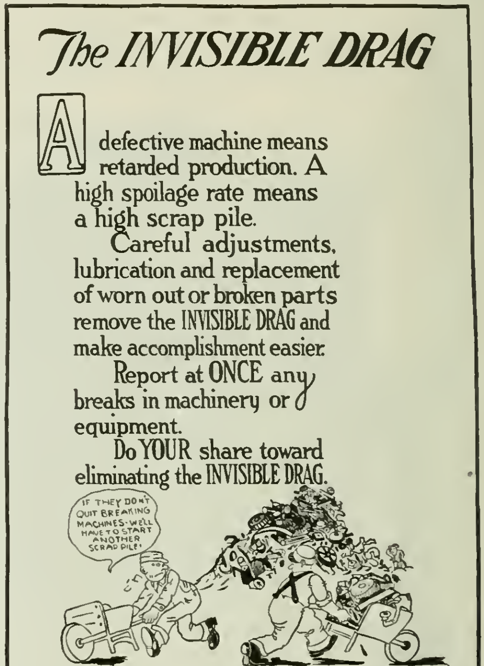

Fig. 2. Poster emphasizing the Need of Careful Adjustments, Lubrication and Replacement of Worn Parts of Machines

ENGINEERING EMPLOYMENT SERVICE

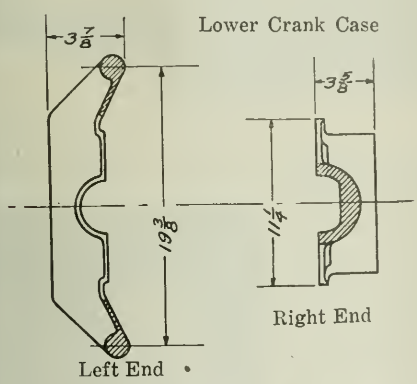
In recognition of the need of a clearing house of engineering services from which engineers of specific qualifications may be obtained, the Federated American Engineering Societies, representing a combined membership of about 50,000 professional engineers, has established at their headquarters, 29 W. 39th St., New York City, an employment bureau for engineers of every kind of training and experience. Applicants must be members and must submit a complete educational and professional record, carefully classified, so that as the special requirements of any position are received, the records of men of suitable qualifications can be submitted. The services of the bureau are free, and negotiations will be treated as confidential if desired.

Milling two parallel surfaces at one pass on the Cincinnati 48-in. Automatic Duplex Miller

Time per piece, 75 seconds. Average on a day's run, 40 pieces per hour.

The operator loads one end of the Indexing Fixture while the other end is milling.

The photograph below shows how we modified the 48 inch wide bed Duplex Miller to meet special needs.



Our Engineering Service Department modified our 48 in. Automatic Duplex to suit this job. We designed and made the fixtures and built the equipment complete ready for maximum production the minute the belt was on. These parts are cast-iron crank cases. Two surfaces at one end and one at the other are milled at one pass. The clamping arrangement is simple and the fixture inclines slightly toward the center to help in chucking. About 1/8 in. metal is removed. The thin metal section makes a relatively slow feed rate necessary. But the production is high, because—

The fixture is handy.

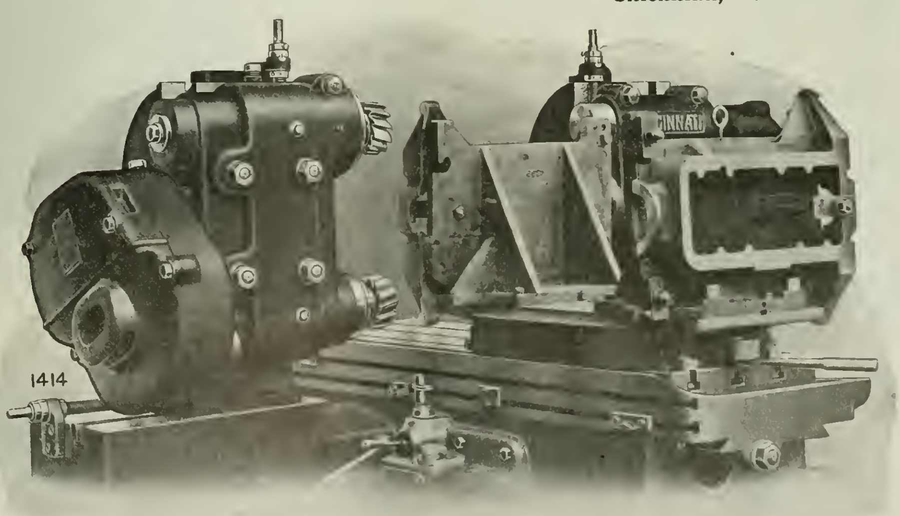
The Index Base allows the operator to chuck one piece while the machine is milling the other.

The fixture being loaded is always at the point nearest the operator.

The machine is automatic, and the operator has nothing to do but chuck and handle pieces.

All this can be applied to your work. If it requires special equipment, our Service Department will modify our Automatics to suit. Let us see your blueprints.

The Cincinnati Milling Machine Company
Cincinnati, O.



PERSONALS

George O. Gridley has resigned as manager of the Windsor plant of the National Acme Co. His outside interests have become of such volume and importance that he has decided to devote his entire time to banking, development work, and other affairs. Mr. Gridley's work in the building up of the manufacturing organization of the Windsor plant from its small beginning to its present proportions covers a period of a quarter of a century, during which time he brought into play his ability as an inventor, a business organizer, and a financier.

Mr. Gridley was born in Harwinton, Conn., in 1869. In industrial work he was first employed by the Waterbury Button Co., and then went to Springfield, Vt., to learn the machinist's trade. He studied stenography during his leisure hours evenings, and was employed for a few months with the Jones & Lamson Co. as stenographer and office-man, also spending some time on the road as salesman. From there he went to Indian Orchard, Mass., where he started the Indian Orchard Screw Co., making bicycle parts, and later he went to Windsor, Vt., as superintendent of the Windsor Machine Co. In 1902 the Gridley single-spindle automatic was developed; later, the idea of the multiple-spindle machine was gradually evolved, until the first machine was built in 1908. From that time on the business grew rapidly.

In 1915, when the National Acme Co. took over the Windsor Machine Co., Mr. Gridley was appointed manager of the Windsor plant. Previous to that he had been vice-president and general manager of the Windsor Machine Co., and he was also vice-president of the firm of Potter, Johnson & Gridley, Ltd., of England, which built a large factory in Birmingham. This factory was taken over by the British Government at the outbreak of the war. Mr. Gridley was a charter member of the Society of Automotive Engineers. From 1917 to 1919 he served as a member of the Vermont House of Representatives. He is president of the State National Bank of Windsor.

C. B. Cole has opened a consulting engineer's office at 546 W. Washington Blvd., Chicago, Ill. He will specialize in tools, gages, interchangeable manufacture, and inspection systems.

John D. Hurley, president of the Independent Pneumatic Tool Co., 600 W. Jackson Blvd., Chicago, Ill., manufacturer of "Thor" air and electric tools, returned on September 9 from a six weeks' trip abroad, during which he visited all the principal points of continental Europe.

Ogden R. Adams, machinery merchant, of Rochester, N. Y., has been elected president and general manager of the Seneca Falls Mfg. Co., Seneca Falls, N. Y., manufacturer of "Star" and "Short-cut" lathes. Mr. Adams still remains at the head of, and actively identified with, his Rochester business, which will not be interrupted in any way by his new connection.

Robert L. Crane, for twenty-three years western New York manager of Henry Prentiss & Co., Inc., Buffalo, N. Y., and well known throughout the United States as a machine tool salesman, has terminated his connections with that company and will continue in the same line of business under the name of Crane Machinery Co., with offices at 501 D. S. Morgan Bldg., Buffalo, N. Y. Mr. Crane is now establishing selling connections with a view to opening branch offices in the near future in Rochester, Syracuse, and Albany.

W. La Coste Neilson has been appointed general sales manager of the Norton Co., Worcester, Mass., succeeding Carl F. Dietz, who has left the Norton Co. to become president and general manager of the Bridgeport Brass Co., Bridgeport, Conn. Mr. Neilson has been with the Norton Co. for fourteen years. For a few years he was assistant sales manager, and later was placed in charge of all foreign business, including the sales and management of the two foreign plants of the Norton Co. at Wesseling, Germany, and La Courneuve, France, his office being located in London, England. He was made a vice-president of the Norton Co. two years ago. Mr. Neilson returned to Worcester last month, and took charge of the general sales October 1. He will, in addition, continue to look after the company's foreign interests.

Carl F. Dietz has resigned as vice-president and general sales manager of the Norton Co., Worcester, Mass., to become president and general manager of the Bridgeport Brass Co., Bridgeport, Conn., his new duties being assumed October 1. Mr. Dietz has been connected with the Norton Co. for ten years, first as plant engineer, then as assistant sales manager, and later as sales manager of the wheel division. Two years ago, when the Norton Co. and the Norton Grinding Co. were consolidated, he became vice-president and general sales manager of the entire business, including both wheels and machines. Mr. Dietz graduated from Stevens Institute of Technology in 1901, and subsequently took post-graduate courses in Berlin, Germany, in metallurgy and mining. He has been employed by the U. S. Steel Corporation, and has designed and built modern ore milling plants for the American Glue Co., the Grasselli Chemical Co., and the Ozark Smelting & Mining Co. In 1908 he became consulting engineer for the Minerals Separation, Ltd., London, and in the interest of this company developed treatment methods for iron ore deposits in Norway, and studied ore treatment methods for properties in Russia, South America, Australia, and Africa.

* * *

OBITUARIES

P. M. Fowl, president and general manager of the Cadillac Tool Co., Detroit, Mich., died August 24, following an operation for appendicitis, at the Harper Hospital of Detroit. Mr. Fowl was born in 1883 at Elyria, Ohio. He started work in several of the plants in the vicinity of Elyria, and in 1907 went to Detroit, where he was connected for a short time with the Ford Motor Co., and the Burroughs Adding Machine Co. He became associated with the sales force of the Strong, Carlisle & Hammond Co. in 1909, and from that time on became well known throughout the machine tool industry. From 1914 to 1917 he was the Detroit manager of the Strong, Carlisle & Hammond Co., and upon leaving that concern became president and general manager of the Cadillac Tool Co. He was also president of the Detroit Garage Equipment Co. His wife and one daughter survive him.

Louis J. Goldman, president of the Cincinnati Electrical Tool Co., Cincinnati, Ohio, died in that city August 22. Mr. Goldman was born in New York City in 1850. When he was two years old his father died, at which time the family moved to Cincinnati, and Mr. Goldman has lived there ever since. At the age of fourteen, he started to work and later engaged in the wholesale clothing business. In 1910 he bought the Cincinnati Electrical Tool Co., and remained its president up to the time of his death. His son, J. Albert Goldman, is treasurer of the company.

COMING EVENTS

October 3-4—Regional meeting of the American Society of Mechanical Engineers in Cleveland, Ohio; headquarters, Hotel Winton.

October 5-6—Twelfth annual convention of the American Manufacturers' Export Association in New York City; headquarters, Waldorf-Astoria Hotel. Secretary, A. W. Willmann, 160 Broadway, New York City.

October 5-7—Fifth annual convention of the Society of Industrial Engineers in Springfield, Mass.; headquarters, Hotel Kimball. Office of the society, 327 S. La Salle St., Chicago, Ill.

October 17-22—Twenty-fourth annual convention of the American Mining Congress in the Coliseum, Chicago, Ill. In conjunction with the convention there will also be a national exposition of mines and mining equipment.

October 17-22—Twenty-seventh annual convention of the National Hardware Association of the United States in Atlantic City, N. J.; headquarters, Marlborough-Blenheim Hotel. Secretary, T. James Fernley, 120 High St., Boston, Mass.

October 17-22—National exposition of mines and mining equipment in Chicago, Ill., under the auspices of the American Mining Congress, Washington, D. C.

October 18-20 — Annual convention of the National Machine Tool Builders' Association in New York City; headquarters, Hotel Astor. General Manager, Ernest F. DuBrul, 817 Provident Bank Bldg., Cincinnati, Ohio.

November 1-4—Annual convention of the Industrial Relations Association of America in New York City; headquarters, Waldorf-Astoria Hotel. Acting executive secretary, E. A. Shay, 671 Broad St., Newark, N. J.

November 2-4—Fall conference of Industrial Cost Association in Pittsburg, Pa. Headquarters of the association, 2828 Smallman St., Pittsburg.

November 4-5—Regional meeting of the American Society of Mechanical Engineers in Kansas City, Mo.

December 1-3—Fall meeting of the Taylor Society in New York City. Secretary, Harlow S. Pearson, 29 W. 39th St., New York City.

December 6-9—Annual convention of the American Society of Mechanical Engineers in the Engineering Societies' Building, 29 W. 39th St., New York City.

May 8-11, 1922—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga. Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

NEW BOOKS AND PAMPHLETS

Welding and Cutting. By Fred E. Rogers. 95 pages, 6 by 9 inches. Published by the Davis-Bournonville Co., Jersey City, N. J. Price, $1.

This is an instruction book on oxy-acetylene welding and cutting and is intended for operators who have mature judgment and some knowledge of metal-working practice. The book is intended to supplement personal instruction and refresh the memory on points of practice not in daily use. It contains eight parts, treating of the setting up of welding and cutting equipment; instructions in welding, including handling of the torch, preparing work for welding, size of tip and flame, etc.; general welding practice; boiler and tank welding; welding machines; oxygen cutting; mechanically operated cutting torches; and the generation of gases.

NEW CATALOGUES AND CIRCULARS

Sterling Grinding Wheel Co., Tiffin, Ohio. Circular containing grading tables, price lists, and speeds for Sterling grinding wheels from 1 to 60 inches in diameter and from ¼ to 4 inches in thickness.

Electric Controller & Mfg. Co., Cleveland, Ohio. Bulletin 1002-A, containing information on the application, design, and advantages of Dinkey ventilated controllers for alternating-current, slip-ring motors.

Michigan Stamping Co., Detroit, Mich. Bulletin 10, illustrating and describing wiring fittings, including outlet boxes, stamped steel fixture studs, covers for outlet boxes, sectional switch boxes, and panel surface cabinets.

General Electric Co., Schenectady, N. Y. Bulletin 46041, descriptive of the Type H2 alternating-current temperature indicator for transformer windings, the purpose of which is to safeguard transformer units from deterioration due to over-heating.

Ingersoll Milling Machine Co., Rockford, Ill. Circular illustrating an Ingersoll 42-inch continuous rotary continuous milling machine machining the sides of both ends of connecting-rod forgings, a production of forty-seven connecting-rods an hour being attained with the equipment shown.

E. J. Kruce & Co., 960 Harper Ave., Detroit, Mich. Circular illustrating and describing the Kruce spiral expansion reamer, which is equipped with an improved expanding device giving a greater range and insuring concentric expansion. These reamers are carried in sizes from ½ to 2½ inches in diameter, and the circular gives prices for the various sizes.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Leaflet 1888-A, describing the applications of storage battery mine locomotives, and illustrating the Baldwin-Westinghouse type of apparatus. Leaflet 1610-C, describing in detail the features of Type A auto-starters, including the auto-transformer, switching mechanism, contacts, overload relays, etc.

Hart Roller Bearing Co., Orange, N. J. Booklet entitled "Prepare for a Boom," containing an article showing the need of installing improved equipment in readiness for renewed business activity. The circular also contains illustrations of Hart staggered roller bearings, and a description of the design, material, workmanship, and application in different classes of machines.

Taft-Peirce Mfg. Co., Woonsocket, R. I. Bulletin 110, containing a detailed description and illustrations of many interesting applications of this company's entire line of production and inspection tools, including sine bars, sine bar fixtures, taper test gages, V-blocks, equalizing jaws, parallels, toolmakers' adjustable knees, universal right-angle irons, measuring irons, bench plates, universal squares, etc.

Norton Co., Worcester, Mass. Calendar for the year August 1921 to August 1922. On the twelve sheets of the calendar are listed the various products of the company, including multi-purpose grinding machines; alundum and crystolon wheels; refractories and laboratory ware; floor stands; grinding wheel dressers; machines for grinding cams, crankshafts, and crankpins; automobile part regrinding machine for repair shops, etc.

Mattingly Automatic Valve Co., Inc., 201 Chouteau Trust Bldg., St. Louis, Mo. Pamphlet containing a description of the construction and operation of Mattingly automatic valves for water gages on steam boilers, ammonia pipes, steam pipes, hose lines, etc. These valves have been designed especially to provide for the safe operation of steam boilers and conducting of fluids under pressure, by preventing false registration of the fluid in the gage glass.

Binghamton Electric Truck Co., Inc., Binghamton, N. Y. Circular containing description and specifications of the "Ideal" industrial trucks and tractors, the main features of which are as follows: A complete power unit mounted on trunnions and interchangeable in all models; a hill-climbing device making possible normal ampere construction on steep grades; an electrically welded frame; ball bearings for all the working parts; and a uniform over-all width for all types of 34 inches.

Edison Lamp Works of General Electric Co., Harrison, N. J. Bulletin entitled "Railway System Lighting Buildings and Yards," containing an article on modern lighting practice in railway shops, terminals, yards, etc., and equipment needed. Pamphlet entitled "Reflectors for Incandescent Lamps," containing a general discussion, classification of reflectors, and illustrations and data covering different types for a wide range of applications, including industrial plants, commercial lighting, etc.

Heald Machine Co., 16 New Bond St., Worcester, Mass. Circular treating of common automobile engine troubles, and describing how they can be corrected by regrinding. The advantages of the grinding process for machining worn or scored cylinders and for finishing new cylinders are pointed out, and a list is given of some of the automobile engines in this country and Europe whose cylinder bores are finished by grinding. The circular illustrates Heald regrinding machines in use in several plants, and describes the process of regrinding.

Flexible Steel Lacing Co., 4622 Lexington St., Chicago, Ill. Book entitled, "Short Cuts to Power Transmission," which is intended to answer many questions relative to the successful operation of belt-driven machinery. The book describes all types of belting and lacing, and contains belting problems and simple calculations. It also gives information on direction to run splices, belt dressings and preservatives, care of beltings, determining horsepower, figuring the size belt to use, margin of safety, etc. Copies will be sent free upon request.

W. S. Rockwell Co., 50 Church St., New York City. Bulletin 232, entitled "The Variety of Furnace Design." This pamphlet is the third of a series dealing with the fundamentals that influence the quality and cost of heated products. It discusses the relation of type and arrangement of heating equipment to cost of production, and the many factors that must be considered in adapting such equipment to individual manufacturing conditions. It contains fourteen pages of illustrations of different types of furnaces designed to meet industrial heating requirements. The section dealing with the relation of type and arrangement of furnaces to cost of production should be of particular interest at this time.

TRADE NOTES

V. Lowsner, 114 Liberty St., New York City, requests manufacturers of looms for fence wire weaving to communicate with him.

C. N. Cady Co., Canastota, N. Y., manufacturer of one- and two-cylinder two-cycle engines and four-cylinder four-cycle engines, announces that an addition to the factory has recently been completed, and that it is intended to employ an additional number of men in the new building. The company has at the present time from eight to ten months work ahead.

Link-Belt Co., 910 S. Michigan Ave., Chicago, Ill., reports that it has recently received a large contract for supplying the elevating and conveying machinery for two locomotive coaling stations for the New York Central Railroad Co., to be located at Solvay and Wayneport, N. Y. The equipment includes gravity-discharge elevator-conveyors, apron conveyors, track hoppers, etc.

Heller Bros. Co., Newark, N. J., announces that the Rex File Co. and the Vixen Tool Co. have become consolidated with Heller Bros. Co. It is believed that this consolidation will result in better service to both dealers and consumers. Walter D. Craft, who has been secretary-treasurer of the Vixen Tool Co. for some time, will act as domestic sales manager of the consolidated companies.

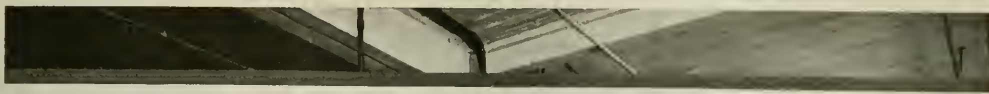
Lumen Bearing Co., Buffalo, N. Y., manufacturer of "Machinebronze" brass and bronze castings and bearings, solders, and babbitts, has found it necessary owing to the increase in its activities, to locate a branch office in Chicago at 15 N. Jefferson St., which will handle the western business of the company. H. S. Huncke is western sales manager, and Henry Waters, associate salesman.

Alexander Milburn Co., Baltimore, Md., announces that it has received two large contracts for oxy-acetylene welding and cutting equipment from the Baltimore and Ohio Railroad, and the Western Maryland Railroad. The contracts call for a number of Milburn "Cut-Weld" combination cutting and welding torches. These torches can be transformed instantly from the cutting to the welding type by merely changing the tip.

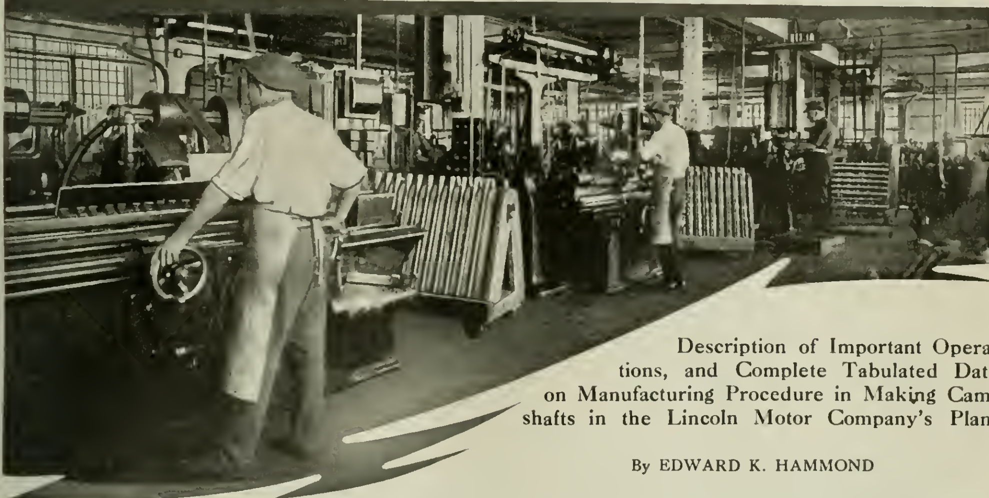
Surface Combustion Co., Inc., 366 Gerard Ave., Bronx, New York City, announces that it is now represented in all the principal European countries, and many large industrial furnace installations have been made. The Compagnie Generale de Construction de Fours, 32-34 Rue de la Grange-aux-Belles, Paris, France, is the sole licensee and manufacturer for the Surface Combustion Co.'s apparatus in France and its colonies, Belgium, Holland, Switzerland, Italy, Spain, and Portugal. British Furnaces, Ltd., Millbank House, 2 Wood St., London, S. W. 1, England, was organized in July for the purpose of manufacturing and selling the Surface Combustion Co.'s apparatus in the British Empire.

Firth-Sterling Steel Co., 312 Hudson St., New York City, announces that the agency arrangement for the sale of sheet-steel that heretofore existed between Thomas Firth & Sons, of Sheffield, an associated company, and Wheelock Lovejoy & Co., of New York and Cambridge, has been terminated, and Horace C. Hides, of Hartford, Conn., who for the last twenty years has represented William Jessop & Sons, has been appointed general sales manager of Thomas Firth & Sons for the United States. A stock of Firth Sheffield sheet steel will be carried in the New York warehouse of the Firth-Sterling Steel Co. Thomas Firth & Sons and the Firth-Sterling Steel Co. are also opening a joint office in Hartford, Conn., where Mr. Hides will have his headquarters and where Henry I. Moore will represent the Firth-Sterling Steel Co.

Henry & Wright Mfg. Co., Hartford, Conn., has been reorganized. The new president of the company is Charles J. Sorrells, senior partner of C. S. Sorrells & Co., New York City; and the vice-president is Jonas O. Hoover, lawyer and business man of Chicago, Ill. Mr. Hoover will also act as attorney, and as chairman of the executive committee, and expects to reside in Hartford after January 1. T. B. Owens, president and owner of T. B. Owens & Co. of New York City, is treasurer, and Mrs. Daniel M. Wright, secretary. Frank M. Rogers, formerly of Chicago, is general manager and assistant treasurer, having assumed his duties on August 1. All the stock of the company is held by the officers mentioned. William G. Allen of Hartford, Conn., the inventor of the Allen screw machine, will be superintendent and factory manager. When business returns to normal, the company proposes to build a factory equal in size to its present building for the development of the Wright dieing machine, invented by the late Daniel M. Wright and later redesigned and standardized by Mr. Allen.



Manufacture of Accurate Camshafts



Description of Important Operations, and Complete Tabulated Data on Manufacturing Procedure in Making Camshafts in the Lincoln Motor Company's Plant

By EDWARD K. HAMMOND

A COMPARISON of methods used in machining corresponding parts of the engine for a high priced automobile, and for one that sells for a lower figure, will frequently reveal the fact that these methods are fundamentally the same in both cases, but that various supplementary operations are interspersed into the schedule of operations followed on the high-priced work. These intermediate steps in the process of manufacture may not appear necessary, but it is the refinements attained through the performance of these additional operations that are responsible for giving to the engine of a high-priced machine its freedom from noise and vibration under normal working conditions. A study of the accompanying table of operations on the camshaft for automobile engines built by the Lincoln Motor Co., in Detroit, Mich., will at once make it apparent that there is considerable duplication in the number of turning, grinding, straightening, and other operations that are performed. However, if an attempt were made to lower the cost of manufacture by reducing the number of turning and grinding operations, etc., there is no doubt that it would be impossible to make camshafts and other parts to the high standards that characterize the work of the Lincoln factory.

A careful study of manufacturing costs is necessary in striving for accuracy in quantity production. The manufacture of high-grade automobiles presents excellent examples of work of this kind. Accuracy and quality are prime necessities; but quantity production at a reasonable cost is also a commercial requisite, and the best production engineering service, the selection of the best types of machine tools, and the working out of the most suitable methods are of the greatest importance in order that the three factors—accuracy, quantity, and cost—may each receive its proper share of attention. In the manufacture of high-grade automobiles, economical manufacturing methods are just as important as in the making of cheaper cars, because the total number of cars built is less, and the great care used, in conjunction with the additional operations performed, would increase the cost beyond the commercial limits permissible, if the best machines and methods for reducing expenses were not employed.

Drilling an Axial Hole through the Shaft

It is the practice of the Lincoln plant to use bar steel for camshafts, and to turn the cams and bearings from the solid metal. The blanks used for this purpose come to the camshaft department cut off to a specified length and annealed, so that the steel is in a condition which is favorable for machining. In the accompanying schedule of operations it will be seen that the fifth step in the process of manufacture is to drill an axial hole through the work, 17/32 inch in diameter for a part of the way and 13/16 inch for the remainder of the distance. In connection with the schedule of operations, reference should be made to Fig. 1, which shows a detailed view of the camshaft, the various surfaces to be machined being indicated by reference letters. Fig. 2 illustrates a duplex rifle barrel drilling machine, built by the Diamond Machine Co., Providence, R. I., which is used for these two drilling operations.

During the war period when a number of American plants were engaged in making rifles, MACHINERY

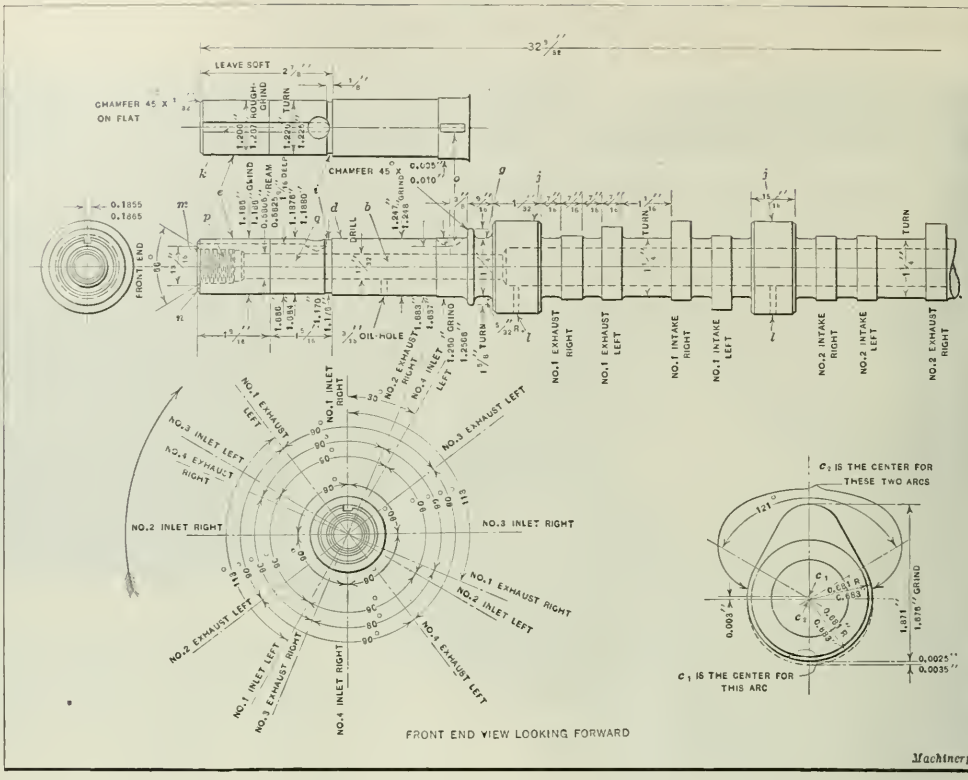


Fig. 1. Detailed View of Camshaft for Automobile Engines made by the Lincoln Motor Co. In Connection with this Illustration Reference

published a complete description of the method of using one of these deep-hole drilling machines. (See MACHINERY, March, 1916.) The drills *A* are of the oil-tube type, and carry oil at high pressure directly to the cutting point, so that the chips are washed out of the deep hole in the work *B* and fall through shields *C* into the pan beneath the machine. On account of the high pressure required to clear the chips from these deep holes, it is necessary to use shields of the kind furnished on this machine, to direct the oil down into the pan, so that it will not spatter over the operator and on the floor.

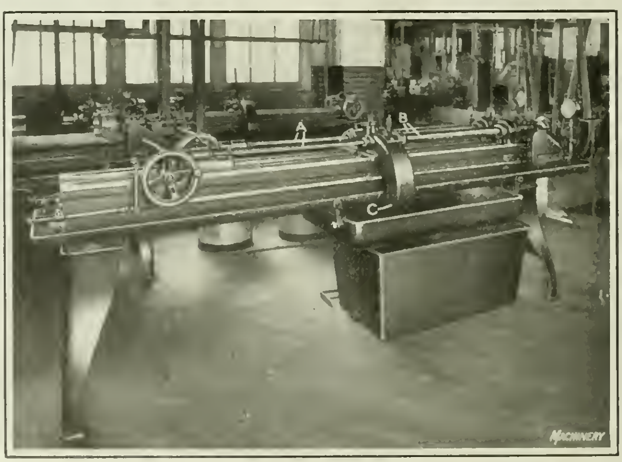

Fig. 2. Duplex Rifle-barrel Drilling Machine used for drilling an Axial Hole through the Rough Steel Bars

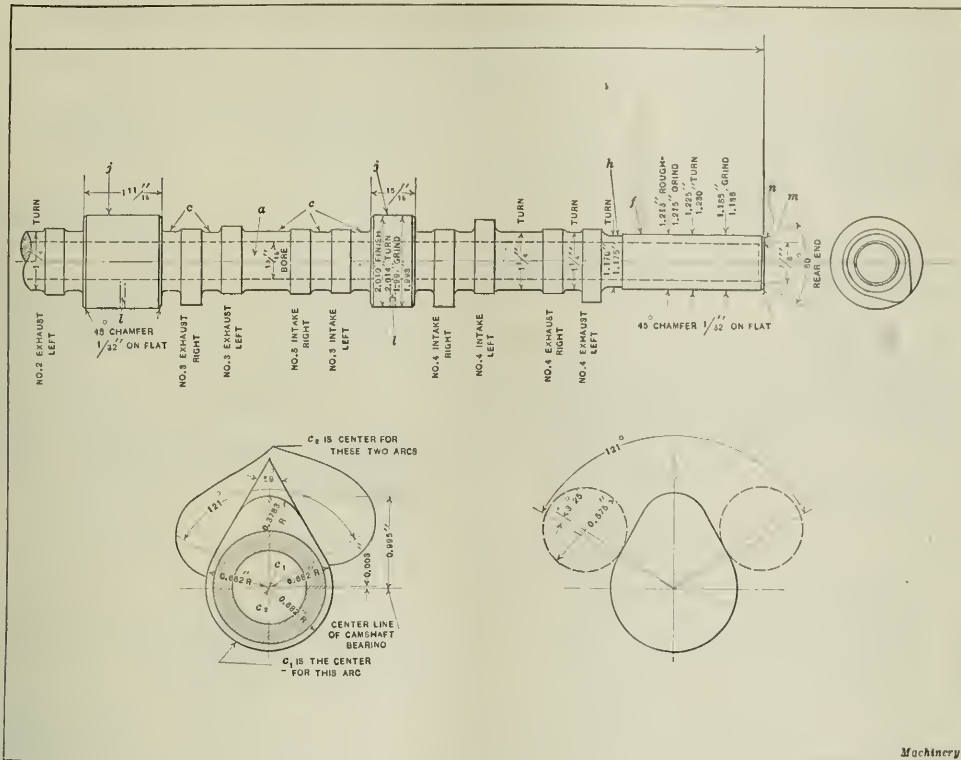
Turning Spaces between Cams

As will be seen by referring to the detailed view of the Lincoln camshaft, in the illustration Fig. 1, there are five spaces to be turned in machining between each group of four cams. For these operations, a Lo-swing lathe built by the Fitchburg Machine Works, Fitchburg, Mass., is employed, and this machine is equipped with a tool-block that carries five cutter bits, so that the tools may be fed inward to finish all of these surfaces at a single cut. Fig. 4 illustrates one of these machines in operation, and clearly shows the tool-block *A*, the camshaft *B* on which the turning operations are being performed in the spaces between the cams, and the five cutter bits *C* which simultaneously perform these turning operations. Little time is required to position the tool-block and the tools for taking successive cuts. Four settings of the tool-block are required to clean up the areas adjacent to the sixteen cams and the line bearings; and stops are provided on the lathe to facilitate this part of the work.

Milling the Cams to Form

As the camshafts leave the Lo-swing lathe illustrated in Fig. 4, the cam blanks have been roughed out in so far as the width is concerned, but they are still concentric with the camshaft. Next in the process of manufacture comes the milling of the cams to the required form. On the Lincoln camshafts the cams are concen-



should be made to the Sequence of Operations and Equipment used for machining these Camshafts, as given in the Accompanying Table

tric for 239 degrees, and the rise and fall occur during the remaining 121 degrees; it is obvious that the rise on each cam has to be properly located so that the firing order of successive cylinders will be correct.

Provision has been made for obtaining the required results on a No. 2 plain milling machine built by the Cincinnati Milling Machine Co., which is equipped with a set of 10-inch index-centers made by the Brown & Sharpe Mfg. Co. The machine is shown in operation in Fig. 3. An end milling cutter *A* is mounted in the horizontal spindle of the machine, and in milling each cam *B* to form, the method of procedure is as follows: In the index-plate of the centers are holes for determining the four points at which each successive cam on the shaft must change its form, so that this equipment not only provides for milling all the cams to the proper shape, but also gives them the correct relationship to obtain the proper firing order for the engine. A brief description of the way one cam is milled will make the procedure clear.

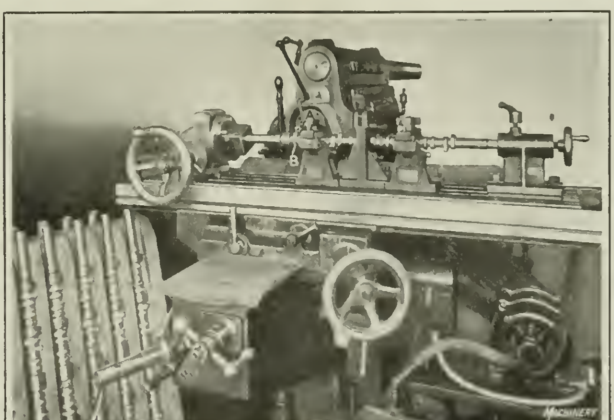


Fig. 3. Plain Milling Machine equipped with Indexing Centers for milling the Cams to the Required Form

It has already been mentioned that the cam is concentric with the shaft through an angle of 239 degrees (see Fig. 1), and for milling this arc, it is merely necessary to rotate the camshaft with the milling cutter in contact with the work. The index-plate on the dividing head determines the starting and stopping points of this concentric portion. Next comes a straight rise on the cam, and to provide for milling this part of the work to shape, rotation of the camshaft is stopped when the index-pin reaches the limiting point, and a vertical feed movement is substituted, so that the work may be fed straight past the cutter. On the milling machine knee, limit stops are furnished to make it a simple matter for the operator to ascertain when he has fed the work the required distance past the cutter in a vertical direction; and upon reaching the second stop, a rotary feed movement of the work is substituted for the straight vertical movement. This rotary movement produces the round top surface of the cam, which is concentric with the shaft.

SEQUENCE OF OPERATIONS AND EQUIPMENT USED FOR MACHINING LINCOLN CAMSHAFTS

Oper. No.	Name of Operation	Type of Machine and Special Tools	Type of Standard Tools
1.	Cut off stock 32⅝ inches long	Newton cold saw	Circular saw blade
2.	Heat-treat	American gas furnace	Bristol pyrometer
3.	Straighten	No. 3A Geier straightening press and roller support for testing trueness	Indicator bracket and No. 5 Ames indicator
4.	Turn both ends to 2 inches diameter by 2.0025 maximum, 1.9975 min., long; face ends to a length of 32 15/32 ins.	Reed 16-inch lathe, steadyrest, and over-all length gage	Cushman three-jaw chuck and Johansson snap gage for 2 ± 0.0025 inch
5.	Drill 13/16 hole a and 17/32 hole b through work (see Fig. 1)	Diamond duplex rifle drilling machine	13/16- and 17/32-inch gun-barrel drills
6.	Center both ends with pilot center	21-inch Cincinnati Bickford upright drilling machine and vertical work-holding fixture	Wiard chuck, 60-degree center drill and 13/16- and 17/32-inch pilot for the center drill
7.	Rough-turn balance of shaft to 2 3/64 inches diameter	3½-inch Lo-swing lathe and roller rest	Driving dog and tool-holder
8.	Straighten	No. 3A Geier straightening press	Indicator bracket and No. 5 Ames indicator
9.	Grind turned diameter 2.045 min., 2.050 max.	Norton 10- by 36-inch cylindrical grinding machine	Johansson snap gage, and driving dog
10.	Rough spaces c between cams and adjacent to bearings, leaving 1/32 inch of stock	8-inch Lo-swing lathe, steadyrest, tool-block, and tool spacing gage	Driving dog and snap gage
11.	Straighten	No. 3A Geier straightening press	Indicator bracket and No. 5 Ames indicator
12.	Finish-turn spaces c between cams	8-inch Lo-swing lathe, tool-block holding five necking tools, tool spacing gage	Snap gages for diameter, width, and spacing of cam blanks
13.	Straighten	No. 3A Geier straightening press	Indicator bracket and No. 5 Ames indicator
14.	Rough-turn front end diameters d and e to 1 11/16 and 1⅝; also rough-turn rear end diameter f to 1 5/16 inch	18-inch Reed engine lathe	Armstrong tool-holder, snap gages, and driving dog
15.	Turn recess g to 1¼ diameter by 5/32 inch radius, and recess h to 1.170 min., 1.175 max., diameter	3½-inch Lo-swing lathe	Gages, driving dog, and turning tools
16.	Turn front end e to 1.225 max., 1.220 min., and recess i to 1.175 max., 1.170 min., by ⅛ inch wide	Leland-Gifford 15-inch lathe	Snap gages and Armstrong tool-holders
17.	Turn rear end f to 1.230 max., 1.225 min., diameter by 3 5/16 inches long	Reed 18-inch lathe	Driving dog, Armstrong tool-holder, Johansson snap gages
18.	Straighten	No. 3A Geier straightening press	Indicator bracket and No. 5 Ames dial indicator
19.	Rough-grind line bearings j to 2.030 min., 2.032 max.; front end diameter e to 1.206 min., 1.207 maximum; diameter d to 1.285 min., 1.287 max.; and rear end diameter f to 1.213 min., 1.215 max.	10- by 36-inch Norton cylindrical grinding machine	Johansson limit snap gages and driving dog
20.	Rough-mill keyway k to 0.170 max., 0.165 min., in width, and burr	Pratt & Whitney spline milling machine, keyway milling fixture, tool setting gage	Two-lipped fish-tail cutter and gages
21.	Mill cams to form	No. 2 Cincinnati milling machine	Brown & Sharpe 10-inch plain index-head and center, Johansson snap gages and end milling cutter
22.	Chamfer bearings and burr all over	Reed engine lathe	Flat files, driving dog and steadyrest
23.	Inspect		Gages for all dimensions
24.	Copperplate 0.005 to 0.008 inch thick—Inspect	Electroplating bath and rack for holding in copperplating bath	
25.	Recenter ends		

Machinery

Rotary feed movement is again stopped when the index-pin of the dividing head drops into its next hole in the plate, and a vertical downward movement of the knee is substituted for the rotary feed, until the lower stop is reached, which limits this vertical movement. At this point, the cutter has returned to the position where it started to mill the concentric portion of the cam over an angle of 239 degrees, and this completes the cycle of operations. Then, the work is withdrawn from the milling cutter, and rotated until the index-pin enters the next hole in the plate. This rotates the camshaft into the proper position to start milling the 239-degree concentric portion of the next cam, after the work has been traversed longitudinally to bring the next cam blank opposite the milling cutter. When this has been done, the machine is again set in motion. By repeating this cycle of operations sixteen times, all the cams on the shaft are milled to shape.

Grinding the Cams

After roughing out the cams to the required form by milling, as just described, the work goes to a Norton 10- by 50-inch cam grinding machine for the first grinding operation. The machine is shown in operation in Fig. 7. It is provided with the usual arrangement for rocking the work as it rotates in contact with the grinding wheel, this oscillation being accomplished by means of a master cam which is of the same form as the cams to be ground. Hence, it is a simple matter to perform this cam grinding operation in accordance with standard practice. It will be apparent that for performing this cam grinding operation, the master cam must be an exact duplicate of the cams on the camshaft in the form they have reached after the first grinding operation. This is true both as regards the allowance for metal to be removed by subsequent grinding, and the angular positions of the cams around the shaft, in order to give exactly the proper firing order for the engine cylinders.

Testing Hardness of Cams and Bearings

All cams and bearings of the Lincoln camshaft are hardened, and as the finished shafts go to the inspection department, the first step is to test the hardness of these members with a Shore scleroscope *A*, Fig. 5. This instrument is mounted on a special machine which holds the camshaft on a table *B* that may be moved longitudinally under the scleroscope, so that a minimum amount of time is required to bring successive cams and bearings into position for making the hardness test. This is a typical example of the usefulness of the scleroscope in testing a finished product, as it enables an accurate determination of hardness to be made without damaging the finish of the surface.

SEQUENCE OF OPERATIONS AND EQUIPMENT USED FOR MACHINING LINCOLN CAMSHAFTS

Oper. No.	Name of Operation	Type of Machine and Special Tools	Type of Standard Tools
26.	Grind copper off line bearings j to a diameter of 2.018 min., 2.020 max.; rear bearing f to a diameter of 1.203 min., 1.205 max.; and front bearing d to a diameter of 1.265 min., 1.268 max.	20- by 36-inch Norton cylindrical grinding machine	Johansson snap gages and driving dog
27.	Grind copper off cams to a diameter of 1.378 min., 1.382 max.	Norton 10- by 50-inch cam grinding machine	Norton master cam, grinding wheel and Johansson snap gage
28.	Drill 3/32-inch oil-holes l in bearings j	Leland - Gifford sensitive drilling machine and jig	Jacobs drill chuck, twist drills, and countersinks
29.	Inspect	Over-all length gage	Johansson snap gages

40.	Straighten	No. 3A Geier straightening press	Indicator bracket and No. 5 Ames dial indicator
41.	Inspect location of cams	Special testing machine	Ames No. 5 dial test indicators
42.	Rough - grind line bearings j, and front and rear bearings d and f	Norton 10- by 36-inch cylindrical grinding machine and back-rest	Johansson snap gages and driving dog
43.	Drill and tap hole p, ream hole q, and counterbore	Cincinnati Bickford drilling machine. Vertical work-holding fixture	Wiard quick - change chuck, drill, tap, reamer, and counterbore
44.	Recenter	Reed 18-inch lathe	Armstrong tool-holder, and driving dog
45.	Finish-mill keyway k to 0.1855 min., 0.1865 max., in width	Pratt & Whitney spline milling machine and keyway milling fixture	Two - lipped fish - tail milling cutter and gages
46.	Mill Woodruff keyseat o	No. 6 Whitney hand milling machine and work-holding fixture	Woodruff keyway cutter and holder, and gages
47.	Grind line bearings j to 1.999 min., 2.000 max., diam.	10- by 36-inch Norton cylindrical grinding machine	Johansson tolerance snap gage and driving dog
48.	Grind cams to 1.367 min., 1.368 max., diameter	Norton 10- by 50-inch cam grinding machine	Johansson tolerance snap gages, Norton master cams and rollers
49.	Finish - grind cams to 1.366 max., 1.3655 min., diam.	Norton 10- by 50-inch cam grinding machine	Norton master cams and rollers. Johansson snap gages
50.	Finish - grind line bearings j to 1.998 max., 1.997 min. diameter; front bearing d to 1.248 max., 1.247 min. diameter; Woodruff keyseat bearing o to 1.2505 max., 1.250 min. diameter; front end e to 1.1880 max., 1.1875 min. diameter for 1 5/16 inches, and to 1.1860 max. 1.1850 min. diameter for balance of length; finish-grind rear bearing f to 1.186 max., 1.185 min. diameter.	Norton 10- by 36-inch cylindrical grinding machine	Tolerance snap gages and driving dog
51.	Stone off sharp corners on cams, and burr	Blount 11-inch speed lathe	Carborundum oilstone and driving dog
52.	Hand tap	Bench fixture	No. 4 Bay State tap wrench and tap and limit thread plug gages
53.	Inspect	Machines for testing opening and closing points of cams, and concentricity and spacing of cams and bearings	Johansson tolerance snap gages
54.	Test hardness	Shore scleroscope	

Machinery

Testing Concentricity and Spacing of Cams and Bearings

For testing the concentricity of the four line bearings, and of the two bearing diameters at the front end of the shaft, use is made of six dial test indicators mounted on the fixture illustrated in Fig. 6. The work is carried on supports which allow it to be rotated with the bearings in contact with the plungers of the dial indicators. If the needles of any of these instruments indicate an error of more than 0.001 inch, the work is sent back to the machine shop for correction or else it is discarded, according to the seriousness of the conditions which are discovered. On this testing fixture, there is also a spacing gage-bar *A* at the opposite side of the work from the dial indicators. This gage has spaces machined in it to receive each of the cams and line bearings, so that if there is any error in the longitudinal spacing of these members, it will be impossible to place the work in the gage.

Ascertaining the Accuracy of the Intake and Exhaust Points on the Cams

In connection with the preceding description of the method used for rough-milling the cams, mention was made of the importance of locating each cam accurately on the shaft, so that the firing order of the engine cylinders would be accurate. Obviously this is a most important point, and great care must be taken in inspecting the finished camshafts to make sure that these points on the cams have all been correctly located. For this purpose, use is made of an inspection fixture which is shown in use in Fig. 8. This consists of a dial test indicator, carried by a bracket *A* which is free to slide along a bar *B* at the rear of the fixture.

In this way, it is an easy matter to bring the plunger of the indicator into successive contact with each cam; after a plug *C* at the front of swinging bracket *A* has been brought down into contact with a corresponding block *D* mounted on the front of the fixture frame, the indicator dial is set to zero, with the plunger in contact with the 239-degree concentric portion of the cam. Then the camshaft is rotated until the indicator plunger comes sufficiently beyond the extreme of this concentric portion to deflect the needle over a 0.001-inch space, after which the inspector observes the position of a fixed index mark on bracket *E* relative to two limit marks scribed on the rim of a wheel *F* that is turned with the camshaft. This wheel is keyed to the camshaft, so that a definite relationship always exists between the position of the opening or closing point on each cam and the corresponding graduations on the rim of the wheel.

There are thirty-two sets of graduations around the wheel *F*, which indicate the limiting positions for the sixteen cams that actuate the opening and the closing of the intake and of the exhaust valves for the eight cylinders. When the dial indicator needle has been deflected over a 0.001-inch space in the manner previously described, the fixed graduation at *E* must lie between the two limit graduations on wheel *F* for that point on the cam. Then the inspector turns the wheel *F* in the opposite direction until the indicator needle is again deflected over a 0.001-inch space, and observes whether the fixed graduation at *E* lies between the two limit graduations on the rim of the wheel. After making this test, the bracket *A* is moved along bar *B* to bring the plug *C* into contact with the next plug *D*, after which the test is repeated for the next cam. This cycle of movements is gone through sixteen times, in order to test the opening and closing points of each of the cams on the shaft. The method is one which enables extremely accurate determinations to be accomplished with a minimum expenditure of time.

DEMAND FOR LOW-COST GARAGE MACHINERY

By J. ARTHUR GLATTLY

The whole trend in machine tool design has been toward the production of machinery that would perform a large amount of work in a minimum of time. It is the writer's belief that there is now a large potential field for machine tools designed along somewhat different lines. This field includes machines that are low in initial cost, but which nevertheless should have capacity for a wide range of work. Machine tools of this class have received comparatively little consideration. In making this statement the writer has in mind the requirements of small repair shops and garages.

There are about nine million automobiles and trucks in use in the United States today, and every one of these requires more or less maintenance work. Many of these automobiles were built by companies no longer in existence, and it is often difficult and usually requires considerable time to obtain replacement parts for them.

Machines for Regrinding Cylinders

The matter of regrinding cylinders is an important one. It is necessary to regrind the cylinders at least once during the life of the average car if satisfactory operation is to be maintained. Regarding cylinder grinding machinery, there is little to be desired in the way of improvements in the standard machines now on the market, so far as accuracy or production is concerned, but the average price of these machines is somewhat high for small garages or repair shops. What is needed is a machine that will handle a large variety of cylinders the first cost of which will be within the reach of the man who owns a small garage and who has a limited amount of this work to do, but who cannot afford to make a heavy initial investment for what may be termed a standard machine. A machine to meet these requirements need not be capable of high production rates. There are many devices for reboring cylinders, but reboring does not give the desired finish. The writer believes that a regrinding machine that would cost, say, about $500 to $800 would have a vast potential market.

Milling Machine Developments

In regard to milling machines the same condition obtains as in the case of grinding machines. No heavy initial expenditure in tool equipment, however, need be made if fly cutters are used in place of milling cutters. There is no reason why some of the lighter types of hand milling machines could not be equipped with table feeds at no great

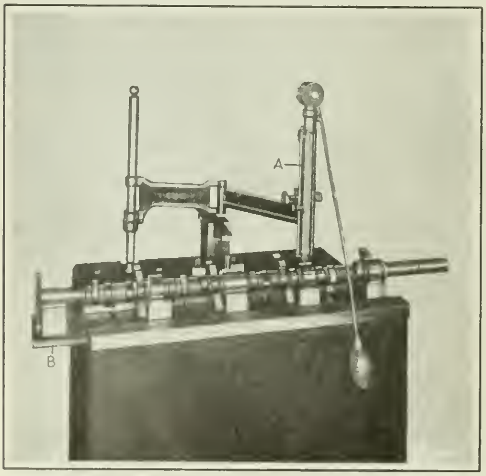

Fig. 5. Testing the Hardness of the Ground Cams and Bearings with a Scleroscope

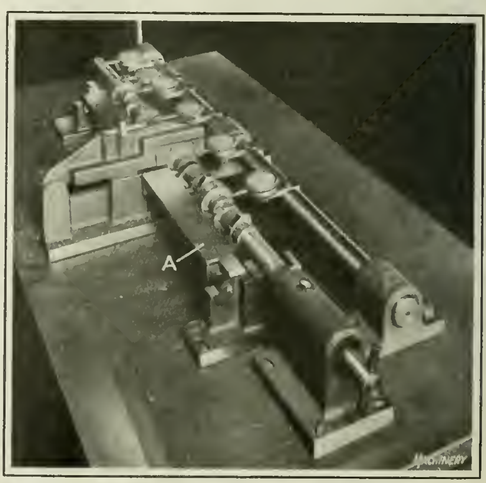

Fig. 6. Testing Spacing of Cams and Bearings, and Concentricity of Bearings

additional cost. By the use of fly cutters, machines so equipped would be capable of handling a wide range of work. In fact, the writer believes that the possibilities of the fly cutter are overlooked to a great extent at the present time in our large shops and tool-rooms. For the small shop, however, the possibilities of the fly cutter are almost limitless.

With the development of the electric furnace and electrical temperature recording instruments, the problem of heat-treating small quantities of gears has become a simple matter. The time is not far distant when there will be many shops throughout the country which will be equipped to replace gears for automobiles made by companies no longer in business.

Improvements in Drilling Machines

In regard to drilling machines the writer believes that there is room for development, notwithstanding what has already been accomplished along these lines. For a small shop there is need of a drilling machine that has a wide range of speeds and feeds and one which has simple provision for taking up the lost motion in the spindle bearing. A taper roller bearing would, the writer believes, make adequate provision for spindle bearing adjustment.

The small shop owner cannot afford several drilling machines, and it is therefore necessary that he have a machine which will be capable of handling all sizes of drills, from the small "numbered" drills up to the large sizes having taper shanks. It should be borne in mind that a drilling machine in a small shop can be used to good advantage on many boring jobs, but at the same time it must be remembered that the cost should be kept as low as possible and the machine made as simple as is consistent with the work it is intended for. In regard to lathes and external grinding machinery, the writer believes that the possibilities of design, as far as the needs of the small shop are concerned, have been well covered.

A well-equipped machine shop will become more and more a necessary adjunct to every first-class garage. This shop will be successful in handling its work just as soon as machine tool builders develop and produce a line of machinery which is adapted especially to the peculiar needs of the garage and the small repair shop.

COURSE IN INDUSTRIAL PUBLISHING

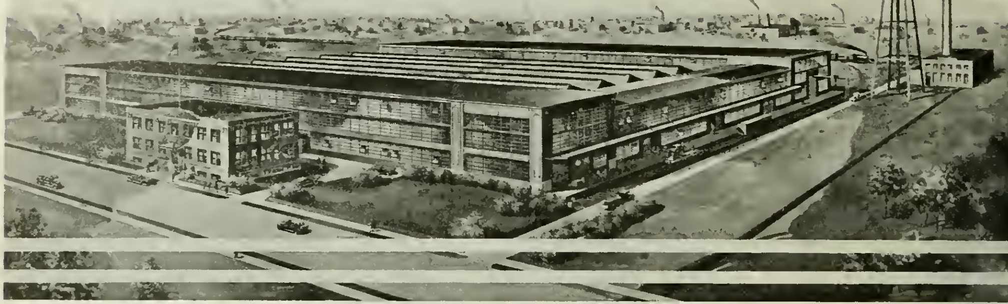
At its September meeting, the New York Business Publishers Association announced the establishment of a course in industrial publishing. The course has been organized and will be conducted under the direction of the educational committee of the association by the Business Training Corporation, which has been retained for that purpose. It will include lectures, conferences, text-books, problems, and a personal commenting service. Classes are now being organized in New York and will soon be organized in other publishing centers. The course will also be conducted by correspondence for people who are unable to attend classes. Although designed primarily for the benefit of members of the editorial and business staffs of trade and technical periodicals, it will be open to all who are interested in the field. It is intended not only to give instruction, but to develop the business as a whole by setting up higher standards of editorial and business service and showing how these standards can be attained.

The following topics will be covered: Distinctive features of industrial publishing; its code of ethics; personal qualities required for success; determining editorial policies; getting the right kind of articles; securing accurate reports and data; writing for industrial papers; building up circulation; creating advertising; departmental management; service to the industry; service to advertisers; and basic policies and tendencies. "We look upon this undertaking," said H. M. Swetland, president of the United Publishers Corporation and chairman of the educational committee, "as one of the most important steps ever taken toward making industrial papers even more valuable to their readers and advertisers. Our own prosperity will grow in direct proportion to our growth in ability to render useful service." Those interested can obtain further information regarding the course and the classes by communicating with the secretary of the course in industrial publishing, 185 Madison Ave., New York City.

* * *

It is estimated that at the current rate of construction, the output of American shipyards for the present fiscal year will be about 2,250,000 gross tons, as compared with 3,735,000 gross tons, constructed during the year 1920.

Factory Lay-out as an Aid in Reducing Costs



A Description of the New Plant of the Colburn Machine Tool Co., Cleveland, Ohio, which has been Laid out with a View to Economy in Manufacturing

THE new plant of the Colburn Machine Tool Co., on Ivanhoe Road, Cleveland, Ohio, presents an example of how a well thought-out factory lay-out may aid in reducing production costs. A description of this plant will point to many desirable features in modern plant construction. A general view is shown in the heading illustration, the office building being located in front, but directly connected with the factory by a passageway.

The buildings are practically fireproof, being constructed of steel, brick, and cement, with steel window sashing and frames, and provided with a complete sprinkler system. The shop building, which is 310 by 280 feet, is designed with a front and rear flat-roof bay or head-house extending the full length of the building, these bays being connected on the north end of the structure by a third bay; the remainder of the space is covered with a saw-toothed roof, and is divided into five bays. The three high-roof bays are provided with traveling cranes, and serve as an assembling floor and receiving, shipping, and stock rooms, while the five bays in the center are devoted mainly to machining operations.

The office building contains, in addition to the executive offices, the engineering and advertising departments, which are located on the second floor. From the office a covered passageway leads into the shop, which is unusually well lighted and ventilated. The important factor of good lighting has been carefully considered in its effect upon production. All girders and steel framework are painted light gray, and the roof and window sash are white.

The front and rear bays, extending the full length of the building, are each 50 feet wide. From a point about midway of the front bay a main central traffic aisle extends to the rear, dividing the machine shop area and leading into the high bay at the rear. The main aisle and several side aisles, which lead into it, as shown in Fig. 2, are laid out by painting white boundary lines on the floor, which is paved with creosoted wood blocks set on a bed of solid concrete, 6 inches thick. The aisles are kept free and clear to facilitate transportation of materials, which is done either by means of a flat car, such as shown on the narrow-gage track extending through the shop to the yard at the rear, or by industrial motor trucks. The boundary lines are laid out and painted on the floor in the bays as well as in all aisles, the advantage of this traffic regulation being obvious.

There is a 15-ton Cleveland traveling crane, with a 5-ton auxiliary hoist, in the front head-house, with crane tracks extending the entire length of the bay. This crane travels on tracks placed high in the bay—about 8 feet higher than another crane of like capacity and design which is provided in the side bay that runs along the north side of the building. The tracks for this crane extend out into the front and rear head-houses, the object being to permit material to pass directly from one to the other by running the lower crane under the upper one. This arrangement, which is identical in both head-houses, is shown in the background of Fig. 1.

The north bay is another clear passageway, 50 feet wide, extending the full depth of the building between the front and rear head-

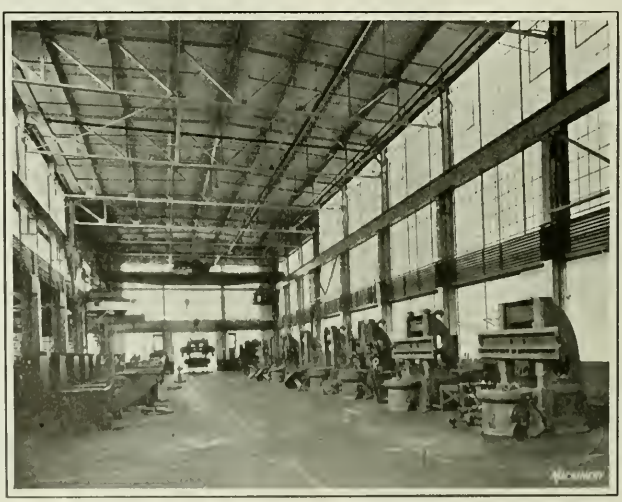


Fig. 1. View in Front Head-house used as Erecting Floor

Fig. 2. Central Traffic Aisle, which runs entirely through the Shop, from Front to Rear Bay

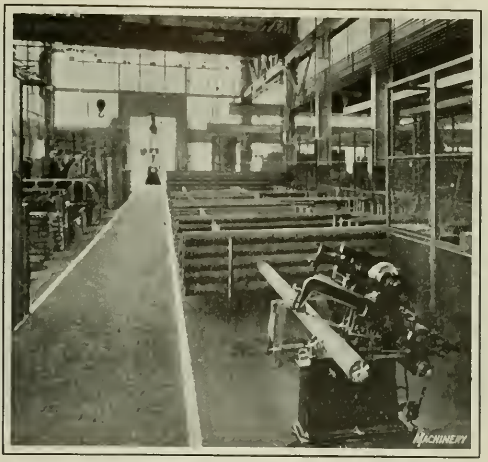

Fig. 3. Transportation Facilities provided from Receiving Platform to Storage Space

houses. Six double doors in the north wall lead to the receiving and shipping platform which also extends the full depth of the building. Running parallel with this platform is a concrete roadway for the accommodation of express trucks, etc., and between the platform and the roadway there is a spur track of the Nickel Plate Railroad. The convenience of this lay-out for handling material going to and coming from the cars will be apparent from an inspection of Fig. 5. The floor of the platform is made of concrete, and it is equipped with labor-saving facilities for loading and unloading freight cars. Two wire cable winches are installed under this platform so that heavy machines may be easily moved, or when locomotive power is not available, freight cars may be towed in from the main tracks, which are 1600 feet distant from the platform.

Cemented into the platform floor at both sides of the last door (which leads into the rear head-house) are two snatch-block hooks, provided so that tackle may be used to facilitate the unloading of material from the cars. From the platform it is picked up by a monorail traveling hoist, the overhead rail of which extends through the doorway out beyond the tracks of the railroad siding. This enables material to be delivered directly to the floor of the rear head-house. Fig. 3 is a view looking toward this doorway from the interior of this head-house, and shows, in addition to the hoist, the overhead crane installation, which is similar to that in the front head-house, previously described.

Arrangements for Storing Material

The rear head-house is used mainly as a storage room for property and stock, and is separated from the rest of the factory by sheet-metal and wire-mesh partitions. In this connection, it may be mentioned that all receptacles, desks, benches, racks, etc., as well as all partitions in the building are made of steel, and there are no wooden closets or shelves where inflammable material may accumulate and increase the fire hazard. All sheet-metal factory accessories used in the shop were furnished by the Hausermau Co., of Cleveland. Attention is directed to the appearance of the farther left-hand corner of this bay, in Fig. 3, where the larger castings are neatly arranged. The large bar stock is supported by sections of I-beam, laid in orderly fashion on the floor, and the smaller bar stock is stored on floor stands. This illustration also shows in the right foreground the metal-partitioned stock-room office, which is equipped with metal files for recording stock, and also the power cut-off saws.

The opposite, or south end of this bay contains metal bins which are used for storing jigs and fixtures and for such small parts as bolts, nuts, screws, gears, bushings, shafts, small castings, and similar parts; the electric power room in which the current converter and main switchboard are installed; the portable oil-tanks, industrial motor trucks, and certain millwright equipment such as rope and cables, tackle-blocks, ladders, etc. The storage room does not occupy the entire length of the rear head-house, but is partitioned off to provide space for the heat-treating department in the southwest corner of the factory. The end of the stock-room used for storing small parts is shown in Fig. 4.

Fig. 4. Stock-room, showing Bins used for storing Small Parts

Wash-room and Coat Room

The wash-room, which can be partially seen at the left in Fig. 2, is located near the left-hand corner of the main aisle and front head-house. Enamelware wash basins, hot and cold water, and complete sanitary equipment for the men are provided. An all-steel tool-crib is located at the rear of the wash-room and almost in the exact center of the shop, so it is convenient to all departments.

Fig. 5. North Side of the Factory, showing Facilities for loading Machines on Flat Cars

The workmen's entrance is on the south side of the building adjacent to the front head-house and leads into a well-arranged coat room constructed entirely of sheet-metal and wire-mesh. Metal hangers are suspended from an overhead framework, each of which is suitable for the accommodation of ten or a dozen men's clothing. Above the hooks for the clothing there is a shelf on which such things as lunches, towels, and other personal belongings may be placed, and they are protected from dust by a hood, or roof, which extends over the shelf. Ample space is left between these hangers for the men to pass without interfering with each other. Here again, the provisions for prevention of fire hazards and accumulation of dust and dirt are in evidence. During working hours a sliding door between the manufacturing floor and the coat room is kept closed.

There are no benches extending along or near the walls of the shop. Instead, individual portable metal benches are provided. There are many advantages to be derived from this departure from the usual shop arrangement, some of which are the elimination of a hiding place for debris and combustibles, better light, and more available working space.

Machine Installation and Arrangement

The machines in the manufacturing departments are arranged in rows with a spacious aisle between, each leading to the main aisle and its narrow-gage car track. All machine equipment is driven by individual motors which, in some cases, necessitated a rather complete change-over from the original drive of the machine. Fig. 6 shows a battery of Cleveland automatics on each side of the aisle, and also illustrates the mounting of individual motors and the method of connecting them with the machines. Operators are not permitted to tamper with the panel boxes from which the various motors receive their current. These boxes are attached to a post near each machine, out of the men's reach. The arrangement is well illustrated in both Figs. 6 and 7; the latter illustration shows one such box open, exposing to view the four switches which it contains. Each machine is provided with a start-and-stop push-button switch for switching the power on or off.

In reference to the installation of such equipment as automatic screw machines, attention is called to a provision for confining the dripping oil to the vicinity of the machine so that it will not be tracked into the aisles and all around the shop. The machines are each surrounded by a strip of angle-iron, forming a shallow drip-pan, 1 inch high, under the machine, which is filled with dry sawdust, the supply being replenished as occasion demands. This precaution keeps the passageway between the machines in a neat condition, and eliminates the danger of slipping on oily floors.

All machines are grouped in such a manner that the flow of work during the process of manufacture is always in the general direction of the front head-house, where the erecting of Colburn heavy-duty drilling machines and vertical boring and turning mills is done. Another group of machine tool equipment which shows the uniformity of arrangement is illustrated in Fig. 7, this being a line of multiple- and single-spindle drilling machines of this company's manufacture.

The heat-treating department, shown in Fig. 8, is situated in the southwest corner of the plant. Special care has been taken to provide for the removal of fumes, heat, and smoke by covering the furnaces with an overhead hood, which has flues that deliver impurities out of doors.

Electric Wiring System and Facilities

It has been mentioned that all machine tools have individual motor drive, and in this connection reference has been made to Figs. 6 and 7. The advantages gained by thus eliminating all overhead pulleys and belting are well known. The electric wiring is carried in wrought-iron pipe conduits with suitable switch panels and distribution stations located conveniently throughout the factory. By arranging all pipe lines, including sprinkler systems and feed pipes for the heating coils, so that they may be suspended near the roof, the entire space above the machines is left open.

The main electric current is furnished by a converter installed in the power room in the rear head-house. From the converter the current is delivered to six distribution panels located at various points throughout the shop. Two of the panels are for lighting purposes and four for furnishing power to the machines. These six panels are mounted high up in the sawtooth roof space, one panel being shown in Fig. 6 attached to the upper framework of the building. Between the distribution panel which serves any particular group and each machine in that group, there is a switch panel to which reference has previously been made. The

Fig. 6. Aisle in the Automatic Screw Machine Department, showing Individual Motor Drive

only person who has access to the switch panels is the regular shop electrician, who systematically examines the switches, blows out the dirt from the motors, and gives all the electric equipment general attention. It requires one week for him to make the complete rounds, giving each motor and switch the necessary attention, so that all equipment is visited at least once in that period of time.

One interesting feature of especial note in connection with the electrical equipment is the provision of testing machines on the erecting floor. The entire row of columns between the front head-house where the erecting is performed and the adjacent parallel bay in which the assembling department is situated is equipped with special switch boxes. The switch boxes are arranged so that not only the motor for driving the machine may be plugged in, but small electric tools may also be connected up by the use of sockets, as, for example, portable drills, which are often required in the final finishing of a machine before shipment. This enables a drilling machine or boring mill to be tested wherever it is located, without moving it. Much time is thus saved, and the result is a considerable and direct reduction in the cost of performing this necessary work. This factor in the lessening of production costs should always be taken into account by the manufacturer, especially if the product is heavy, as is usually the case with machine tools.

Fig. 8. Heat-treating Department—Note Provision of Overhead Hood for carrying off Fumes and Smoke

A complete auto call and intercommunicating telephone system is provided, and also a Stromberg time recorder. Horns located in various parts of the shop which announce starting and stopping time operate automatically and are synchronized with the time system.

Relation of Systematic Lay-out to Production

The incoming raw material when it arrives on the receiving platform can readily be transported by means of the crane system and other equipment, either to the storage space and thence to the machine shop, or direct to the manufacturing department. The lay-out of the cranes and traffic aisles is the result of careful planning, and the arrangement finally evolved is such as to offer the least resistance to the steady flow of the product being machined. If the material is in the form of bar stock, it is cut to length on a power saw in the stock-room and then routed to the first-operation machine. The lay-out is such that the material always moves in the same general direction, arriving in the front head-house for erecting without unnecessary handling.

Upon arrival of the finished product in the erecting department, it is subjected to the usual fitting, scraping, and testing, and is then picked up by the crane in the front head-house and delivered to the auxiliary side-bay crane, and thence to the shipping room which occupies a section of the side bay adjacent to the shipping and receiving platform. Here there is installed suitable woodworking machinery for crating machines.

* * *

WELDING BROKEN ARMATURE SHAFTS

Large armature shafts occasionally break at the junction of the journal and the pulley end. While recognizing the adaptability of the thermit welding process to the welding of large steel shafts, operators sometimes, in this case, decide to scrap the old shaft, fearing that the heat of the steel produced by the thermit reaction might injure the armature coils and produce short circuits. However, it has been the experience of the Metal & Thermit Corporation, of New York City, that when the armature coils can be separated from the fracture by a few inches of molding sand (at least about 4 inches in the case of a 3-inch diameter shaft) a repair by this method is entirely feasible without injuring them, if the following simple precautions are observed. There is no danger of damaging the armature windings through the effect of direct heat, as the fracture is completely surrounded by molding sand and all preheating is confined within this molding sand. The heat which is conducted along the shaft is readily taken care of either by directing an air blast on the shaft or, where necessary, by using a specially constructed water-cooler box with a packing box on the shaft to prevent the possibility of any water coming in contact with the windings. The windings themselves are further protected by being totally encased in an oil-cloth and burlap bag.

In case the keyway of the pulley end of an armature shaft becomes badly worn, this end can be removed and a new over-size extension welded on and machined down. A large number of such extensions have been thermit-welded satisfactorily. As an example of costs, an extension to a 3½-inch shaft can he thermit-welded for about $35.

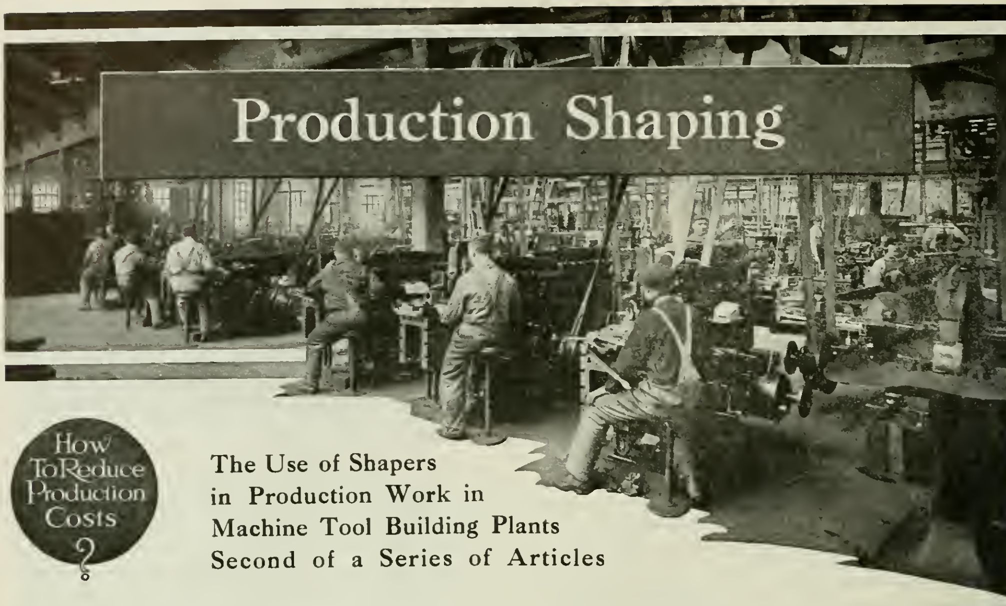
Production Shaping



How To Reduce Production Costs ?

The Use of Shapers in Production Work in Machine Tool Building Plants
Second of a Series of Articles

In the first installment of this series of articles dealing with the use of shapers on production work, attention was called to the various advantageous features of machines of this type. In shops engaged in the building of shapers, it will be obvious that it is desirable for the manufacturer to have such machines in operation in his plant, which are then available for exhibition purposes. This can be done to peculiar advantage because in the manufacture of shapers there are many parts of small or medium size, for the planing of which the shaper is especially well adapted. Typical examples of such work are illustrated and described in this article; in addition to showing the range and flexibility of the shaper, the methods are of general application, so that they could be applied with equal success on many other lines of work, for reducing costs and increasing production.

Planing Steptoe Shaper Column Castings on the Shaper

On shapers built by the John Steptoe Co., the ends of the column castings are planed, and this work was formerly done on a shaper. Little thought will be required to make it apparent that work of this kind is too large to be advantageously handled on this type of machine; but the present example clearly shows the capacity of a shaper in an emergency. Fig. 1 shows this job set up on an old-style triple-geared Steptoe shaper.

A fixture *A* is hung on the shaper cross-rail in place of the apron, which provides for feeding the work transversely or for adjusting its vertical position; the fixture is also provided with a graduated swivel, so that the work may be adjusted for planing different surfaces. This is the means of effecting a substantial saving of time in setting up these castings, because after the end of the shaper column has been planed, as shown in the illustration, it may be swiveled through 90 degrees for planing the ends of the bearing bosses that carry the transverse shafts. Then the work can again be swiveled through 90 degrees to bring the opposite end of the casting under the tool for planing the bearings for the cross-rail, after which a third swiveling of the work brings the opposite side into position for planing.

Thus it will be apparent that all four sides of the work can be planed at a single setting, and even though the shaper may be a little slower than the planer, the possibility of completing all the machine work at a single setting would offset the difference in speed, so far as the total production is concerned. Notches are cut in the flange of the rotary fixture, one notch being shown at *B*, so that the column can be properly located in successive positions for performing the planing operations.

Planing Shaper Table Support

At the plant of the John Steptoe Co. a shaper of this firm's manufacture is employed for planing the table support for Steptoe shapers. These would be rather difficult pieces to hold on any other type of machine, and it has been this company's experience that the work can be done to the best advantage on a shaper. In Fig. 2, which illustrates a Steptoe shaper equipped for this operation, it will be seen that the shaper table has been removed, and that holes have been drilled and tapped in the apron to receive two bolts *A* which hold each casting in place while the operation is in progress.

A method of this kind constitutes a simple means of attaching the work to the machine, but obviously there would be too much overhang if some adequate form of outboard support were not provided. For this purpose, two jacks *B* are utilized, one end of which is entered into T-slots in the apron, the opposite ends engaging a flange in the outer extreme of the work. The planing operation is not unusual, use being made of a round-nosed tool for taking a roughing cut on the area surrounding the slot *C* in the table support, and a square-

---

It might be expected that builders of shapers would have machines of this type operating in their plants under the most advantageous conditions, and the visitor who has an opportunity to see the work done in some of these plants will find this to be true. Shaper builders have developed the use of their machines to a high standard of efficiency, and the results they obtain in everyday practice give ample evidence of the possibilities of the shaper in regular production work. In selecting material for this series of articles, the operations have been chosen with a view to showing what the shaper is capable of accomplishing when employed on manufacturing jobs.

---

nosed tool for performing the finishing operation.

Planing a Hendey Shaper Ram

In the illustration Fig. 4 is shown a 20-inch crank shaper built by the Hendey Machine Co., which is equipped for performing a planing operation on the top of the ram for a shaper of this company's manufacture. The point of special interest in this connection is the application of an extension table *A* for handling long pieces of work. This table extension is a substantial casting of triangular outline. The top or working surface is of uniform thickness and has T-slots corresponding with the top surface of the regular table. The side supporting walls of the extensions are under-cut, to save metal. The dividing line between the main table and the extension is shown by the termination of the T-slots on the side. The extension is fastened to the front end of the table by means of five bolts and two tapered dowel-pins, so it can be readily taken off when desired, and replaced in perfect alignment.

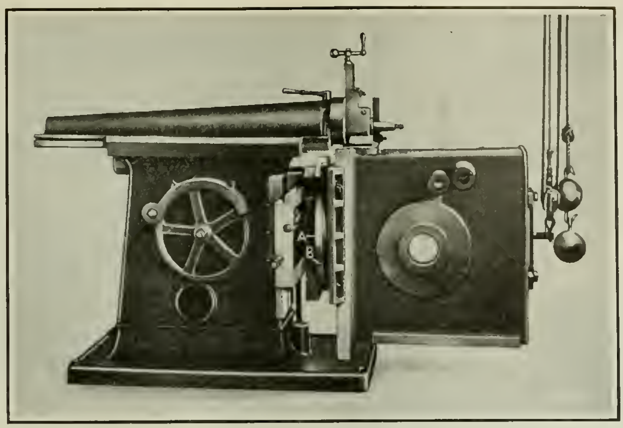


Fig. 1. Fixture used in holding Column Casting of a Shaper for planing Four Sides of the Work at a Single Setting

The shaper ram *B* has had the dovetailed bearing planed on its under side before being set up on the shaper for performing the operation here illustrated. The casting is set on two parallel blocks *C*, and held down by bolts entering the table T-slots and straps *D* extending over the top of the work. The planing operation consists merely of taking roughing and finishing cuts over the flat surface surrounding the slot at the top of the ram.

Planing Rocker Arms for Springfield Shapers

On the so-called "stroke" or rocker arm for the single-geared shapers built by the Springfield Machine Tool Co., there is a cylindrical member *A*, Fig. 3, at the top, which is machined to the required form on a Springfield shaper equipped as shown. The machine is furnished with a special rotary fixture that provides for revolving the work as the tool reciprocates back and forth across it, thus generating a cylindrical shaped pivot *A* of the required form. This is the method employed for machining rocker arms for 12- and 15-inch single-geared Springfield crank shapers.

The fixture is so arranged that it is only necessary to set the casting in position and locate the cylindrical pivot that is to be planed from a round disk on the fixture. This disk is directly behind the work, and serves the double purpose of locating the casting, and of providing a reference point from which the tool is set in order to plane the work to the required size. It will be noticed that the circular feed is taken from an auxiliary ratchet *B* connected to the feed mechanism of the shaper, and transmitted through a worm on shaft *C* that meshes with worm-wheel *D* on the fixture. The operation is performed at a single cut, with a very fine feed, and it requires about forty minutes to set up the casting and finish it to the required form.

Shaping Operations on a Queen City Shaper Rocker Arm

In machining rocker-arms that transmit motion from the crank to the ram on shapers built by the Queen City Machine Tool Co., it is required to face off the bearing bosses on the inside of a yoke at one end of these castings. The operation, as performed on a 24-inch shaper of this company's manufacture, is shown in Fig. 5. The side of the rocker arm that rests against the table, and the wide slot for the crankpin sliding block, are machined previously. The work is drawn squarely against the side of the table by the two bolts *A*, and the thrust of the cut is taken by

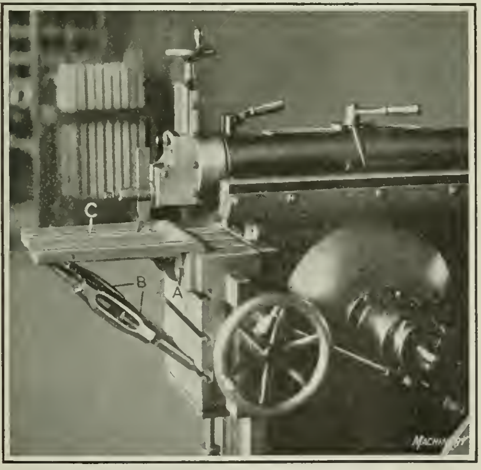

Fig. 2. Method of setting up Shaper Table Support for performing a Short Planing Operation on the Shaper

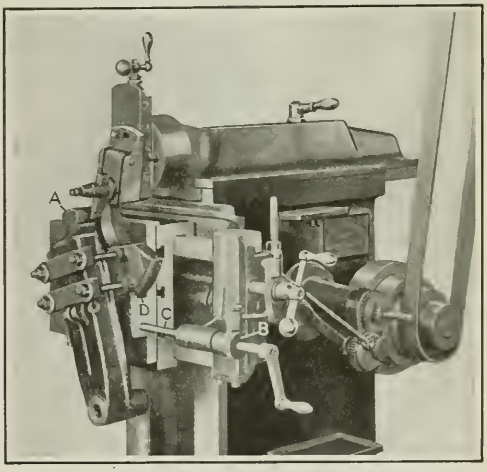

Fig. 3. Use of Rotary Fixture for holding Shaper Rocker Arm to guide Work for shaping Bearing A

a long block fitted to the slot in the rocker arm and bolted and tongued to a vertical T-slot on the side of the table.

After the work has once been set up, the table remains in this position, the operation of facing down the two opposite bosses being performed with a tool-holder carrying two cutter bits that machine the faces of the bosses simultaneously. A roughing and a finishing tool are employed, and a tool-setting gage is used to insure the correct relation between the tool and the finished face on the side of the arm. The simplicity of the holding devices, as well as the adaptability of the shaper for this job, enables an average production time per piece of only six minutes to be attained.

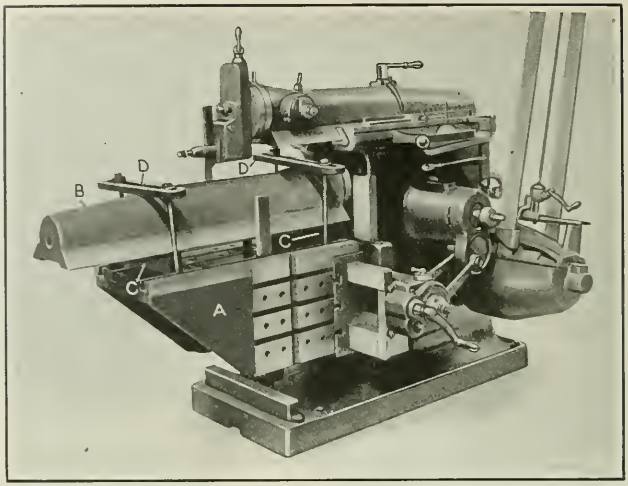

Fig. 4. Use of a Table Extension to afford Outboard Support for a Shaper Ram while performing a Short Planing Operation

Planing the Slot in a Smith & Mills Shaper Rocker Arm

For machining the rocker arms used in shapers built by the Smith & Mills Co., use is made of one of this company's 28-inch back-geared, single-pulley drive machines for finishing the slot in the arm that receives the sliding crank block. Fig. 6 illustrates this operation, and it will be seen that a tool-holder with two cutter bits is used for simultaneously machining the two sides of this slot in order that they may be finished parallel with each other and with exactly the required spacing between the sides. This is a regular production job, and the special work-holding fixture shown in the illustration is used for holding the work.

Mention has previously been made of the three-point principle for obtaining a preliminary support for rough castings, in order to compensate for slight inequalities in their size, and to insure obtaining a firm foundation for the work. This fixture has three screws by means of which the casting is leveled up, the correct setting being determined with a surface gage; and after this part of the setting has been accomplished, the work is lined up in the fixture by the adjustment of four screws *A*, which also tend to hold the work against sidewise movement. Tests for accuracy of alignment are made from the edge of the table to the work with a surface gage. Final clamping is accomplished by means of straps *B* that hold the work down on the fixture. After the casting has been leveled up and brought into alignment with the line of travel of the shaper tool, the tool is centered over the work by the regular adjustment of the saddle on the shaper cross-rail.

Both the roughing and the finishing tools are of the double-point type shown in Fig. 6, but the finishing tool is required to bring the width of the slot to exactly the desired dimension, and in order to compensate for wear that occurs in sharpening, there is a wedge *C* that is forced down between the two cutter bits *D* by means of an adjusting screw *E*, so that the tools may be adjusted to plane the slot to exactly the required width. For both the roughing and finishing operations, the feed is 0.032 inch, and the

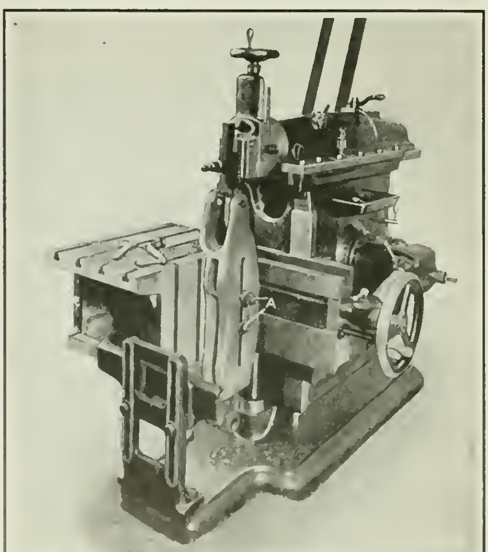

Fig. 5. Application of a Duplex Tool for simultaneously planing Inside Faces of Yoke Bosses on a Shaper Arm

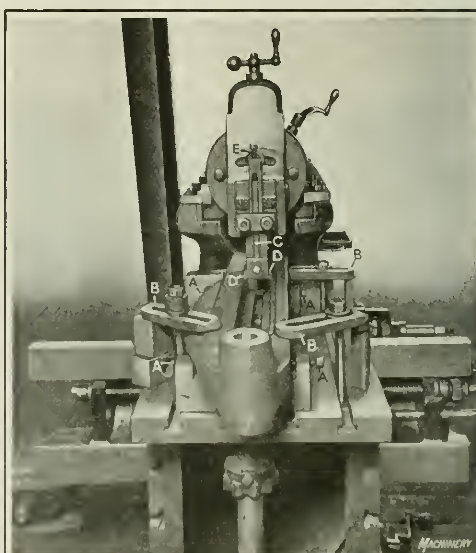

Fig. 6. Crank Shaper equipped for simultaneously planing Sides of Slot in Rocker Arm for a Shaper

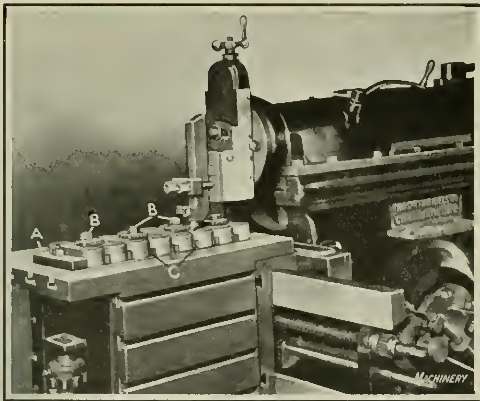

Fig. 7. Crank Shaper equipped for planing the Bosses on a String of Eight Shaper Pendulum Links

cutting speed 35 feet per minute. The time required for this operation is one hour and a half, which includes the time necessary for planing the horizontal top face of the rim which surrounds the slot.

Performance of String Planing Operation on a Shaper

In many plants where there are limited numbers of small and medium sized parts on which it is required to plane the faces of bosses and to perform similar operations, it will be found that a shaper is well adapted to the requirements of such work. Fig. 7 illustrates a Smith & Mills 28-inch back-geared shaper with single-pulley drive, which is used

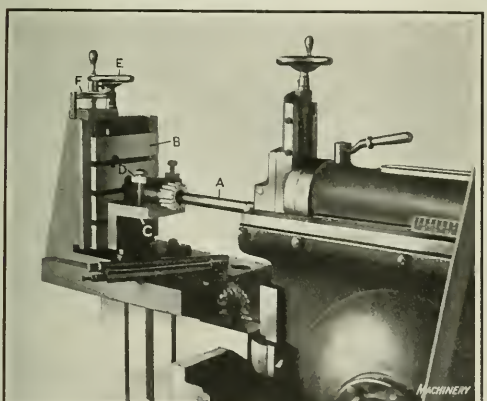

Fig. 8. Use of a Keyseating Fixture for machining the Keyway in Bronze Sleeve Gears for Shapers

in this company's shop for planing both sides of bosses at opposite ends of short links of the form shown clamped to the table of the machine. It will be seen that eight of these pieces are set up at a time, and there are four faces to be finished on each link.

The operation is quite simple, consisting of taking a roughing cut with a round-nosed tool and a finishing cut with a square-nosed tool. The method of setting up the work is also simple, and is well shown in the illustration. A bar A is utilized as an end-stop, and this serves the double purpose of squaring up the work with the line of travel of the ram, and of supporting the end thrust of the tool. It will be seen that straps and bolts B are placed between each pair of castings to hold them down on the table, and small blocks C are put between the ends of each pair of links, because these pieces of work are larger at the center than at the ends, and if some precaution of this kind were not taken there would be a tendency for the thrust of the tool to swing them about their central points. For taking a roughing and a finishing cut on both sides of both ends of eight of these links, that is to say, planing thirty-two faces, the production time is about one hour and twenty-five minutes.

Application of the Shaper for Keyseating Bronze Sleeve Gears for Steptoe Shapers

Another application of a shaper in the John Steptoe Co.'s plant is shown in Fig. 8. This is a keyseating operation in the bronze sleeve gear for machines of this company's manufacture. In this illustration one of the gears is shown lying on the table, and a second gear will be seen in place in a keyseating attachment that is supplied as an auxiliary equipment for use in shops that have an occasional keyseating operation to perform. It does not find wide application, but in repair shops where there would not be sufficient

Fig. 9. Using an Indexing Shaper Fixture for planing Gear-boxes

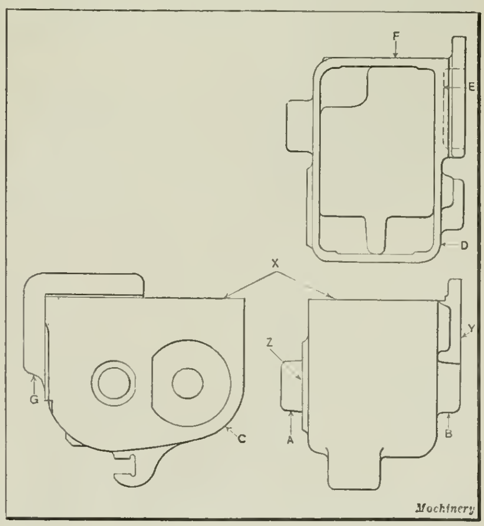

Fig. 10. Outline of Gear-box planed in Fixture shown in Fig. 9

work to justify purchasing a keyseater, this fixture is often found useful.

The tool-holder *A*, mounted in the shaper ram, is made of sufficient length so that it can be reciprocated back and forth through the axial hole in the gear and its shank. The attachment is provided with a vertical table *B* having T-slots planed in it for attaching various work-holding fixtures. In the present instance the fixture consists of a block *C*, bolted to the table and provided with two clamping bolts and a strap *D* for holding the work down. The position of the vertical table *B* is adjusted by a screw having a handwheel *E* on the end. A stop-screw that is positioned by a graduated dial *F* enables the depth of the keyseat to be accurately controlled.

Indexing Shaper Fixture for Planing Gear-boxes

In the plant of Gould & Eberhardt, shapers of this concern's manufacture are used for short planing operations on gear-boxes. One of these machines is shown in operation in Fig. 9, where it will be seen that the gear-box casting *A* is set up in a box-type work-holding fixture pivoted at *B*. An index-pin provides for locating the fixture in successive positions, so that planing operations may be performed on three sides of the work without requiring the casting to be reset. This is the means of effecting a substantial saving of time in the performance of planing operations.

Fig. 10 shows an outline drawing of the gear-box casting. It rests on the trunnion fixture on fixed supports which make contact with the casting at points *A*, *B*, *C*, *D*, *E*, and *F*. Point *G* rests on a support which is adjustable to compensate for variations in the casting. The latter is clamped in place in the fixture by set-screws located directly opposite the supporting points to eliminate distortion. The first operation on the part consists of roughing and finishing the top surface *X*; the second operation consists of roughing and finishing the back surface *Y*; and the third and final operation consists of roughing and finishing front surface *Z*. Means are provided on the fixture for accurately and quickly setting the tool so that the three finished surfaces are machined in the correct relation to the rough casting.

* * *

CREDIT SERVICE FOR SHOP EQUIPMENT

The Black & Decker Mfg. Co., Baltimore, Md., manufacturer of portable electric drills, grinders, and electric air compressors, has recently put into effect a unique credit service. The company sells its products entirely through jobbers, and the new credit service enables users of Black & Decker equipment to buy through their regular jobber by paying 23 per cent of the price in cash and the balance in six equal monthly payments. Nothing is added to the standard price for the long-term credit, and no interest is charged. A conditional sales agreement is made, whereby the product sold becomes the security for the sum to be paid until entirely paid for. The Black & Decker Mfg. Co. shares the responsibility equally with the jobber for the fulfillment of the sales agreement. The purpose of this service is to enable the user to put cost-reducing equipment into his shop without a heavy investment, and to make it possible for the equipment to practically earn its own cost while it is being paid for. It is generally acknowledged that the principal obstacle in the path of normal sales today is a financial one, and the purpose of this plan is to overcome this difficulty as far as possible.

ESTIMATING THE WEIGHT OF BAR STEEL

By HYMAN LEVINE

Tables giving the weights of bar steel per running inch and per running foot may be found in nearly all engineering handbooks; and by the use of these one can easily calculate the weight of steel bars of almost any length and section. It frequently happens, however, that inspectors, salesmen, draftsmen, designers, and shop executives require a rough estimate of the weight of bar steel when a handbook is not available.

The formulas given in the accompanying table will be found particularly useful in such instances, as they provide a means of calculating the approximate weights of various sections and lengths of steel. The formulas are so simple that they may be readily memorized, and the results obtained are sufficiently accurate to warrant their use for many practical purposes. It is possible, of course, to rearrange these formulas so as to avoid the necessity of making any additions or subtractions; thus for round steel the weight per inch of running length would equal $\frac{2\frac{1}{4}D^2}{10}$, approximately, and for square steel $\frac{2\frac{7}{8}D^2}{10}$, approximately.

FORMULAS FOR ESTIMATING WEIGHT OF BAR STEEL

Section	Pounds per Inch of Running Length	Error	Pounds per Foot of Running Length	Error
Round (D = diameter)	$\frac{2D^2}{10} + \frac{1}{10}\left(\frac{2D^2}{10}\right)$	1 per cent low	$2.5D^2 + \frac{1}{10}(2.5D^2)$	3 per cent high
Hexagon (D = width across flats)	$\frac{2.5D^2}{10}$	2 per cent high	$3D^2$	2 per cent high
Square (D = side of square)	$\frac{3D^2}{10} - \frac{1}{20}\left(\frac{3D^2}{10}\right)$	1 per cent high	$3.5D^2 - \frac{1}{20}(3.5D^2)$	1 per cent low

Machinery

Experience has shown that it is easier mentally to multiply by 2 and then increase this result by 10 per cent or 1/10 than to multiply by 2¼. It is likewise less difficult to multiply by 3 and subtract 5 per cent or 1/20 than to multiply by 2⅞. In some instances sufficiently accurate results may be obtained by disregarding the amount to be added or subtracted.

In using the formulas, dimension *D* must be given in inches. Thus a bar of 3-inch round steel, 10 inches long, would be estimated to weigh

$$\left[\frac{2 \times 3^2}{10} + \frac{1}{10}\left(\frac{2 \times 3^2}{10}\right)\right] \times 10 = 19.8 \text{ pounds}$$

or approximately 20 pounds. The actual weight of this bar is 20.03 pounds. A bar of 1-inch hexagon steel, 5 feet long, will be estimated to weigh $(3 \times 1^2) \times 5 = 15$ pounds; while the actual weight is 14.65 pounds. A bar of ½-inch square steel, 8 inches long, would be estimated to weigh

$$\left[\frac{3 \times (\frac{1}{2})^2}{10} - \frac{1}{20}\left(\frac{3 \times (\frac{1}{2})^2}{10}\right)\right] \times 8 = 0.570 \text{ pound}$$

The actual weight is 0.566 pound. Where the size of the steel cannot be easily calculated mentally, a handbook may be used.

* * *

The Pittsburg chapter of the American Society for Steel Treating plans a number of activities for the coming season. Many prominent speakers have been secured for coming meetings, which will be held on the first Tuesday of each month. At the meeting held in September, Prof. MacIntosh of the Carnegie Institute of Technology, Pittsburg, spoke on the metallurgy of iron and steel. The October meeting was addressed by Mr. Carpenter, president of the E. F. Houghton Co., Philadelphia, Pa., his subject being "Individualism versus Socialism." This month, Professor Sauveur of Harvard will speak on the heat-treatment of steel, and in December Professor H. F. Moore of the University of Illinois will discuss fatigue testing and resistance of materials. In January, the subject will be alloy steels. For further information address E. C. Cooke, 108 Smithfield St., Pittsburg, Pa.

Machine Tool Markets in Asia*

By W. H. RASTALL, Chief of Industrial Machinery Division, U. S. Department of Commerce, Washington, D. C.

THE largest proportion of the foreign market for machine tools has always been in Europe. In 1910, 81 per cent of the foreign shipments went to Europe; in 1913, 76 per cent; in 1915, 89 per cent; in 1918, 74 per cent; in 1919, 69 per cent; and in 1920, 57 per cent. Because of this large market in Europe there has been a temptation to overlook other machine tool markets of the world. Asia has never been considered a very good market—at least it was not so considered previous to the war, but there have been great changes since. Asia is developing in a way that few understand unless they have given this subject close attention.

Past Machine Tool Exports to Asia

In 1910, all the countries of Asia bought only $156,000 worth of American metal-working machinery. In 1913, this export grew to $200,000, and in 1915 to $500,000. A tremendous change in this market took place about 1918. In that year, metal-working machinery to a value of $5,900,000 was exported to the Asiatic countries, the exports in 1919 being $8,800,000, and in 1920, $7,400,000.

In spite of the tremendous expansion industrially that has taken place in Europe, the ratio of industrial expansion in Asia has been even more rapid in the last few years, and has been practically sustained during recent months. The indications are that the exports of metal-working machinery to Asia for 1921 will be valued at about $6,000,000. In other words, the 1921 market in Asia will probably show an even better result than in 1918.

Comparison of Asiatic and Other Foreign Markets

If we compare the Asiatic market with that of other non-European markets, we find that whereas Asia took $7,400,000 worth of metal-working machinery in 1920, Australia absorbed not much more than $1,000,000, and South and Central America, $4,000,000. The significance of this tremendous development in the absorption of metal-working machinery by Asia should be duly recognized. Asia has absorbed more metal-working machinery from America in the last three years than she would have absorbed in an entire century at the rate at which metal-working machinery was imported previous to the war.

Whatever has wrought the change, the fact remains that during the war there was a great industrial agitation in Asia, which has continued since. The Japanese market is comparatively well known, because Japan has absorbed important quantities of machinery for several years. However, it has been felt that Japan was a little different from the rest of the Asiatic continent. Speaking in round numbers, Japan has absorbed 50 per cent of the machinery shipped from the United States to Asia during recent years. China, on the other hand, in spite of her large area, tremendous population, and resources, has absorbed but 15 per cent.

Both the Chinese and Japanese markets are comparatively well known to the American manufacturer, but the markets of British India and the markets of the Dutch East Indies are not so well known. It is therefore of importance that American machine tool builders recognize the great change that has taken place and the relative importance of the markets of all the Asiatic countries. Of all the metal-working machinery shipped abroad from the United States, Asia absorbed in 1913 only 1 per cent, and in 1915 only 2 per cent. But in 1918 Asia took 11 per cent; in 1919, 15 per cent; in 1920, 17 per cent; and the indications are that in 1921 Asia will absorb 25 per cent of the machine tool exports. These figures should be carefully considered.

When the conditions as they exist in Asia today are contrasted with those in the Latin American countries and in Europe, the most startling differences will be found. Latin America, comparatively speaking, is unpopulated; Asia is densely populated. The resources of Latin America possibly are unexplored, but at any rate, so far as they are known and accessible, they are comparatively limited. The natural wealth of Asia is enormous, the mineral wealth alone being equal to or greater than that of any other continent. Asia is now developing rapidly in an industrial way, and probably the most rapid development is taking place in British India.

British India as a Machine Tool Market

Before the war it appears that it was British policy to keep India as a producer of raw materials and to take these to Europe, manufacturing them into finished materials in the United Kingdom. This policy has been changed, and now the government of India, native and British financial interests, and everybody concerned with controlling the destinies of the Indian Empire appear to have decided upon the policy that India shall be industrialized. That statement should be brought home to American manufacturers with all the emphasis that it is possible to put into it, because a definite step is being made to establish, in a methodical way, industries throughout the Indian Empire. The natural resources of the country are being studied. It has been stated that it is possible to produce pig iron in India and lay it down in San Francisco at the competitive price. One large steel plant has been developed, mostly under the guidance of American engineers, and there are now several other large enterprises in the metal-working field being planned—foundries, railway car shops, rolling mills for both rails and structural steel, and machine-building shops.

It is impossible to say how much and how rapidly this development will grow, but it may be stated with certainty that India is being industrialized as rapidly and as effectively as British and Indian interests can accomplish it. The figures of exports of American metal-working machinery to India will illustrate this point. In 1910 the exports were valued at $45,000; in 1913, at $43,000; and in 1915, at $23,000. A great change took place between 1915 and 1918, when we find the exports amounting to $1,250,000. In 1919 they amounted to $900,000, and in 1920 to $1,375,000, this last figure representing nearly 20 per cent of the entire metal-working machinery export to Asia.

Selling Machinery in Asia

One of the first questions that will be asked is, "How should one sell machinery in Asia?" Fortunately, it is easy to give a definite answer. One hundred per cent of the machinery sold in Asia is sold through the import merchant there. This import merchant corresponds more or less to the export merchant as he is known in the United States. The only practical way to sell machinery is through these merchants. The Department of Commerce at Washington is now doing everything it can to assist machine builders in developing their foreign business. The department has reasonably complete lists of machinery dealers in every important city in the world, and this information can be obtained either by correspondence or by a personal call at the Bureau of Domestic and Foreign Commerce.

EDWARD K. HAMMOND, WESTERN EDITOR

REDUCING PRODUCTION COSTS

The articles in October MACHINERY describing some of the modern machines, tools, and other interesting devices and methods for reducing manufacturing costs, have received a great deal of attention, and MACHINERY acknowledges the receipt of many favorable comments, but especially appreciates the active cooperation of the manufacturers in this serious effort to spread useful information on the greatest need of our time in industry.

Material along the same definite lines will be found in the present number of MACHINERY, and in December and January there will be substantial additions to it. In this number, specific examples of cost reduction will be found in the articles on "How Factory Investigations Reduce Costs"; "Production Work in the Locomotive Shop"; "Machining Hudson Super-six Pistons"; "Drawing Dies for Manufacturing a Carburetor Bowl"; "Production Shaping"; and others. All of these articles give practical suggestions indicating how machine tools and accessories may be used to best advantage in different lines of manufacture.

It is no longer wise to say that prices *will be* reduced, that competition *will be* keen; prices *have been* reduced, competition *is* keen, and the way to meet this changed situation successfully is to adopt machines and methods which produce with the lowest relative operating outlay.

A great many manufacturers have wisely used the time this period of slackness has forced upon them to investigate new machines and improvements for getting results and cutting costs. Those who utilize the dull present to make a thorough study of the machines, shop methods and varied equipment and materials now available in a buyer's market for giving better results at lower costs are laying up solid foundations upon which to build the business they must work harder to get and hold than ever before.

* * *

A DEVELOPMENT IN GRINDING

The extensive use of the automobile has developed a new kind of repair shop, of which hundreds have been started all over the country, for the purpose of regrinding automobile cylinders. These shops are usually independent enterprises, soliciting their work both from the garages in the vicinity and from individual automobile and truck owners. Grinding machines have been developed especially to meet the mechanical needs of these shops, and the demand for them has created an additional outlet for the product of some grinding machine manufacturers which has helped to keep their shops running during the present depression.

Many machinists who were out of employment have started small shops of their own in the regrinding business, often taking on a general line of repair work in addition. In some instances these shops undoubtedly will expand into larger enterprises.

The regrinding of automobile engine cylinders, when carefully and accurately done, may add years to the life of a car and make it possible to maintain or even improve the running qualities of the engine. It is likely that within the next few years many developments will be made in appliances for repairing and maintaining automobiles, and some machine tool manufacturers will doubtless specialize in providing equipment for shops engaged on this kind of work and in repair work in general.

SPECIAL AND STANDARD MACHINES

The demand, created largely by the automobile industry, for machine tools intended for a few special operations—sometimes for one operation only—has greatly stimulated the production of such tools. In the near future, with keen competition and reduced prices, quantity production will be an important factor in lowering costs, and the demand for special machines to perform a single operation or series of operations will undoubtedly increase. There is a definite indication of this in the inquiries that have been received by the builders of special types of machine tools, especially in the milling, drilling, and multiple-spindle automatic machine fields.

On the other hand, what are generally known as standard machine tools—the engine lathe, turret lathe, milling machine, upright and radial drilling machine, planer, shaper and slotter, grinding machines of various standard types and a number of other machine tools in the same category, will always be in demand, because only a comparatively small portion of the entire machine shop work of the world can be done on the quantity production basis. Steam turbines and engines, large gas and oil engines, heavy mining machinery, large units of electrical machinery and many other types of machines and appliances cannot be built in quantities; and there are many machines that, while they will be built in fair-sized lots, will never be produced in such quantities as sewing machines, typewriters, cash registers or automobiles. Machine tools themselves are examples of this class. The special machine for producing in quantities, so effective in the automobile plant, would seldom be of service in a shop that produced machine tools only.

Both types of machines meet definite requirements, and while the present demand for special types appears to be better than for the standard machines, this does not indicate that the former are likely to replace the latter. Neither type really encroaches on the field of usefulness of the other.

* * *

ELECTRICAL DRILL STANDARDIZATION

Recent correspondence with a well-known manufacturer of machine shop accessories emphasizes the need for standardizing electric drilling equipment. It would be a decided advantage to all users of such equipment if manufacturers employed the same size and kind of fittings for attaching chucks of the same capacity. Instead of there being a standard means for doing this, some manufacturers use a taper arbor, while others employ a threaded spindle. A further advantage would be gained if drill chuck manufacturers would establish standards so that all drill chucks of the same capacity would have the same size recess to receive an arbor. This would relieve dealers from the necessity of carrying a large variety of arbors in stock and enable manufacturers to produce them in such quantities that they could be sold at lower prices. The user would gain added convenience from the interchangeability of different drill chucks, and the cost of the equipment would be less.

At this time, when production problems are not pressing, such changes involving a saving in time or money might well be considered by manufacturers. Their satisfactory solution would help the machine building industry and add another step toward the standardization of machine shop equipment.

National Machine Tool Builders' Convention

THE twentieth annual convention of the National Machine Tool Builders' Association, held in New York City October 18, 19, and 20, was unusually well attended, and a great deal of interest was displayed at all the sessions. The address by the president, August H. Tuechter, at the opening session covered many of the important questions now facing the machine tool industry. It reviewed the past history of the association and the business in the machine tool field, and contained much sound advice for the future.

The President's Address

In welcoming the members to the convention, Mr. Tuechter pointed out that he was called upon to preside at the most important annual meeting the association has ever held, because of the period of dullness through which the industry is passing. "We had four years of false prosperity," said Mr. Tuechter, "due to the war, when our industry was called on to increase its capacity and output far more than we ever dreamt possible. How well it met the call is a record to which we can point with pride. After the armistice, we had a slackening in business, which we rather expected, but to our surprise another period of false prosperity began in 1919. However, this did not last long, because new orders fell off from January, 1920, and kept slipping down until July, 1921."

In order to compare present conditions with those that the industry has passed through since the association was formed, extracts from the addresses of former presidents of the association at various conventions were read, dating back to 1904. From these extracts it was evident that during this period the machine tool industry has passed through a number of successive cycles of prosperity and depression in business. Seven slumps have been experienced in twenty-one years, and Mr. Tuechter expressed the hope that the mistakes made in the past in times of depression will not be repeated again, especially when the association now has in Mr. DuBrul, its general manager, an able advisor and competent observer who can give warning of shoals ahead and of clear sailing, and of the rise and fall of the business barometer. In this connection it was stated that the most promising and the most necessary activity in which the association is now engaged is the organization of the statistical service for each group of machine tools for which it is possible to render such service.

Waste in Industry

Mr. Tuechter referred to the Committee on Waste appointed by the Federated American Engineering Societies, the work of which has been to call public attention to the sources of waste in industry, and to arouse industrial leaders to the necessity and profit of eliminating waste. During the past year the association has assisted Fred J. Miller, formerly president of the American Society of Mechanical Engineers, in making studies of the machine-building industry. "This investigation," said Mr. Tuechter "seemed to show a probable waste of about 40 to 45 per cent. The report of the committee is very interesting, and it shows that in the machinery industry not a large proportion of this waste can be chargeable directly to labor restrictions; therefore, the responsibility for elimination of waste in the machinery business rests largely on the shoulders of management. There is a large excess of facilities that are not used to the fullest extent. There is badly planned management. Efficient planning and guidance of production is the duty of management; better employment service and policies lie within the power of management and not of the employes." The old proverb says that a dollar saved is a dollar earned, and Mr. Tuechter recommended to the members that they investigate every opportunity to save waste in their own shops, waste of every kind—in equipment, in time, in material, and in organization.

Uniform Cost Accounting

Another work carried on by the association during the past year is that relating to uniform cost accounting. It was advocated that this work be continued until the members all have some system of figuring the proper elements of cost. Unless this is done, there will be a false basis upon which false prices are founded. The man who does not charge enough into his costs is prone to make mistakes in his prices, although his cost system should automatically provide for the proper charges. Especial emphasis was placed on the point that a uniform plan should be used for calculating a normal burden, and that cash reserves should be put away in boom times to carry over depressions. If this had been done, the industry would be in a better condition than it now seems to be. The cost-accounting work, therefore, is one of the important phases of the association's activities.

Statistical Service

The statistical service recently organized was referred to in detail. A chart was shown, exhibiting the great irregularity to which the whole industry has been subjected, with an excessively high peak indicating the war activity; this peak showed that the number of machines manufactured at that time were something like 150 per cent in excess of the number manufactured at the most prosperous period previous to the war. It was pointed out how impossible it is to judge the wisest course from mere individual experience, and how much more accurately the future may be predicted if the information of manufacturers in regard to past business cycles is pooled in a statistical service. Other trade associations, it was said, have found this to be the most valuable service they can render their members, and Mr. Tuechter pointed out that the whole world gains much from the monthly reports of output that the iron industry has published for many years. All industry is closely related, and by proper study and interpretation of conditions it would be possible to better stabilize industry and to have ready for the consumer all the goods that he needs at any given time, at the same time avoiding an excess of goods when the consumer is not likely to need them. The individual manufacturer, confronted with a business situation such as the one through which we are now passing, is groping blindly, when guided only by his own knowledge and experience. He is much more subject to losses than if he had full information as to the total current output and sales of his particular product throughout the country, together with reliable information as to finished stock on hand, the amount in process, and the rate at which this stock is moving.

The statistical service of the association has already compiled figures of shipments of certain groups of machine tools for the last twenty years. The figures thus obtained make it possible to form quite a fair conclusion as to the pre-war trend, and in the light of that information an intelligent plan can be laid down for future policies. When complete monthly reports and charts are made out for each group, the actual flow of business can be easily seen, whether it is improving or falling off. Such statistics can be made of great value to the country at large, because it is evident that the slump in machine tools in any period of depression precedes the decline in general business by several months and perhaps a year.

Standardization

Mr. Tuechter referred to the standardization work of the association in the following words: "For many years this association has talked about the possibilities of standardization. The time has now come to stop talking and go to work. The American Society of Mechanical Engineers has taken up a number of subjects that directly concern the machine tool builder, and we shall have to be represented on committees on these subjects. A recent letter from Mr. Einstein, chief engineer of the Cincinnati Milling Machine Co., who is now in Germany, says that the German machine tool builders are very busy with standardization work. Each committee should seriously and promptly formulate opinions as to what things can be standardized, and then go into the work of standardization.

"A general plan would be to have a general committee of the association which could make recommendations to the Engineering Standards Committee. Each machine group should have a special committee on standardization which would report its findings to the general committee. This is the practice of other organizations. We should take our proper position in these matters. If we do not do this work ourselves as affecting our own interests, we will have no just cause for complaint if others attempt to do it for us and do it badly, because of lack of understanding of our problems.

"We should not let the matter lie as we have heretofore, but we should make this a vital and active part of our association program. It will finally be a very profitable undertaking, as has been demonstrated by standardization work in other fields."

Report of the General Manager

The general manager of the association, Ernest F. DuBrul, presented a comprehensive report referring mainly to the statistical work that is being carried out by the association under his leadership. He emphasized the value of cooperation between the members, and between the members and the association's office. He outlined the methods used in distributing information and the value to the members of exchanging ideas. The bulletins sent out by the association to its members were referred to, and the value of the bulletins emphasized.

The main part of Mr. DuBrul's report, however, was devoted to the statistical work done by the general manager's office. In referring to this work, Mr. DuBrul reiterated the statements made by the president in his address. "It is well demonstrated," said Mr. DuBrul, "by many trade associations, that the most valuable service that can be rendered is to gather and distribute statistics of production, shipments, stocks, and sales. Without information of this sort, each manufacturer must simply grope blindly in the dark, making the wildest kind of guesses as to conditions that he must anticipate in the future. The poorer his information of a general situation, the worse his guess is likely to be.

"The first thing a man wants to know is whether he is getting his share of the business at any time. He can tell this if he knows the total number of machines in his line being sold in a month, and the total capacity of his group. If he knows that the present state of demand is only fifty machines a month, and that he is getting his share of that limited demand, he will not be tempted to do things that will compel his competitors to fight him, to his own detriment. But if he is ignorant of the facts, he is pretty sure to do something that will work against his own pocketbook. In no other way can he know, except by joining with his competitors in a composite report of conditions. When he has that report he can then compare his own conditions with those of the group as a whole.

"It is for the purpose of developing that sort of information for each group that we are organizing monthly statistical services of orders, concellations, production, shipments, factory stocks, and dealers' stocks for various groups. The groups who have already put this service into operation are the shaper, radial drilling machine and upright drilling machine groups.

"To give some groups a picture of their past, so that they can have a guide for the future, we have gathered statistics of shipments for the last twenty years. These are far from complete, but are fairly typical. The group charts show the situation not only for the group as a whole, but for the different sizes of machines made by the groups reporting."

The subject of how to provide a reliable and simple barometer of the machine tool industry that will indicate at all times with a fair degree of accuracy the conditions not only in the entire industry but in certain groups was dealt with in detail. Every industry should have such a barometer, and suggestions have been made both by Mr. DuBrul and by Mr. Charles Oesterlein, with a view to solving the problem in the machine tool building field.

Addresses Made at the Meeting

Charles L. Underhill, member of Congress from Massachusetts, made an able address on the subject "How Present Political Policies Affect Business," in which he pointed out the importance of business men and manufacturers taking an active interest in political matters, and informing their employes of business conditions and of the effect on their particular business of any political action. An address on "Business Cycles" was made by Professor David F. Jordan, which was followed by a discussion led by C. L. Cameron of Gould & Eberhardt, Newark, N. J., and by E. F. DuBrul. This discussion covered the questions: "What things should machine tool builders do?" and "What should they avoid at various stages of the business cycle?"

An address containing much information of value to machine tool builders was delivered by W. H. Rastall, chief of the Industrial Machinery Division of the Department of Commerce, Washington, D. C., on "The Orient as a Machine Tool Market." J. H. Drury, treasurer of the Union Twist Drill Co., Athol, Mass., spoke on "Conditions in Europe," giving his impressions from a recent business trip in several European countries.

At the meeting of the Executive Committee held Thursday morning, October 20, three questions were raised for general discussion, as follows: "What can be made in idle machine tool plants during times of slack demand for regular product?" introduced by H. L. Flather, treasurer of Flather & Co., Inc., Nashua, N. H.; "What reductions in prime costs may be expected in the machine tool industry during 1922?" introduced by P. M. Brotherhood, vice-president of Manning, Maxwell & Moore, Inc., New York City; and "Can sane methods be devised to grant long terms with proper credit guarantees or insurance in foreign trade?" introduced by J. E. Andress, secretary of the Barnes Drill Co., Rockford, Ill.

Officers of the Association for the Coming Year

The officers of the association were re-elected, but as the secretary Carl F. Dietz had resigned, Howard W. Dunbar, Norton Co., Worcester, Mass., was elected to fill his place. The other officers for the coming year are: President, August H. Tuechter, Cincinnati Bickford Tool Co., Cincinnati, Ohio; first vice-president, E. J. Kearney, Kearney & Trecker Corporation, Milwaukee, Wis.; second vice-president, C. Wood Walter, Cincinnati Milling Machine Co., Cincinnati, Ohio; and treasurer, Winslow Blanchard, Blanchard Machine Co., Cambridge, Mass. In addition, the following members were added to the executive committee: J. B. Doan, American Tool Works Co., Cincinnati, Ohio; C. E. Bilton, Bilton Machine Tool Co., Bridgeport, Conn.; and Fred L. Eberhardt, Gould & Eberhardt, Newark, N. J.

The British Machine Tool Industry

From MACHINERY'S Special Correspondent

London, October 12

At the present time industry may be said to be trying to find its feet, a process that is bound to occupy some time, even though it is generally believed that many of the labor difficulties have been permanently relieved. The most serious barrier is the price of coal. The anxiety to start to produce is evidenced by the many inquiries that reach the machine tool makers. Even if some of these inquiries are merely for the purpose of sounding the market, it must still be assumed that there is a great deal of work ahead for the machine tool industries. Many of the machine tool makers are now building for stock, and most of them are of the opinion that the low point of the depression has been passed. Firms who specialize in jigs, fixtures, and tool lay-outs are busier than for months past, and this again must be construed as a hopeful sign, particularly as such orders generally point to a well defined manufacturing program on the part of the customer. Textile machinery manufacturers are becoming increasingly active.

A revival in the shipbuilding industry appears to be imminent, and there are indications that railway and locomotive building shops intend to resume buying. The latter continued to buy long after most of the other branches of the industry had gone out of the market. The main reasons for their withdrawing when they did were the instability of prices and lack of funds.

With regard to the automobile industry, most firms are working steadily, but the trade is seasonal, and an ebb invariably sets in about this time of the year and continues until after the automobile shows. The demand is more particularly for light cars, and various manufacturers, who previously have been exclusively engaged on the heavier and more expensive types, are making rapid progress in their arrangements to produce smaller models.

Another branch of the engineering industry that has maintained its activity is that specializing on marine Diesel engines. There are brisk inquiries for general brass-foundry work, for which Birmingham is world-renowned. The conclusion of the strike of joiners in the shipyards is good news for this industry, and it is hoped that many orders which have been held up by conditions in the shipbuilding trades will now be released.

One or two instances are noted where reductions of approximately 10 per cent have been effected in machine tool prices. While the recent reduction in wages is bound to have an ultimate effect on the price question, it requires some courage to begin cutting list prices, and makers prefer to quote on the conditions ruling at the time of the inquiry.

Overseas Trade in Machine Tools

There is a certain amount of business to be had in railway machine shop equipment for shipment to various European governments. The terms of payment, however, are such as to produce caution in booking orders. For example, the Bulgarian State Railways will pay only 10 per cent of the price on shipment, and the remainder after the machines are erected and satisfactorily at work in the shops. Orders for machine tools of the heavier types are coming more freely from Japanese sources, and India still continues to afford a profitable field to some British manufacturers of machine tools.

For the month of August the exports of machine tools amounted to £183,391, the tonnage being 1144. Although this showed a slight fall from the exports for July, the figures are exceptionally high as compared with imports, which again show a decided drop, reaching only £17,480 in value, for a tonnage of 65. The value per ton of imported machine tools rose from £166 in July to £269 in August, the value per ton of exports remaining fairly constant at about £160. The class of machine tools that represented the greatest export value was lathes, reaching a value of £54,000, spread over 192 machines. Drilling machines were exported in fairly large quantities and reached a value of £29,824, spread over 87 drilling machines. The only machines that in July compared somewhat nearly in value for exports and imports were grinding machines; the value of the imports was £4532 and of the exports £6448.

Developments in the Machine Tool Field

The practice of grinding the teeth of hardened gears is growing quite rapidly; one firm that makes a specialty of this work is the Gear Grinding Co., Ltd., of Birmingham. The method employed by this concern is to grind the wheel teeth with a grinding wheel dressed to the exact form of the tooth faces required. The wheel-dressing diamond is controlled from an enlarged form through a pantographic device. The indexing is by automatic means, and the machine will handle work up to 36 inches in diameter by 8 inches face. By the substitution of formers, teeth of any pitch or pressure angle, in either stub or full-tooth forms, can be ground accurately.

Thomas Shanks & Co., Ltd., Johnstone, Glasgow, have recently completed a very large machine for shipment to Japan. The machine is designed for turning very large gear blanks, and has a center height of from 110 to 123 inches, adjustable by means of packing blocks. The distance between centers is 40 feet, and the bed is 18 feet 6 inches wide. There are four saddles, each weighing 21 tons, and the total weight of the machine is 330 tons. The faceplate is 15 feet in diameter, and is capable of carrying parts weighing 100 tons. The main journal is 27 inches in diameter by 36 inches long.

Some large overhanging type hydraulic forging presses are being built by A. Rice & Co., Leeds, for the Great Indian Peninsula Railway. These presses have both vertical and horizontal rams, each of 200 tons, and the presses, except for the rams which are of cast iron, are built of cast-steel members. Hydraulic wheel presses have also recently been supplied by Messrs. Rice to the Polish Government railways. Two of these presses are for 7-foot wheels and exert a pressure of 300 tons.

A machine which has created a great deal of interest is a crankpin turning machine that has been developed by George Richards & Co., Ltd., Manchester. In this machine, the crankshaft is held rigidly while the tools rotate around the pin to be machined, and are held in a circular carriage that rotates in a housing through which the crankshaft is passed. The tools can be made to turn the full width of the pin at one cut, or narrower tools can be used and a traverse applied to the tool-holder housing. The feed of the tools is arranged in an unusual manner. An internally and externally cut gear ring is rotated differentially with the tool-holding ring, the difference in speed of the two resulting in advancing or withdrawing the tools, suitable gearing being provided to control the differential effect. The machine has been designed with the object of rapidly producing crankshafts with fairly inexpensive labor, but is said to be capable at the same time of machining a crankpin to an accuracy of within one-quarter of a thousandth inch of size.

A grinding machine of considerable interest has been put on the market by Alfred Herbert Ltd. of Coventry. It is for the purpose of grinding cutting tools with a curved lip, so that a comparatively acute cutting angle can be obtained, with sufficient support to prevent crumbling. The machine uses a circular grinding wheel, and the tool is traversed below the wheel, the path of the tool relative to the wheel axis being variable so that the periphery of the wheel presents to the cutting tool anything from a straight line, through the whole range of ellipses, to a full circle. By using the extreme lower edge of the wheel, various forms of curve can be obtained behind the tool cutting edge.

A die-sinking machine built on rather novel lines has been designed by Bryant-Symons & Co., London. The work and a former to an enlarged scale are placed on a horizontal table, and above them are two vertical spindles, one carrying a tracer point and the other an end milling cutter. The spindle carriages are arranged on a horizontal arm, pivoted horizontally and vertically at one end of the machine, and arranged to be moved across the table by means of a rack and pinion, the relative position of the heads being controlled by a pantograph. The arrangement of the machine makes it equally suitable for die-sinking or profiling work, and cuts up to 0.3 inch deep can be taken.

J. Parkinson & Son, Shipley, are building for the market a Sunderland patent double-helical gear generator. These machines produce a continuous double-helical tooth without any finishing or correction by hand. The sizes of machines now in hand are for gears up to 3 inches in diameter by 10 inches face width, and for pitches up to 3 diametral pitch.

Prices of Materials

In the iron and steel trades, current demand shows only an insignificant improvement. Most of the works are getting their raw material from the Continent, some from Belgium, others from France and Luxemburg; and a certain proportion of the half-finished products which British manufacturers are working up comes from Germany. Home prices are approaching closer to foreign, but some materials, like wire rod, can be obtained cheaper from Germany.

Labor Conditions

The number of unemployed in the engineering and allied trades is approximately half a million, about one-third of the total number of unemployed in the country, and until some of the present handicaps to production are removed, it is not to be expected that conditions will improve. The cost of living is still a cause of grave dissatisfaction. Although it is generally admitted that the 12½ per cent war bonus must come off wages, it is the belief among those who should know, that the necessities of life could come down in price—thus offsetting the drop in wages—and still leave a reasonable profit. Retailers and middlemen in particular are blamed for profiteering on articles of food.

British Trade Ship

A project which is now receiving active attention is that of sending a trade ship to the principal ports of the world, carrying an exhibition of British manufactures. The ship will be called *British Industry*. She will have a gross tonnage of 20,000, and there will be eight decks, four of which will be devoted to the exhibition proper. The voyage will last about eighteen months.

Machinery

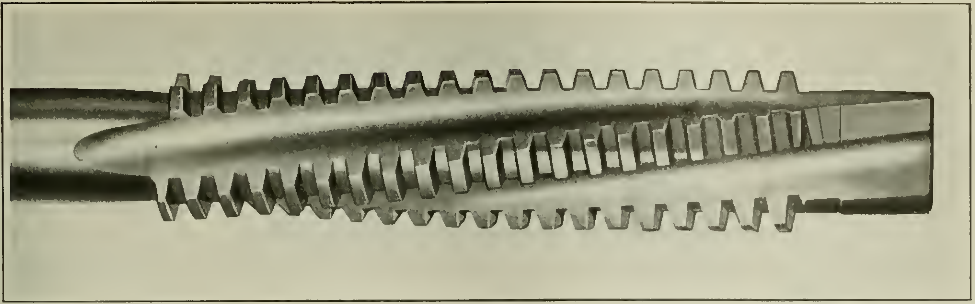

Fig. 1. Acme Double-thread Finishing Tap having Relief, Spiral Flutes, and Taper in the First Threads

Making an Accurate Acme Thread Nut

By B. M. W. HANSON, President, Hanson-Whitney Machine Co., Hartford, Conn.

THE Acme thread, as is well known, especially among machine tool builders, has practically replaced the square thread. It has proved to be the most efficient type of thread for such purposes as lead-screws on lathes and for screws employed for moving and adjusting slides on various kinds of machine tools, because it wears much better and it is more easily produced than other types of threads. If there is any criticism against the Acme thread it is on account of its large tolerance at the top and bottom of the thread, which is probably unnecessary. Half the tolerance would doubtless be sufficient for adjusting screws and slide screws.

Machine tools of the present day invariably have a micrometer dial on the adjusting screws; therefore these screws have in a way become micrometers, and if a machine tool is furnished with a combination adjusting screw and micrometer, it is important to have such a screw accurate and to make sure that it maintains its accuracy. The only practical way of maintaining the accuracy of the screw is to have a large bearing surface, properly lubricated, in the nut. In order to obtain a good wearing surface, it is necessary to make the nut long, and the best practice in modern machine tools is to have the nut as long as two diameters of the screw. In the majority of cases, there is no reason why a nut could not be made four diameters in length, provided the lead of the thread in the nut were the same as the lead of the thread on the screw. If such a nut were well lubricated and well protected from dust and grit, the wear would be reduced to a minimum and the accuracy of the screw would therefore be maintained for a long time.

Difficulty of Obtaining Proper Contact between Screw and Nut

On important work it has been found necessary to chase the thread in the nut, but if the nut is small in diameter in proportion to its length, it is not a very easy task to chase an accurate thread, and the practice in such cases is to finish the nut with a finishing tap. If the tap is not of accurate lead, however, it will not improve the thread in the nut, and although the screw may go through the nut and seemingly fit, it will actually bear on the end threads only and full contact between the screw and the nut will not be obtained until they have worn together, at which time the accuracy of the screw is gone.

If a machine tool were taken apart after having been used for a few months, when the screws were taken out of the nuts, which are usually made of bronze, it would be seen that the oil (if there is any) is yellow in color. The yellow color comes from particles worn away from the bronze nut, and even if the screw has been well lubricated there will be a considerable amount of bronze particles in the oil, mainly because there has not been proper contact between the thread of the screw and the thread in the nut, or because the nut is too short in proportion to the load it is working under. The writer's experience has been that there

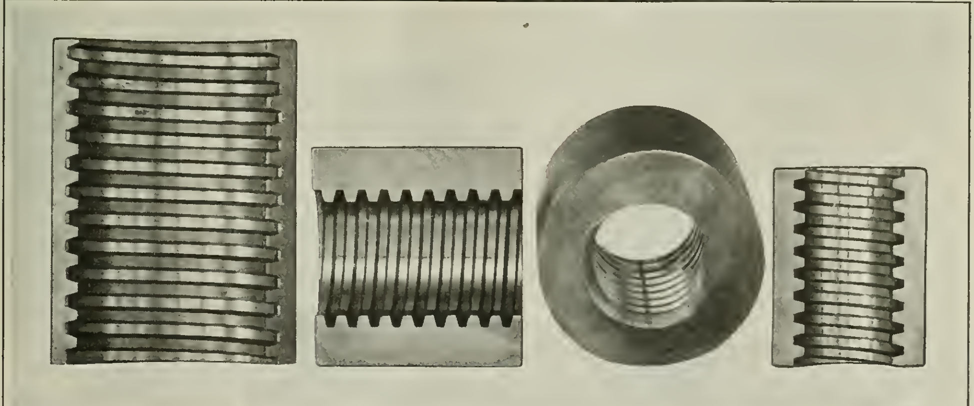

Fig. 2. Tapped Bronze Nuts of Fine Finish and Exceptionally Accurate Lead and Shape

has never been any proper means of producing an accurate nut, and although screws have been made very nearly accurate it has been a difficult matter to make nuts that fit them.

Use of Roughing and Finishing Taps

During the last few years the writer has made a great many experiments in an attempt to produce accurate threads in nuts, and after a comparatively short time was able to make taps of the U. S. standard form and the Whitworth form that are very accurate in lead and size, as described in the article "The Problem of Accurate Thread Cutting" in July MACHINERY. The Acme thread, however, presents other difficulties, as it is very much deeper in proportion and has a much slighter angle than the V-shaped threads have. Also, accuracy is of even greater importance in places where Acme threads are used.

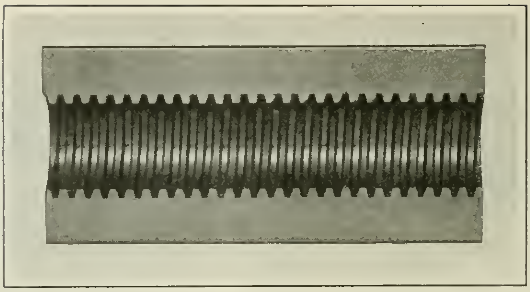

Fig. 3. Tapped Cast-iron Nut, 6 Inches Long, with Thread of very Accurate Lead

After making a good many sets of taps of different forms, clearances, shapes of flutes, and different proportions for removing stock quickly, the following method has finally been adopted: One or more roughing taps are made according to the length of nut and depth of thread. The roughing tap leaves the thread almost the full diameter and too wide, which is the same as making the space between the threads too narrow. Next a finishing tap is made, having the proper clearance and a thread on the end narrow enough to enter the nut. The width of the thread is gradually increased by making the tap gradually larger in diameter in the angle of the thread; the threads are also stepped by proper amounts to give the chips the proper thickness, and the straight part of the tap is not made longer than twice its diameter. This tap is finished to accurate diameter and lead after hardening. By this method it is possible to obtain a finished thread in a nut that will fit an accurately made gage. The thread will have a mirror-like finish.

Experiments have been made in bronze, cast iron, and machine steel, and it is possible to produce a finish in any of these materials that is surprisingly fine, as well as to maintain a lead in which it is very hard to detect any error. Figs. 2 and 3 show nuts that have been cut in half, but one must see the actual work to appreciate fully its fine finish. As a general rule, it is possible to obtain these results with one roughing tap and one finishing tap, but a combination roughing and finishing tap has also been made which gives excellent results. It is merely a matter of economy as to whether one or more taps should be used. One of the finishing taps is shown in Fig. 1.

Lubrication when Tapping

Ideas vary as to the lubricants to use when tapping different materials. For steel it is generally accepted that lard oil or sperm oil is best when using small taps. After several weeks of experimenting with different taps, accurately made, having different clearances and different thicknesses of chips for each tooth, it was found that in tapping cast iron, steel, and bronze, good lard oil gives the best results.

Nuts were tapped in cast iron with taps 1¼ inches in diameter and 6 inches long, using a copious stream of lard oil. The tapping was done in a turret lathe. Excellent results were obtained, and the temperature of the piece being tapped, as well as of the taps, was very little different from what it was before tapping. Hundreds of nuts were tapped in this way out of different materials, and different clearances or reliefs were provided on the taps to see which produced the smoothest work and operated the easiest. Although it is possible to improve the results by varying the clearance on the tap according to the material to be tapped, an average clearance can be provided which will be satisfactory for almost any material. It was found that the thickness of chips that each tooth was taking with a reasonable relief and proper lubrication made a combination that always produces good results.

In making an Acme tap in the old way, that is, by finishing it first and hardening it afterward, no matter how much care has been taken to see that each tooth takes the correct thickness of chip, the chip thickness will vary after the tap has been hardened. It will be found that thick chips and scrapings are produced and that most of the chips are in two flutes, whereas with an accurately made Acme tap that has been finished and corrected after hardening, the chips will be of uniform thickness and shape, and the same amount of chips will be found in each flute. Even in tapping cast iron with an accurately finished tap, the chips will be distinctly curved, about the same as when turning cast iron with a tool that has a certain amount of rake.

Acme screws are often made double-thread or even triple- and quadruple-thread, so the lead angle in such a thread is considerable. Every mechanic knows the difficulty of tapping holes with a thread of this kind, but by properly designing the tap and making the flutes of such a spiral that they will be at right angles to the tap teeth, the tap will work practically as easily as a single-thread tap. With tools of this kind it has been fully demonstrated that not only extremely accurate work can be done, but that the work can also be done with a large saving of time. Nuts such as shown in Figs. 2 and 3 have been produced in a few minutes.

Holding an Acme Tap in a Turret Lathe

A turret lathe is a convenient machine to use in tapping Acme nuts. It generally has the proper holding devices, power, and good facilities for lubrication. In using the roughing tap, unless the operator is very skillful and careful he is likely to ream the hole before the tap takes hold, and this may happen even after the tap takes hold if it is rigidly fastened in the turret, as it is difficult for the operator to follow up with the turret-slide at the same speed as the tap is traveling. If he pushes too hard, he will widen the thread, and the same thing will take place if he retards the motion of the slide; if he does not attempt to follow up with the turret-slide, the tap will have to

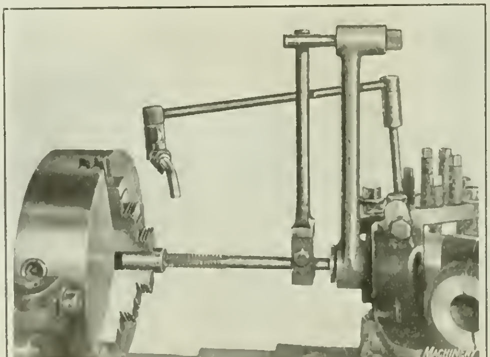

Fig. 4. Floating Tap-holder for Turret Lathe

drag the slide along, and this will also cause the thread to be widened.

It is important that a roughing tap should not cut the thread (or rather the space between the threads) too wide, because in that case there would not be enough metal for the finishing tap to remove. The roughed out thread, as previously stated, should be wider than the finished thread. Fig. 4 shows a floating holder used to hold an Acme tap in a turret lathe. It will be seen that with this device a tap will be allowed to make its own lead without having to drag the turret-slide along or without it being necessary for the operator to try to follow up the lead except roughly.

The shank of the tap in this holder has a free running fit in the bushing, and the wrench-shaped arm which fits the flats of the tap shank rests against a pin in the stationary arm of the holder. This prevents the tap from turning around, but the shank can slide in and out in the bushing, and if the arm is 12 inches long from the contact point of the rod to the center of the shank, the pressure on the outer end of the arm will be approximately one-twelfth of what it would be if the tap were held rigidly by the ordinary square at the end of the shank. Therefore it is possible for the tap to float in and out while sliding on the arm, which has a reduced pressure contact. With this device it is only necessary for the operator to follow up with the turret-slide so that the arm does not slide off the rod, and hence the tap has very little chance of dragging so as to widen the space between the threads.

When the finishing tap is used, the operator proceeds in the same way, except that he turns the finishing tap in by hand until the sides of the thread of the tap are in contact with the walls of the roughed out thread. Acme taps of the type described in the preceding are manufactured by the Hartford Tap & Gauge Co., of Hartford, Conn.

SOUTH AMERICAN TRADE

Efforts are being made to re-establish American business relations with South America, a thing difficult to do because of conditions developed during the war and the present disadvantage of an unfavorable money exchange which protects the European trade in South America against American exports. The American Trade Bureau, in the interest of which Colonel S. Graae has recently sailed for South America, in order to organize trade connections, states that the real difficulties to be overcome are those due to the lack of harmonious understanding between American representatives in South America and South American business men, the insufficient support given by the banks, and last but not least, the fact that the Latin business men have not always been handled with that diplomacy and tact which is one of the main factors leading to success in doing business in South America. The European countries, according to Colonel Graae, are daily progressing in South America, not only because the exchange rate is in their favor, but because they have thoroughly studied the customs of the Latin race and won their confidence. With the quality of goods that America can offer, the right kind of trade representation would assure success.

Care in relation to certain apparently minor details is often the means of securing the good will of South American concerns, as, for example, in the matter of postage. In this connection attention is called to the recommendation of Commercial Attaché W. L. Schurz, of Rio de Janeiro, that American manufacturers should discontinue sending heavy catalogues to South America by parcel post. Such publications should be sent by express, or by any other means available. A large number of packages sent by parcel post are piled up in the custom-house at Rio de Janeiro, and it requires so much time and expense to get a package out of the parcel-post section of the customs that many persons prefer to leave their packages unclaimed.

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, October 11

Orders for machine tools are few and, as a result, French builders of machine shop equipment are producing far below their normal capacity. Because of this low production, the costs of machine tools have increased considerably. This market is also flooded with the stocks of importers, and with machines purchased by the various government bureaus for the devastated regions, and machines coming from Germany. The selling season for agricultural machinery which is now being terminated has been rather good, the sales at least equalling, and possibly surpassing, those of the same period in 1920. The market for this class of machines remained firm throughout the whole season, but a certain quantity of left-over agricultural machinery can be obtained at the present time at reduced prices.

Improvements in Various Fields

In the automobile field the situation has improved slightly, although, as yet, there is but a limited activity in most plants. The Peugeot plant produces 700 automobiles and 250 motorcycles a month; it also produces 9000 bicycles. Another automobile manufacturer near Paris produces 200 16-horsepower cars per month and an equal number of smaller cars. The accessory manufacturers state that their business is fair.

During the last few weeks the makers of aviation products have begun producing to a slight extent, a few orders having been received from foreign governments and private sources. Another noteworthy order is that of the War Department for 150,000 sets of special breathing apparatus, which will be filled by Leconge & Willmann. The order amounts to 5,025,000 francs (about $366,000, present exchange).

There has been a slight improvement in the iron and steel field. Buyers have decided to place orders while the market remains firm, because they fear an increase in the cost of raw material which would, of course, cause prices to rise. Conditions, however, are far from what could be considered normal. Good quality scrap iron and iron castings are still in demand, principally for export, a large quantity being bought by Belgian dealers and destined principally for Germany. In northern France and in the vicinity of Paris, the market for scrap iron has also improved.

There has been a decided improvement in the bolt and nut field. Conditions in this field are different from those in other branches of the metal-working industry, as no scale of production is fixed by organized labor, and this leaves the manufacturer free to reduce production costs and quote prices accordingly. Prices have been reduced, and although they do not yet seem stable, further large reductions are not anticipated. It is interesting to note the wide variation in prices of the past week. An offer for 810 metric tons of bolts was accepted at 65.6 francs per 100 kilograms ($2.12 per 100 pounds, present exchange) while another offer for 37 metric tons of bolts at 121.9 francs per 100 kilograms ($4.02 per 100 pounds) was rejected.

Labor Conditions

There is no indication of an ending of the strikes in the textile industry in northern France, as neither side seems willing to modify its viewpoint. It is believed that, due to the instability of prices of raw materials, the owners are not anxious to resume operation. The workers in the iron and steel field have also declared a strike to show their strength, but it is thought that this strike will be of short duration. Labor conditions in the rest of France are quiet, except for some slight disturbances occasioned by reductions in wages. The slight improvement in the manufacturing field has contributed toward decreasing the number of unemployed.

American Gear Manufacturers' Convention

THE fall convention of the American Gear Manufacturers' Association, held in Rochester October 13 to 15, was largely attended, and the program was crowded with important reports on gear standardization. The meeting was opened by a welcome to Rochester by Andrew C. Gleason of the Gleason Works, after which the president of the association, F. W. Sinram, of the Van Dorn & Dutton Co., Cleveland, Ohio, in brief opening remarks gave voice to the conviction that the lowest point had been reached in the industrial depression, and that industry is now on the upgrade. Two new member companies were elected, the Central Products Co., of Detroit, Mich., and the Harris Engineering Co., of Bridgeport, Conn. The association now has 94 member companies, 112 executive members, and 61 associate members. The extent of the industry represented by the association may be estimated from the fact that reports from less than half of the member companies show that they employ together nearly 20,000 men.

Papers Read before the Convention

Several papers of direct interest to the gearing industry were read before the convention. S. O. White, chief engineer of the Warner Gear Co., Muncie, Ind., read a paper on "Gear Tooth Wear," reviewing some valuable experiments that have been made in the laboratory of that company, relating to the wear of gears made from different materials and heat-treated in different ways. This paper also indicated the remarkably high efficiency that may be expected from gearing properly cut and heat-treated—96½ per cent in the case of a train of four spur gears.

A comprehensive paper on "Duralumin as a Material for Worm and Other Gearing" was read by R. W. Daniels of the Baush Machine Tool Co., Springfield, Mass., and one on "Tooth Forms" by E. W. Miller, chief engineer of the Fellows Gear Shaper Co., Springfield, Vt. Abstracts of these papers will appear in a coming number of MACHINERY. An address was also made by E. S. Sawtelle, assistant general manager of the Tool Steel Gear & Pinion Co., Cincinnati, Ohio, entitled "First-hand Impressions of Europe," in which Mr. Sawtelle related some interesting experiences and impressions from his visit to Europe this summer.

The Society's Standardization Work

The most important part of the society's work is that of standardization in the gearing field. The society has already dealt with a number of the important phases of the work met with in the gear-cutting industry, and has made great headway in the direction of standardization, but until recently there has been no comprehensive standardization program that would act as a complete guide for the entire work of the association in this direction. Hence, at a meeting of the members of the General Standardization Committee held last summer, a definite standardization program was adopted with the idea that by having such a program constantly before the association, better aid could be obtained by the committees from the members. As no standardization in gearing has been attempted in this country up to this time, except by the American Gear Manufacturers' Association, the objects of the standardization activities of the association will doubtless be of interest to the entire mechanical engineering industry. The program laid out by the association is therefore partly republished, in order that the cooperation of engineers everywhere may be obtained—a factor essential in any real standardization work in this field. Those who may desire to communicate with the association in connection with the standardization program should address B. F. Waterman, chairman of the General Standardization Committee, American Gear Manufacturers' Association, Brown & Sharpe Mfg. Co., Providence, R. I.

Standardization of Spur Gears

The objects of the Committee for the Standardization of Spur Gears are as follows: (1) Nomenclature and symbols in conjunction with the Nomenclature Committee; (2) preparation of a standard spur gear for general industrial use, by means of a diagrammatic illustration of various types of spur gears, including a spoked wheel, a webbed wheel, and a solid pinion, with proper formulas covering width of face, rim, arm proportions, and hub proportions, in conjunction with the other committees; (3) development of general horsepower formulas with the view of developing tables for horsepowers; (4) investigation of allowable stresses for A. G. M. A. materials in connection with the Metallurgical Committee; (5) arrangement of means for communicating with the general membership regarding gear installations (using standard chart) to determine the proper design of gear sets and gear mountings under various conditions; (6) standardization of automotive spur gears, as to tooth forms, form of blank, horsepower, wear of teeth, method of mounting, stiffness of shafts, clearance, materials, tolerances, lubrication, etc.; (7) cooperation with Committee on Tooth Form to standardize spur gear tooth forms; (8) inspection.

Standardization of Bevel Gearing

This committee will take up the following subjects: (1) Nomenclature, symbols, and formulas in conjunction with the Nomenclature Committee; (2) materials—all kinds to

be considered in conjunction with the Metallurgical Committee; (3) mounting of bevel gears, location of bearings in the surrounding case, or supports and lubrication; (4) bores and their relation to diameter of gear; (5) keyways; (6) radial and thrust loads—method of calculation and their relation to strength and wear; (7) backlash for various conditions of service; (8) bottom clearance; (9) tolerances for blank gear and teeth; (10) length of face and its effect on strength and wear; (11) tooth form and addenda proportions (generated gears, form planed gears); (12) thickness of teeth; (13) strength—rules for horsepower; (14) wear of teeth; (15) heat-treatment in conjunction with the Metallurgical Committee; (16) inspection in conjunction with the Inspection Committee; (17) body proportion (arms, web, and hub) in conjunction with other committees; (18) accumulation of records of successful and unsuccessful bevel gear drives transmitting limiting power, using standard chart for the purpose.

Standardization of Worm-gearing

(1) Nomenclature, definitions, abbreviations, symbols, and formulas in cooperation with the Nomenclature Committee; (2) materials for worm and wheel and heat-treatment in conjunction with the Metallurgical Committee; (3) recommendations for the best sizes of worms for each pitch and style (hole or shaft worms) to reduce the number of sizes to a minimum; (These will cover worms for industrial and automotive use, and tables or lists of the recommended sizes will be compiled.) (4) compromise in a commercial, practical, and scientific manner, the various factors which affect the practical use, manufacture and efficiency of worm-gearing; (5) recommendations for the design of worm-gears for all kinds of service, and their mounting and housing; (6) strength or load-carrying capacity—horsepower rules—method of calculating tooth and bearing pressures; (7) tooth form and proportions for various applications; (8) wear of teeth; (9) design of body of worm-wheel (arms, web, hub) in conjunction with the other committees; (10) accumulation of records of successful and unsuccessful worm-gear drives transmitting limiting loads, using standard chart for the purpose; (11) inspection in conjunction with the Inspection Committee; (12) recommendations as to the design of the worm-wheel to enable the present existing hobs to be used to best advantage. Such items as material, blank proportions, tooth pressures, bearing loads, mounting and lubrication will be considered.

Standardization of Herringbone Gearing

(1) Nomenclature, symbols, and formulas; (2) most suitable spiral angle (of teeth with axis), pressure angle; (3) rules for calculating diameters for various ratios of hobbed gears where corrections are made for under-cut; (4) width and depth of groove in center of face for solid blanks or rims for different methods of hobbing; (5) formulas for strength (horsepower, using safe working stresses of A. G. M. A. materials); (6) recommendations for the use of standard (stock) 14½-degree pressure angle hobs. Method of calculating blank diameters; (7) design of gears and mountings; (8) accumulation of records of successful and unsuccessful installations to determine the proper design of gear sets and mountings, using standard chart for the purpose; (9) inspection.

Standardization of Keyways

(1) Recommendations for suitable sizes of keyways for various shaft sizes; (2) keyway-stock sizes and materials; (3) review of existing splined shaft standards with the object of recommending more suitable limits and tolerances; (4) consideration of keyways now recommended for special purposes; (5) cooperation with committees of other organizations now considering keyways; (6) consideration of key strength; (7) tables showing depth of vertical wall for keyway sizes recommended; (8) methods of inspection.

Standardization of Tooth Forms

(1) Nomenclature, symbols, and definitions, in cooperation with the Nomenclature Committee; (2) recommended standard tooth form (to include pressure angle, addendum, whole depth of tooth, clearance, fillet, and backlash); (3) stub tooth standard; (4) investigation and comparison of the merits of teeth having equal addendum and dedendum with those having a long addendum for the driver; (5) methods of inspecting tooth forms.

Standardization of Inspection Methods

(1) Methods of inspecting gears, testing machines, etc.; (2) inspection of threads, in conjunction with other interested organizations; (3) inspection of raw materials in conjunction with the Metallurgical Committee; (4) inspection of hobs and cutters; (5) investigation of possible methods of determining the degree of gear noise.

Standardization Reports Accepted at the Meeting

The committee on gears and pinions for electric railway service presented a report which was accepted as recommended practice for the members of the association. The Metallurgical Standardization Committee also presented a report covering forged or rolled steels, brass, and bronze, and steel castings, which was accepted as recommended practice. Another report also accepted at the meeting covered sprocket wheels and chains.

Friday afternoon, October 14, the representatives and guests present at the convention were invited to the Gleason Works for luncheon, which was followed by an inspection of the plant. Saturday afternoon the members and guests were again the guests of the Gleason Works at a clambake at Corbetts Glen, a short distance from Rochester.

Reducing Costs by Rotary Milling

Examples of Work Advantageously Handled on Becker Vertical Rotary Milling Machines

METHODS that open the way to higher production, particularly those that employ standard machine tool equipment, are essentially cost-reducing methods. A number of representative examples of parts which have been machined on the Becker rotary type of milling machine at a saving in production time are cited in the following, and data furnished regarding the equipment used and the time consumed.

The first job to which attention is directed is that of milling the interior bearing surfaces of a 48-inch solid truck tire mold, and the set-up used is illustrated in Fig. 1. The steel casting is shown strapped to a special table, which for this job is substituted for the regular machine table. This table is tapped for a number of long tie-rods so that the deep casting, which is 12 inches wide on the tread, may be conveniently held down. A special high-speed end-mill extending the full depth of the casting is used, and it is driven at 45 revolutions per minute, which is equivalent to a cutting speed of 30 feet per minute. The depth of cut is 3/8 inch, and the time required to complete this operation is forty-five minutes—ten minutes of which is required to set up the work. In locating the steel casting centrally, use is made of a stud assembled in the center of the special table. A radial arm is fitted to this stud, the arm being swung about this center to quickly and effectively centralize the casting.

The particular point of interest in the set-up shown in Fig. 2 is the multiple fixture employed. This fixture has eighteen loading stations, in each of which two pieces of work are carried. The stations in the lower and upper parts of the fixture are staggered relative to each other, as a means of relieving the strains set up by the cutters. The parts to be machined are small drop-forged steel yokes, and the clamping element is so devised that a pair of yokes is located by one stop at each station between the two parts, and also each pair of yokes, when thus located, is secured by a single strap and bolt. This makes a very convenient arrangement for loading the fixture, and a quickly operated one. Two special double-staggered inserted-tooth milling cutters, 7 inches in diameter, are used, which work at a cutting speed of approximately 55 feet per minute. It will be seen that the lower end of the cutter-spindle is provided with a bearing, which prevents the spindle from springing out of alignment due to the stress set up by the cutters, thus safeguarding against inaccuracies resulting from this cause. The table feed is 2 inches per minute and the production rate is ninety drop-forgings per hour.

Milling Operations on Rotary Worm-gear for Milling Machines

Figs. 3 to 6, inclusive, show set-ups for the various operations required to machine a rotary worm-gear used on Becker vertical milling machines, prior to cutting the teeth. The first operation, Fig. 3, is the taking of a surfacing cut on one side, this surface being used as a locating surface in later operations. This worm-gear is made of cast iron, and is 28 inches in diameter. The cutter used is an 8-inch high-speed inserted-tooth face mill, which takes a cut 1 1/4 inch deep over a surface of 7 inches wide. The cutter revolves at 30 revolutions per minute, which is equivalent to a cutting speed of about 60 surface feet per minute. The table feed is 6 inches per minute, and the cutting time twelve minutes, exclusive of the six minutes required to set up the work. It will be noted that no special equipment is required to hold the gear blank, ordinary screw-operated clamping jaws being employed for this purpose.

In the second operation, which is set up as shown in Fig. 4, the work is reversed and strapped securely to the table, being located by the previously milled face. The operation illustrated is the milling of a 30-degree beveled surface in two cuts, using a 60-degree high-speed angle cutter. The depth of the roughing cut is 1/8 inch, during which operation the cutter revolves at 40 revolutions per minute, using a table feed of 10 inches per minute. During the finishing cut the same table feed is employed, but the rotative speed of the cutter is increased to 50 revolutions per minute. The setting up time is from six to seven minutes, and the actual cutting time eleven minutes for the roughing cut, and from nine to ten minutes for the finishing cut, making a total time of about twenty-seven minutes per casting. There is no setting up time included in the finishing operation, it being unnecessary, of course, to reset the work.

It is a generally recognized principle in machine shop practice, and particularly in the manufacture of parts in quantity, that any method that permits the cutting tools to operate continuously upon the work while the loading and unloading of jigs and fixtures is done with the machine in operation, adds greatly to the economy with which the machining can be performed. One of the best examples of this principle of manufacturing is found in the application of rotary milling, and advantage is being taken of the savings made possible by this process of machining to an ever-increasing extent. In quantity production, the rotary milling process has been found to be a valuable means of reducing costs.

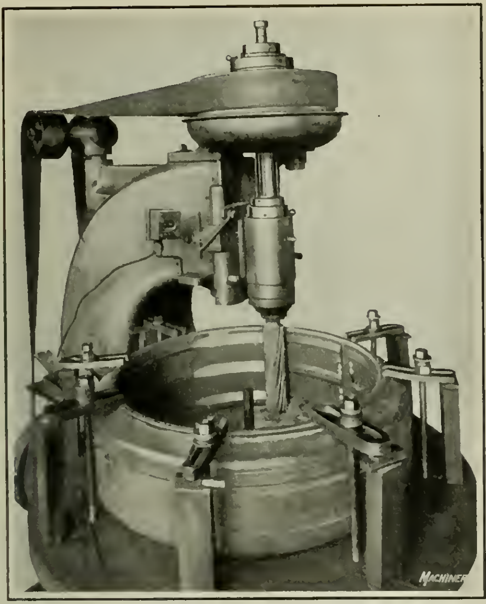

Fig. 1. Vertical Rotary Milling Machine set up for milling Truck Tire Molds

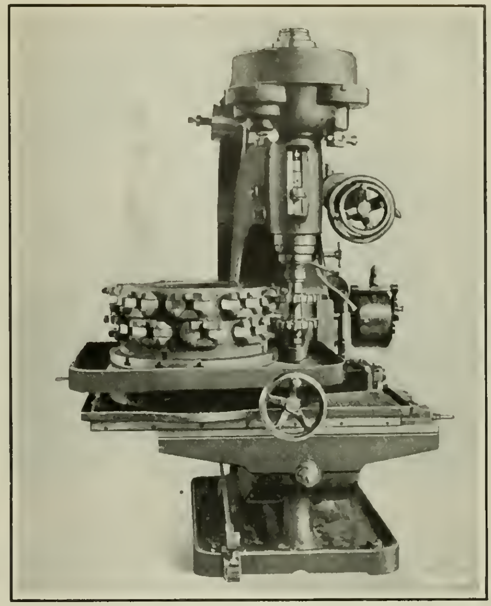

Fig. 2. Straddle-milling Yokes, using a Continuous Rotary Milling Fixture

The third operation on the worm-gear blanks is milling the outside diameter to 18 inches, the work being located in the same position as in the previous operation, as shown in Fig. 5 and the only work required in resetting being simply the changing of the position of the clamps so as not to interfere with the passage of the cutter during the cut. A 2½- by 3-inch high-speed face milling cutter is used and the depth of cut required to finish the castings to the specified outside diameter is 3/16 inch. The cutter revolves at 45 revolutions per minute, or at a cutting speed of about 30 surface feet per minute. The table is fed at the rate of 8 inches per minute, and the approximate time for completing the operation is eleven minutes per casting. It has been estimated that this job would consume about twenty-five minutes if machined by turning in a lathe.

Fig. 6 illustrates the final milling machine set-up required to rough out the blanks, and consists of milling the groove in which the teeth are finally cut. In changing from the third operation to this, it is only necessary to change the cutter and set the table over to give a depth of cut of 7/16 inch, and then proceed without changing the work from the position occupied in the previous operation. A special high-speed steel form cutter is employed which works at 45 revolutions per minute, in conjunction with a table feed of 6 inches per minute. The production time is twelve minutes per casting. The outstanding features of

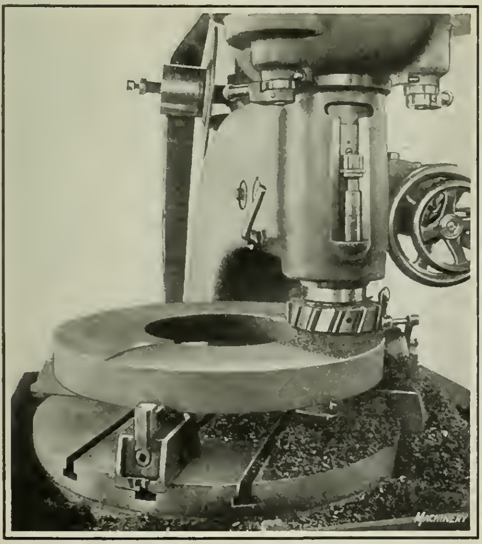

Fig. 3. Surface-milling a Worm-gear Blank

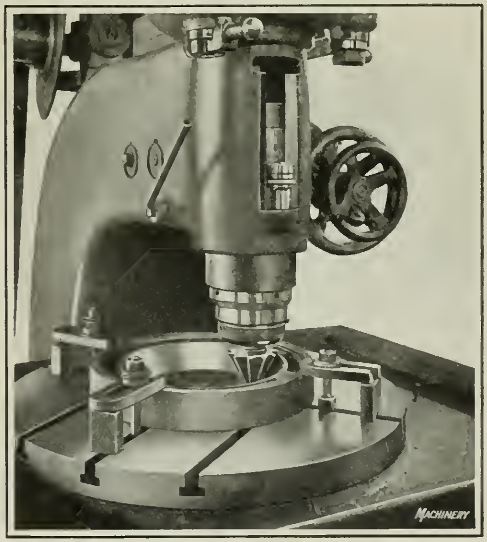

Fig. 4. Milling a 30-degree Bevel on a Gear Blank

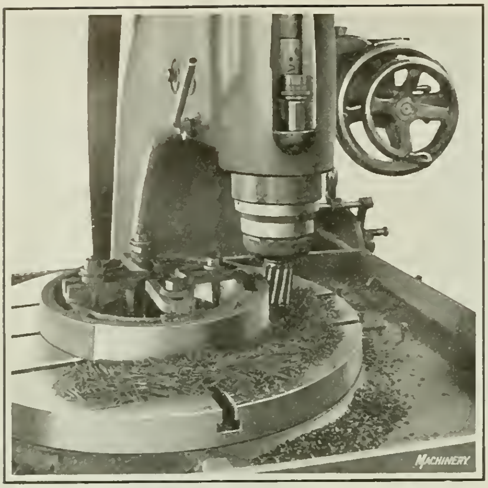

Fig. 5. Milling Outside Diameter of Gear Blank

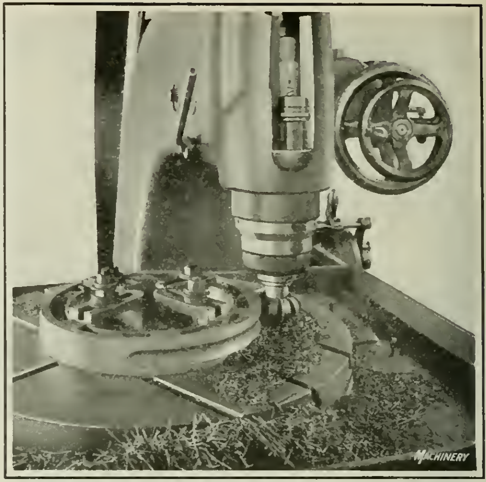

Fig. 6. Milling the Groove for the Gear Teeth

the job just described are the simple and effective means that can be employed for holding work when machined by rotary milling, and the speed with which the several operations may be completed.

Milling Crane Sheaves

Three operations are performed on cable sheaves for hoists and cranes by means of the application of the vertical rotary milling method. These three operations are shown in Figs. 7, 8, and 9. In the first operation, the outside diameter is milled to form the groove where the cable operates, and the rim is straddle-faced. A gang of three milling cutters is employed—a form cutter for the groove and two inserted-tooth face milling cutters for straddle-milling the rim. The sheaves are steel castings, and are machined as described, with the set-up illustrated in Fig. 7, in thirty minutes, exclusive of setting up time.

The work is located on a special fixture attached to the table of the machine, the fixture being provided with elevating blocks for holding the work sufficiently above the base of the fixture to allow operating space for the lower straddle milling cutter. The three blocks by means of which the sheave is thus elevated carry a pair of clamping bolts each, their location being such that a strap may be used over every other arm of the sheave to clamp the work down by means of the bolts. This arrangement is shown in the illustration. The side milling cutters are 8 inches in diameter, and the form cutter 6 inches in diameter. The cutters revolve at 28 revolutions per minute, or at a cutting speed of approximately 44 feet per minute. The rate of table feed is 3 inches per minute.

The second operation on the sheaves consists of boring a 6¾-inch hole in the top of the sheave, as illustrated in Fig. 8. The work is located in the same manner as in the first operation, there being a substantial fly-cutter substituted for the milling cutter. A roughing and a finishing cut are required to machine this hole, in the first of which ¼ inch of stock is removed. The cutter speed is 28 revolutions per minute, and the rate of feed is ¼ inch per minute. It will be understood, of course, that this feed does not apply to the rotation of the milling machine table, as in previous operations, but rather to the vertical feed of the machine spindle. The time required to complete this operation is twenty-four minutes.

The third and last milling operation on these sheaves is illustrated in Fig. 9. The operation consists of straddle-milling the faces of the hub, using two side-milling cutters of 6 inches diameter. The milling machine spindle is fed down by hand until the lower cutter has passed through the bored hole in the hub to a sufficient depth to bring the two cutters into the proper vertical relation with the surfaces to be faced. The table of the machine is then fed over so that the center of the spindle is eccentric relative to the center of the bored hole, thus enabling the cutter to extend beyond the outside diameter of the hub. The spindle speed is 36 revolutions per minute, the table feed is 2 inches per minute, and the depth of cut, ⅜ inch. The time required to straddle-mill a sheave is fifteen minutes.

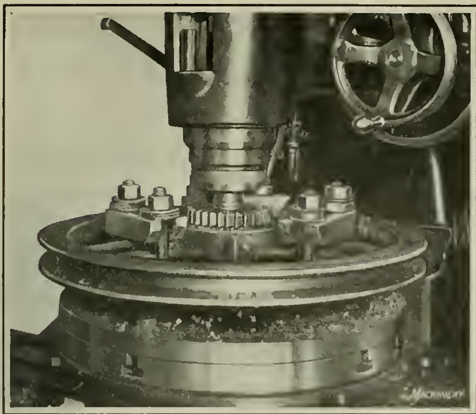

Fig. 9. Straddle-milling the Face of the Huh of a Crene Sheave

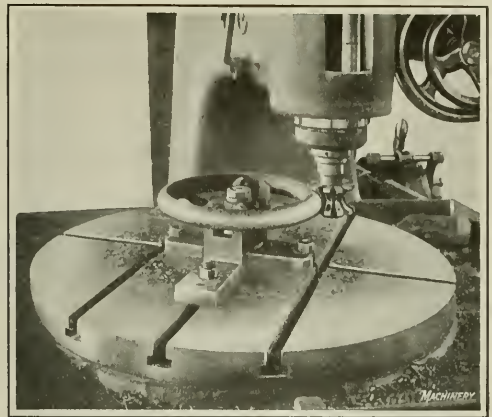

Fig. 10. Set-up for machining Rim of Milling Machine Handwheels

Machining the Rim of Milling Machine Handwheels

Handwheels used on Becker machines are first bored and faced on Gisholt turret lathes, and then finished on the rim by rotary milling and polishing. Fig. 10 shows the set-up used in the milling operation. After being received from the turret lathes, the handwheels are located for machining from the previously bored hole and faced hub, using a central stud and clamping nut to secure them in place. Two driving arms in the form of angle-plates are used, these being machined to straddle opposite arms of the casting. The central locating stud for the handwheel is carried in a base casting which can be quickly and conveniently attached to the machine table as shown. A special high-speed concave milling cutter, operating at a speed of 45 revolutions per minute, is used. The table feed is 7 inches per minute, and from 1/8 to 3/16 inch of metal is removed. The wheel is 10 inches in diameter, and it required approximately four and one-half minutes to complete the work.

After the milling operation, the milled rim is finished by holding it loosely on an arbor, against the workman's leather apron, and spinning it against a felt buffing wheel. This buffing wheel is faced with 60-grain alundum, which is glued to the felt. A final polishing operation is performed with a formed-face felt wheel, using 120-grain alundum.

PLANING STOCK REEL SUPPORTS FOR AUTOMATIC SCREW MACHINES

Figs. 1 and 2 show a 24- by 30-inch planer, built by the Putnam Machine Co., Fitchburg, Mass., engaged in planing the base pads for a stock reel support for an automatic screw machine. This planer is used by the National Acme Co. in its plant at Cleveland, Ohio. The planing operation is quite simple, but the fixture which is employed for supporting the casting during the performance of the operation is somewhat unusual.

The fixture consists of a heavy 90-degree angle-block, strapped down to the table, with provision for carrying the end thrust of the tools. On the casting that is to be planed, there are two lugs *A* that project over the top edge of the fixture and rest on hardened steel supporting pads. The casting is then clamped in this position by tightening a strap *B*.

It will be evident that additional support must be provided to hold this large piece of work back in position against the vertical face of the fixture, and this is furnished by a bolt *C* by means of which a long strap *D* is tightened to hold the work back against the fixture. It will be seen by referring to the illustrations that the planing operation is performed by a single-point tool *E*.

Industrial Conditions in Spain

By RAMON CASALS, Manager, Fenwick & Co., Barcelona, Spain

THE metal-working industries of Spain are passing through a critical period. The industrial crisis which the entire world is experiencing is felt here more than in most other countries, due to the abnormal stimulus that the metal-working industries received during the war period, the activity of which cannot be sustained.

During the war and all through 1919 every concern of any importance received a great many orders from the allied nations, and many were also busy on work for the domestic market. During this entire period it was not essential to be a first-class manufacturer, far less to be a specialist, in order to obtain business. Hence, many shops and factories were established employing inferior equipment, material, and workmanship. Those shops that were developed with a view to meeting post-war competition in the world's markets are comparatively few. Hence, as soon as the boom was over, it was easy for Germany, France, and Italy to enter the Spanish market with the result that the imports during the second half of 1920 and the first four months of the present year were very large. This, together with the sudden reduction in prices, was the immediate cause of the crisis which the metal-working industry in Spain is now passing through. As an example of the abnormal conditions, it may be mentioned that some manufacturers, after having developed the design of special machines, have sent the drawings to German manufacturers to have the machines built for about one-half the price at which they could be built in Spain, inclusive of delivery charges. Besides, the Germans have been able to make quicker deliveries.

It is expected that this critical situation will gradually improve, partly because of the increase in import duties that is now in effect, and partly because the manufacturers are beginning to specialize and thereby reduce manufacturing costs. In addition, the industry is hopeful of the passage of an important railway construction bill, now under discussion in the Spanish Parliament. If this bill is passed, it will increase the activity in various metal-working branches.

The Machine Tool Trade

The building of machine tools in Spain, started during the war, has been almost entirely discontinued. During the war some copies were made of American machines. The classes of machines built were lathes, planers, shapers, and simple milling machines and drilling machines. Some of the builders of these machines now have a large stock, and those in particular who were ambitious enough to undertake the building of machines of highly developed designs have been obliged to retire from this business entirely. All firms dealing in machine tools have large stocks on hand, and there are at present very few inquiries. As a matter of fact, scarcely anybody buys anything at the present moment; any orders that may be placed are almost entirely for repair shops, and these small shops want inexpensive machines. They, therefore, rather prefer offers from German makers who quote from 50 to 60 per cent less than the price for American machine tools in Spain, although it is well known and recognized that these inexpensive machines are of rather inferior quality.

American machine tools continue to be highly appreciated in Spain, and more so after some sad experiences which some buyers have had with German machine tools. They believed that they had gained certain advantages in buying some machinery from Germany, but were afterward obliged to return the machines as unsatisfactory, suffering considerable losses. Nevertheless, in spite of experiences like this, there are still firms who prefer to buy inexpensive machinery, but this would not be the case if the difference in price were not as great as it is at present, due partly to the high rate of exchange of the dollar and partly to the actual difference in price.

It is difficult to forecast the future, but there are reasons to believe that manufacturers of standard types of machine tools may expect a fair export trade to Spain when conditions become more stable. It must be borne in mind that there are more than 1500 firms in Spain using machine tools, and 97 per cent of these are so badly equipped that if they do not provide themselves with better machinery, 80 per cent of them will have to close down altogether, because of inability to compete with foreign manufacturers. There are also new industries gradually being developed in Spain. The automobile industry has been rather quiet lately, but it is expected that the increased import duties on automobiles will aid this industry, and that it will show a healthy growth as soon as the commercial and industrial situation becomes more normal.

Spanish Import Duties

In the early summer, a considerable increase in the import duties went into effect. The increase was especially large for machinery of all kinds. A month after the general tariff bill had gone into effect, a further increase in import duties was made affecting machinery imported into Spain from countries with an unfavorable rate of exchange —Germany, France, and Italy. The duties on different classes of machine tools in accordance with these new import duties are given in the following list. On account of the fluctuation in exchange, they are given in pesetas (exchange on October 20, 1 peseta = 13 cents).

Machine tools and parts for machine tools weighing over 501 kilograms (1100 pounds) are assessed at 40 gold pesetas per 100 kilograms gross weight. A gold peseta, of course, is worth the regular normal value (one gold peseta = 19.3 cents) so that when paid in paper pesetas at a lower rate of exchange, the import duty is about 40 per cent higher. For machinery imported from countries with an adverse rate of exchange, as far as Spain is concerned, the import duty is still higher. For instance, if a machine, boxed, weighs 2000 kilograms (4400 pounds) it would pay the following duty:

From the United States	1124.72 pesetas
From France	1416.60 pesetas
From Italy	1597.10 pesetas
From Germany	1814.95 pesetas

In this case the value of the peseta is figured at present exchange, that is 1 peseta = 13 cents.

Machine tools and parts of machine tools weighing less than 500 kilograms (1100 pounds) pay 50 gold pesetas per 100 kilograms gross weight. The custom duties in this case also are increased according to the exchange rate with the country from which the machine is imported, so that a machine weighing 400 kilograms (880 pounds) would pay duty as follows:

From the United States	285.20 pesetas
From France	389.20 pesetas
From Italy	405.00 pesetas
From Germany	560.20 pesetas

The pesetas in this table are figured at present exchange (1 peseta = 13 cents).

Forging hammers pay duty at the rate of 44 gold pesetas per 100 kilograms (220 pounds) plus the addition due to the foreign exchange rate. A forging hammer weighing 5000 kilograms (11,000 pounds) would therefore pay duty at the following rates:

From the United States	3087.50 pesetas
From France	4088.70 pesetas
From Italy	4388.25 pesetas
From Germany	4981.80 pesetas

The foregoing is figured at present exchange (1 peseta = 13 cents).

Small tools pay duty at the rate of 40 gold pesetas per 100 kilograms (220 pounds). Electric motors and other electrical machinery pay very high rates of import duty, as follows:

Up to 100 kilograms (220 pounds)	150 gold pesetas
From 100 to 400 kilograms (220 to 880 pounds)	142 gold pesetas (per 100 kilograms)
Above 400 kilograms (880 pounds)	75 gold pesetas (per 100 kilograms)

When paid in paper pesetas, the rate is 40 per cent higher, and in addition higher rates of duty are paid when the imports are from France, Italy, or Germany or other countries having a low exchange rate.

Important Industrial Plants in Northern Spain

In the metal-working industry, northern Spain presents the most promising field. A number of large companies are located here, of which a few may be mentioned. In Bilbao, we find the Altos Hornos de Vizcaya, an important company owning two factories specializing in the iron and steel field, operating extensive rolling mills for rails and plates, and employing from 4000 to 6000 men; a shipbuilding concern, the Compania Euskalduna, capable of building and repairing ships up to 12,000 tons, and employing from 3500 to 4500 men; and the Vasconia Compania Anonima, which builds aerial tramways and bridges and specializes in many other structural lines, employing from 2500 to 3500 men.

The Sociedad Espanola de Construcciones Babcock & Wilcox in Galindo, province of Vizcaya, has recently been established in Spain for the manufacture of locomotives, both for the Spanish national railways and for export. The shops just erected are very large and imposing, and in addition to the manufacture of locomotives, the company constructs boilers of its own design, manufactures seamless steel tubes, and builds cranes.

An important company devoting itself to the building of ships has three large factories and shipyards located in Sestao (province of Vizcaya), Ferrol, and Cartagena. This company, Sociedad Espanola de Construccion Naval, is partly owned by Spanish capitalists and partly by the well-known firm of Wickers in England. An important factory for general machine shop work, castings, etc., is located in Mondragon, province of Guipuzcoa; this company, La Union Cerrajera, employs over 2000 men. The Compania Auxiliar de Ferrocarriles, Beasain, province of Guipuzcoa, is devoted to the building of railway cars, and is equipped to turn out 2500 cars annually. Besides these factories in northern Spain, there are many others of similar size and importance.

* * *

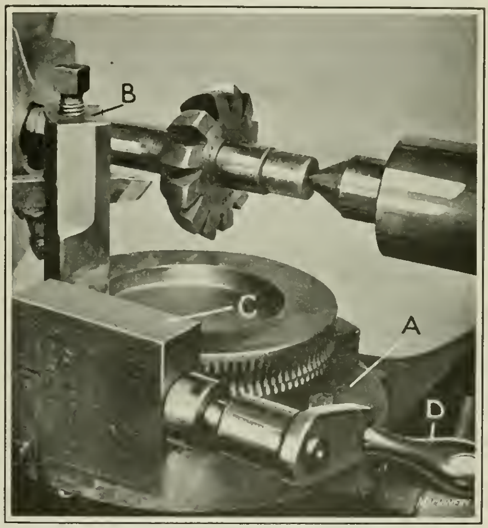
COST OF CHANGING TO THE METRIC SYSTEM

In order to determine the probable cost to manufacturing concerns of the compulsory introduction of the metric system, the American Institute of Weights and Measures, 115 Broadway, New York City, requested a number of manufacturers to study this question and prepare estimates of the cost of changing over to the metric system in each plant. Thirty-one firms located in a number of different states submitted estimates showing that the total cost for changing over in these thirty-one instances would be about $21,500,000. The plants referred to employ about 95,000 men, so that the change would cost over $225 per worker.

RADIUS TURNING FIXTURE FOR TOOL-ROOM

By O. S. MARSHALL

The demand for formed milling cutters and forming tools such as are used on automatic machines, makes it desirable that tool-rooms be provided with some kind of radius-generating device which may be used on an engine lathe for forming the circular part of forming tools. The accompanying illustration shows a simple arrangement designed for this purpose, which can be mounted on the lathe cross-slide in place of the usual compound rest. The base *A* is bolted to the cross-slide, using the bolts employed in securing the compound rest. The toolpost *B* has on the under surface of its base, a hub which extends through the lower baseplate. A nut and collar on the end of the projecting hub serve to hold the toolpost member to the base and provide adjustment for wear. A worm-gear is cut on the base



Radius-turning Lathe Fixture

of the toolpost which is hand-operated by a worm concealed by guard *C*. Handle *D* is used to rotate the toolpost.

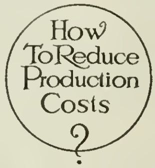
The toolpost member was made from a solid block of steel, the center being bored out and the surplus stock sawed away, leaving a narrow column, as shown, to carry the turning tool. The column is cut down to permit turning through as large an arc as possible when the blank is held on an arbor. This particular fixture will generate inside or outside circular forms such as required on the usual line of forming tools employed in ordinary shop work. The distance from the center of the hub on which the toolpost turns, to the tool point when the tool is drawn back the maximum amount is 2½ inches. For large internal forms the tool may be used with the point extending away from the post. A high degree of accuracy is attainable, and a fine finish is produced on high-speed steel tools.

* * *

Direct government control of the railroads in Great Britain, which has existed for the last seven years, ended in August. The financial results of the operations show that while the income has been doubled during these seven years, the expenditures have been tripled. With the releasing of the control of the railroads from government administration, they will also be deprived of the government support by which the deficit between income and expenditures has been equalized.

How Factory Investigations Reduce Costs

By ALBERT A. DOWD, President, and FRANK W. CURTIS, Chief Engineer, Dowd Engineering Co., New York City



THE factory investigator who produces results is not content with a surface analysis of conditions; he starts at the bottom of things and determines how various parts should be manufactured, estimating the length of time which would be required under first-class manufacturing conditions. After this he looks up the cost records and compares the actual cost with his estimate. If he finds that there is only a small amount of variation in certain parts, he is satisfied that in these instances the loss in production is not heavy. Occasionally a differeuce of 50 per cent or so may be found between his estimate and the actual cost of prodnction; naturally such conditions will require investigation to find out the reason why the costs are higher than they should be.

Effect of Design Upon Cost of Machining

While the engineer is looking through the blueprints of various components of the mechanism which is being manufactured, he considers carefully the design of the parts with respect to their effect upon the cost of machining. Many designers do not consider as carefully as they should the various processes necessary to machine the product, and as a result the tool engineer is frequently forced to design complicated tools in order to machine a certain part, when a few changes in design would make the operations much simpler. The factory investigator looks into these points, at the same time realizing that there is a disinclination on the part of factory executives to permit changes in design unless it can be conclusively shown that specific savings will result. Therefore, before any suggestions of this kind are made, it is always necessary to consider the amount of material which has been purchased for the parts to be machined, especially if the contemplated changes in design make it necessary to use castings, forgings, or bar stock of different sizes from those which may have been ordered for the work. The suggestion may, however, be offered for use in the future, after a certain amount of ordered material has been used.

Under present conditions when a factory is only running part time, there is an excellent opportunity for the manufacturer to call in an expert investigator and seriously consider any suggested changes in design, as these may be the means of saving a great deal of money when he is again ready for production. By preparatory work of this kind and by a careful analysis of design, tools and methods, the manufacturer may be able to reap a future reward in proportion to the pains taken. No manufacturer can afford to neglect the present opportunity to look carefully into his methods of manufacture.

Examples of Savings Realized by a Change in Design

A number of examples can be cited to illustrate the advantages of a design in which manufacturing methods have been carefully considered. Fig. 3 shows an example which illustrates the points mentioned. At the same time the change in design suggested gives a better product and one

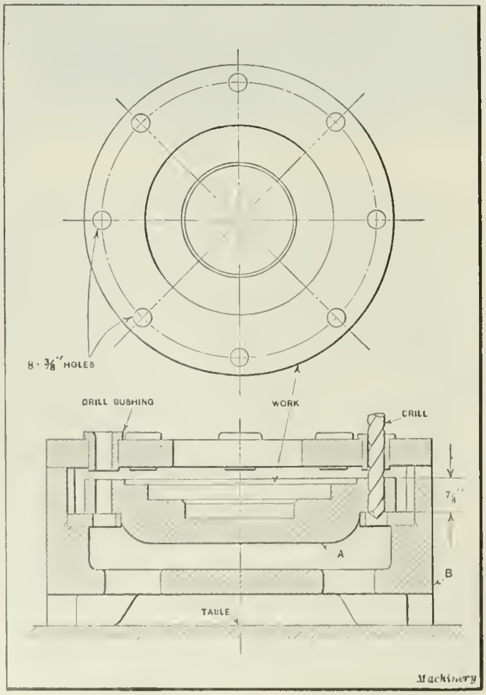


Fig. 1. Jig originally used for drilling Cast-iron Cover

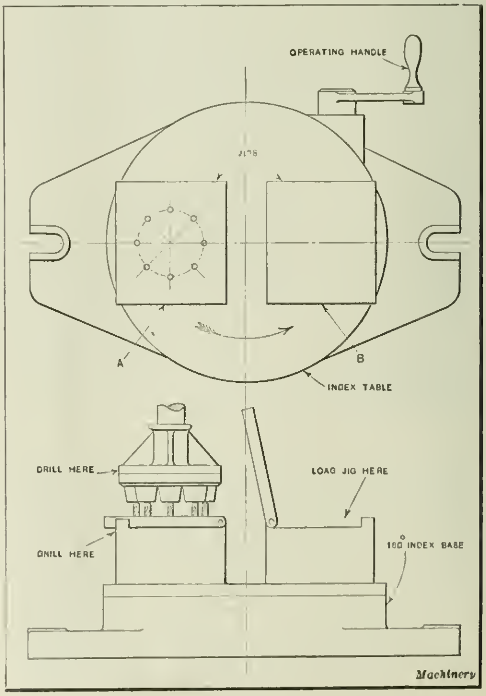

Fig. 2. Use of Standard Index Base for drilling Cast-iron Cover

in which there is less likely to be trouble. The work shown at *A* is a double gear made up of two separate parts *B* and *C*, which are riveted together as indicated. The engineer's attention was drawn to this part on account of the possibility of looseness developing between the two gears after they had been in use for some time. An inquiry developed the fact that trouble occasionally resulted from this cause, but that it had not been serious enough to require any change in the method of manufacture. However, as it would generally be considered better practice to use a single piece in preference to two or more parts riveted together, the investigating engineer suggested making this part as shown at *D* from a solid piece of steel. An analysis of the two methods is given in the following table, and the savings effected can be readily seen.

OLD METHOD

Operation	Time, in Minutes
Operation 1—Blank out both gears complete on automatic screw machine—two machines, one man	2.80
Operation 2—Cut teeth in both gears (twelve pieces per arbor)—two machines, one man	1.10
Operation 3—Drill six rivet holes and countersink both parts	2.60
Operation 4—Assemble rivets and rivet two parts together on riveting fixture—one machine, one man	1.30
Total	7.80

NEW METHOD

Operation	Time, in Minutes
Operation 1—Blank out gear complete on automatic screw machine—two machines, one man	2.50
Operation 2—Cut teeth in large gear on gear-hobber; (two pieces per arbor)—two machines, one man	1.09
Operation 3—Cut teeth in small gear on gear shaper—three machines, one man	1.90
Total	5.49

A comparison of the two methods shows a saving in time effected by the second method of 2.31 minutes. The actual increase in production is approximately 40 per cent, and in addition the new part is much better than the old, as it is a solid piece with no possibility of any change of relation between the positions of the two gears. While there is little clearance between the two gears, the small one can be cut readily on a Fellows gear shaper.

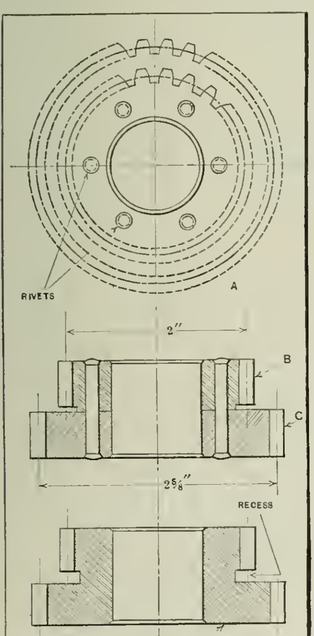

Fig. 3. Change in Design of Gear which lowered Production Costs

On large castings which are designed with brackets applied on angular surfaces, the investigator can often effect large savings by doing away as far as possible with the angular surfaces and making them straight. By so doing awkward and expensive fixtures can be avoided and simple designs used. This point is also of value in connection with the assembling of the completed mechanism, as much less difficulty is experienced in aligning the various members. A good example of this sort is an automobile crankcase having one or more angular pads to which brackets are applied. In machining an angular surface on a large casting, it would be necessary to design a massive fixture on which the work would be set up at an angle, in order to bring the surfaces in the right relation to the milling cutter. The suggested changes in design obviate all this trouble and allow the tool designer to make a simple and inexpensive fixture. Many other cases can be cited to show advantages obtained by improvements in design which assist in making the machining processes easier.

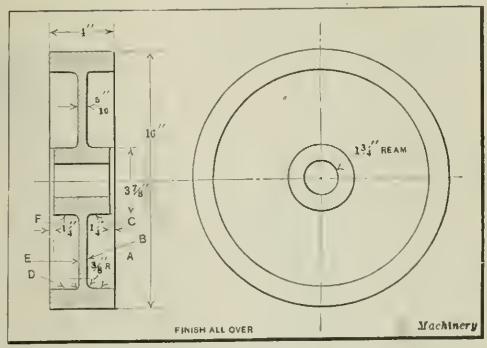

Fig. 4. Flywheel Pulley produced at Lower Cost by Improved Methods

Use of Standardized Equipment

Frequently the equipment of a factory may not be up to date and much time is lost in machining various kinds of work without modern appliances. A number of devices are on the market which are time-savers and which can be installed at a nominal cost. The savings effected will usually pay for such appliances in a short time. The investigating engineer often sees opportunities for using devices which are standardized and may apply them to various operations in the shop with gratifying results. Quick-operating vises, quick-change chucks, quick-acting dogs, index bases and self-centering steadyrests are among the appliances which will be found of great use in saving time and production. Quick-operating vises may be fitted with special jaws to take the place of a milling fixture. Quick-change chucks assist greatly in production by making it possible to change drill sizes rapidly while the machine is still running. Quick-acting dogs save time because they adjust themselves automatically to an arbor on which work is being turned. Self-centering steadyrests are also automatic in their action and save time by the ease with which they adjust themselves to the work. An index base can be applied to many operations in the shop and saves time by allowing two or more fixtures or jigs to be placed on it, so that one can be loaded while the other is in position for machining.

Savings Effected in Drilling

An example which shows the application of a standard index base to a production job and the savings effected thereby is illustrated in Figs. 1 and 2. Fig. 1 shows the work *A* which is being machined in large quantities in a drill jig *B*. There are eight ¾-inch holes in the work, spaced evenly around the flange, and these are drilled by means of a multiple drill head. In order to increase production, the suggestion is made by the investigating engineer that a standard type of index base be purchased, such as shown in Fig. 2. On the table of this mechanism two jigs are fastened at *A* and *B*, in such a position that while the holes are being drilled in *A* jig *B* can be loaded, so that there is very little lost time.

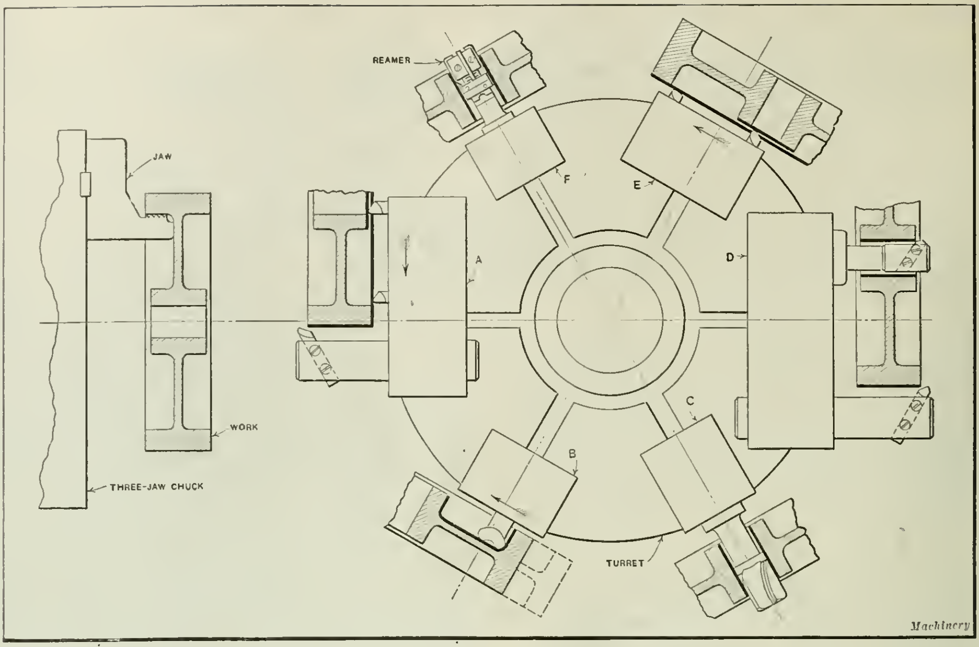

Fig. 5. Standard Tooling Lay-out for Work shown in Fig. 4

A comparison of the two methods is interesting. When using a single jig the work is produced in seventy seconds, or 411 pieces per eight hours. By the new method, using two jigs and an index base as shown in Fig. 2, the work is produced in forty seconds, giving a production of 720 pieces per eight-hour day. The production by this method is increased approximately 75 per cent. The index base and an extra jig represent an investment of approximately $350. The gain in production is such that this outlay is absorbed in about forty-eight days.

Manufacturing a Fly-wheel Pulley

Turret lathe makers furnish a variety of standard tools which are designed so that they can be adapted to various conditions. They are extremely useful for short jobs, and even for certain kinds of high-production work. There are cases, however, when special tool equipment may be found more productive, as it is designed for the particular case in question. Fig. 4 shows a flywheel pulley, 16 inches diameter by 4 inches face, which was finished all over by using standard tool equipment, as indicated in the turret lathe lay-out shown in Fig. 5. The portions *A*, *B*, *C*, *D*, *E*, and *F*, Fig. 4, require rough-machining only, no accuracy being necessary at these points. The work is held by means of the inside chuck jaws as shown in the lay-out. In the first chucking, the outside is turned, and the hub and one side of the flange are faced by means of the standard tool equipment shown at *A*. The turret used is of the cross-sliding type, which allows the tools to be fed as needed for the facing cut. The inside of the flange, the web, and the hub are machined by a double-lip tool in a holder shown at *B*. No further machining is required on this portion, as the roughing cut is all that is necessary. After this operation is completed, a core-drill is used for drilling out the hole in the hub of the pulley as shown in the diagram at *C*. The core-drill is followed by a boring-bar, in combination with a finish-turning tool for the outside diameter. This set-up is shown at *D*. The next operation, shown at *E*, consists of finish-facing the end of the hub and the flange. The final operation is the reaming of the

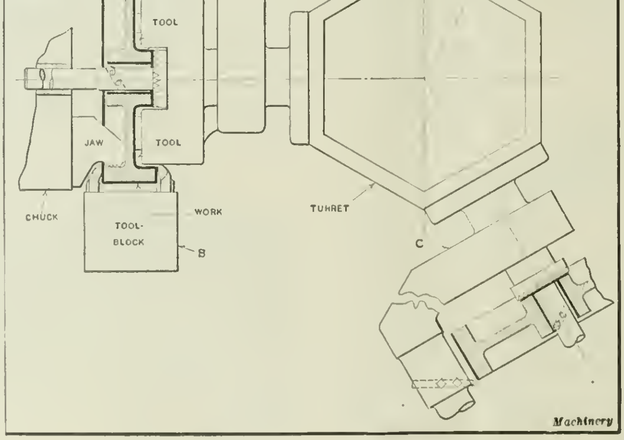

Fig. 6. Special Tooling Lay-out for Work shown in Fig. 4

hole in the hub, which is done by a reamer in a floating holder shown at *F*.

In the second chucking, the work is held by the outside in soft jaws, and some of the same tools are used for turning the inside, and facing the hub and web. The tools not used in the second chucking are the outside turning tools, core-drill, boring-bar, and reamer.

Due to the method of machining, it was found that the hole did not run perfectly true with the outside diameter, and for this reason a lathe operation was found necessary. The work was held on an arbor and a light cut taken over the outside diameter and the two flanges, in order to square them up true with the hole. The total time necessary for machining the flywheel pulley complete in the three chuckings employed with this method was seventy-seven minutes.

The investigator decided, after an inspection of this job, that the work was being turned out much too slowly, and he therefore suggested a revision of the tooling, after finding out that the work was a standard product on which any savings would be much appreciated. The suggested changes in tooling are shown in Fig. 6. In the first chucking, the work is held by the inside of the flange in special jaws in a three-jaw geared scroll chuck, the jaws being cut away so as to permit the facing tools to operate without interference. Two special combination tools were made for turning, facing, and boring, the turning tool being supported in a pilot bracket on the headstock of the machine, as shown at *A*. This means of support allowed heavier cuts to be taken without vibration. In connection with the turning tool, a cutter-head was used with several cutters in it so arranged that they would bore the inside of the flange, face the web and turn the hub at the same time. These tools were staggered so as to break up the chip and make the cutting action easier. A boring-bar was also piloted in a bushing in the chuck, and a face mill used to face the end of the hub. While these operations were in process both sides of the flange were faced by two tools in the cross-slide front tool-block *B*. The cuts mentioned are all roughing cuts, but the finishing operations were performed by similar tools shown at *C*. These consisted of a turning tool in combination with a boring-bar and face mill. While this finishing operation was in process two tools in a special tool-block on the rear of the cross-slide were used to finish-face the sides of the flange. The final operation is the reaming of the hole in the hub. As the boring tools used are of the single-point type, the hole and the outside diameter must necessarily be concentric.

In the second chucking, the work is located on a plug in the center hole, the plug being held in a faceplate and the work clamped by means of straps on the face of the flange. The tools used for this second chucking include only the facing tools used in the first chucking. The turning tools and boring-bars are removed. The reamer also is not used in the second chucking. The total time necessary for both settings by the new method is twenty-four minutes.

A comparison between the old and new methods shows an increase in production of over 230 per cent, as the number of pieces produced by the old method was six per day, while the new method gave twenty per day. The old tool equipment included practically all standard tools, but the new equipment cost $460. The increase in production and decrease in cost of the second method over the first was so great that the new tool cost was absorbed in less than one month from the time when it was put in operation. Savings of this kind are remarkable and considerably more than is generally accomplished. The example given, however, is an actual case, which illustrates conclusively the possibilities of savings which can be effected by a careful investigation of modern practice and up-to-date equipment.

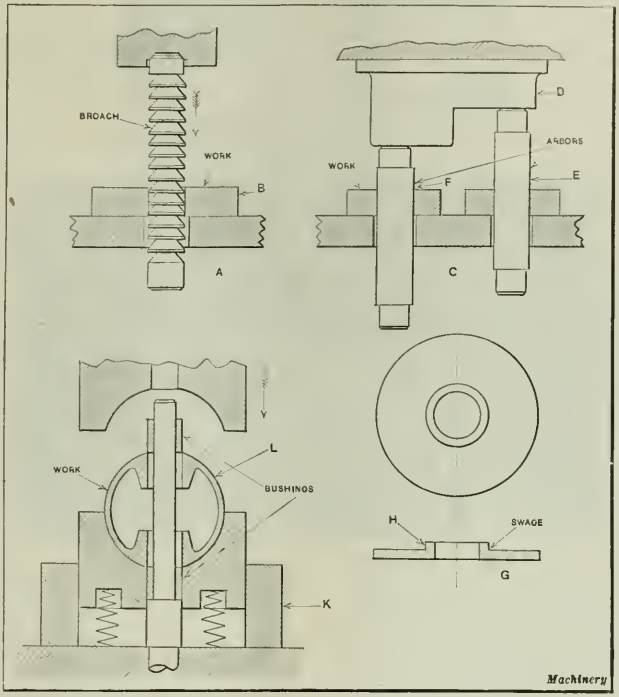

Fig. 7. Various Uses of Punch Press on Production Work

Savings Effected by the Use of the Punch Press

The average manufacturer does not realize the savings possible by using a punch press for various production operations. Shops which do not use sheet-metal work in their product to any extent are not likely to be equipped with punch presses, yet this type of machine is extremely useful for many operations in production work, and as it is comparatively inexpensive such an installation will be found profitable. The factory investigator is often able to suggest applications of a punch press to certain kinds of work not ordinarily done on these machines. For example, a punch press is useful in riveting together two or more parts which are assembled, although it must be remembered that it will not take the place of a riveting machine for all classes of work. However by using a simple fixture several rivets can be headed with one blow of the press, and the results obtained will be found very satisfactory. A little ingenuity on work of this sort will reveal opportunities for economical and productive tools.

Oil-grooves, straight or spiral, can easily be cut either outside or inside of a piece of work by using a punch press and a special fixture. The operation is rapid and the fixture can be of very simple form. Steel or brass work can be centered by means of a punch press instead of using a center-drill. The operation is considerably more rapid, and for certain classes of work fully as satisfactory. For certain kinds of slotting operations, a punch press is very useful and only requires the design of a simple fixture to make it profitable. It can frequently be employed for assembling operations in cases where bushings or pins are required to have press fits.

Fig. 7 illustrates several operations which can be performed on a punch press with a considerable saving over other methods. In the example shown at *A*, the work *B* is to be broached or burnished, and the hole brought to size. A simple broach can be applied to the punch press as shown, and the work accurately sized with very little trouble. The cost of a broach or burnishing tool is naturally dependent upon the shape of the work to be broached, but for sizing operations of irregular or round holes there is often considerable economy in using a method of this kind.

The usual method of placing work on an arbor is by means of an arbor press. This method, however, is rather slow, and a decided improvement on it is shown at *C*, in which a punch press is used for the purpose. The ram is provided with a block, as shown at *D*, and two pieces are set up on the machine at the same time. The arbor *E* is being pressed into the work while that at *F* is being removed. A great saving in time is effected by a method like this.

Parts are occasionally found in production work which require a rather long operation if made on a screw machine. One of these parts is shown at *G*. If the hub *H* is very short, it is easy to swage this on a punch press, so that the piece can be turned out accurately and very rapidly from sheet stock instead of from the bar. When great accuracy is required, a shaving operation can be resorted to for operations which might ordinarily require a profile cut. Many manufacturers think that sharp corners cannot be produced on a punch press, yet it is not particularly difficult under certain conditions.

In the article "Economic Value of Factory Investigations," published in October MACHINERY, two methods of making a small spur gear were compared, and the method of using shaving dies for the finishing cut, thus producing accurate work, was described. This particular operation was mentioned because it really stands in a class by itself, yet it is frequently overlooked by manufacturers who continue to make small gears of certain kinds by the old method. The size of the gear naturally determines whether it can be produced in this way or not, yet slight modifications in design can sometimes be made which will permit the work to be manufactured on a punch press.

An application which illustrates the use of a punch press in connection with a fixture for pressing in bushings in an automobile piston is shown at *K*. The work *L* lies in a nest which is supported on coil springs as indicated. The bushings are placed as shown, and a blow of the press drives them into place very rapidly. There is usually a slight amount of distortion after the operation, but as the piston has not been completely finished at this time, the subsequent operations true it up accurately and bring it to size. Increased production of from 100 to 200 per cent can frequently be obtained by using a method of this sort.

The use of die-castings covers a recognized field, and the savings resulting from this method of producing work are great. The investigator determines whether such work is advisable or economical for any of the parts used in the factory in which he is operating. It is not economical to use die-castings for small lots, as the cost of the die is considerable. For many kinds of work, however, die-castings can be made so that they are complete and do not require further finishing, holes, slots and various surfaces being so carefully made that they are within very close limits of accuracy. The cost of dies on large production work is quickly absorbed by the savings effected.

The examples given in this article are taken from actual practice, and the savings effected are substantial. The fact that the investigator looks at the matter from a different viewpoint from the inside man who knows all the details of the factory, makes it possible for the former to perceive details overlooked by the other man who is too close to the work to see it clearly. There is no better time than the present for the manufacturer to consider his methods of manufacture, and there is probably no better way to obtain results than by a survey of the entire scheme of production.

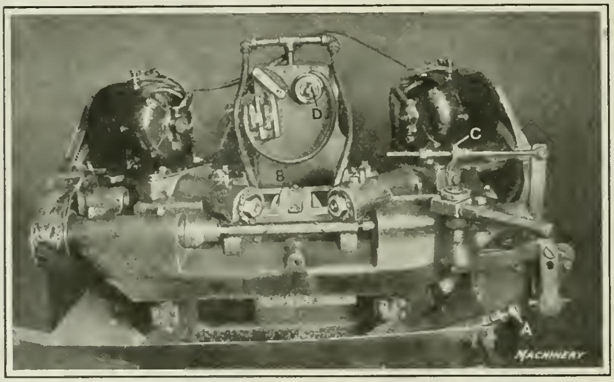
OIL-GROOVE MILLING MACHINE OF SPECIAL DESIGN

The accompanying illustration shows an oil-groove milling machine built and used by the De Laval Separator Co., Poughkeepsie, N. Y. This is a single-purpose machine designed to mill two helical oil-grooves which have opposite-hand leads, as indicated by the shaft shown held in the machine. The shaft is driven by a tongue in the chuck which fits into a machined slot *A* in the end of the spindle, the opposite end being supported by a regular lathe center. There are three motors used in operating this machine, one for driving each of the two cutter-arbors, and one for driving the combination right- and left-hand worm screw *B* and the chuck. The motors which drive the cutter-spindles are mounted on carriages, which move in opposite directions simultaneously, being actuated by the right- and left-hand worm screw.



Special-purpose Machine for milling Two Helical Oil-grooves simultaneously

After two grooves have been cut in a shaft, it is not necessary to return the carriages to the starting point, the work simply being removed and replaced. Then, during the cut on the next piece, the feed of the carriages is reversed so that they travel in opposite directions. By this means no time is lost in traversing the carriages when the cutters are not actually at work. The stop which limits the traverse of the carriage in either direction is shown at *C*, it being evident that the connections with the threaded rod operate the reverse motion of the carriages. The motor driving the right- and left-hand carriage feed-screw is hidden behind the board on which switch *D* is located.

INVESTIGATION OF MOLDING SAND

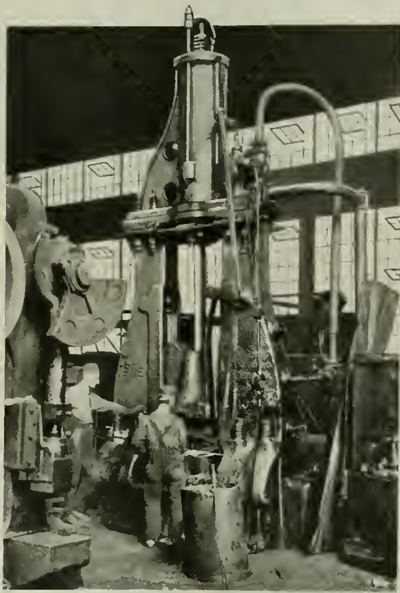
The molding sand investigation carried out by the American Foundrymen's Association in cooperation with the Engineering Division of the National Research Council is well under way. To avoid duplicating investigations already carried out, a summary of the existing literature on natural and artificial sands has been prepared. This summary covers the work of both the American and European countries. A questionnaire has also been sent to members of the American Foundrymen's Association to obtain a knowledge of work done along this line in American foundries. The information collected will be submitted to a committee of representatives from the various branches of the foundry industry and from the interested governmental bodies.

Modern Drop-forging Practice

Comparison of Drop-forgings and Castings, and General Methods of Making Drop-forgings
First of Two Articles

By FRED R. DANIELS

THE development in methods of producing drop-forgings has been due to the increasing demands upon this industry. In its infancy, the industry was confined to small forgings of comparatively plain design, and later, with the advent of the bicycle, to more complicated designs of a small size. With continued use, the inherent advantages of drop-forgings became generally recognized so that, in a great many lines, parts formerly made of malleable or steel castings were made from the stronger and tougher drop-forgings.



Comparison of Castings and Drop-forgings

It was soon recognized that added strength without increase in weight could be obtained by using drop-forgings in place of castings. Thus with the coming of the automobile, a vast field for development in the production of drop-forgings was opened. This also put the metallurgical world to a severe test in evolving special steels, as something better than the previously used steels was required. The development of many different kinds of alloy steels for forgings followed, as well as of steels for die-blocks. Finally came research work to determine the most satisfactory methods of heat-treating.

In comparison with drop-forgings, a casting has a rather coarse open grain, is brittle, and often contains blow-holes beneath its surface. The raw material from which drop-forgings are made, is stronger and tougher than a casting, and is still further improved by working under the drop-hammer. Where quantity is a factor, drop-forgings can often be produced more economically than castings. The advantages of drop-forgings have resulted in their replacing castings in many instances within the last few years. A few examples of parts that are now drop-forged instead of being cast, including mainly motor truck parts, are shown in Fig. 1. Among these are crankshafts, steering arms, axles and engine supports. The gears used in automobile construction are almost invariably machined from drop-forged blanks, and the satisfactory service rendered by gears made in this way has led to the use of drop-forgings for a great many other automobile parts.

The best material to use in making drop-forgings, from the standpoint of workability, is a 0.20 to 0.30 per cent carbon steel made by either the Bessemer or open-hearth process. Comparatively low carbon steels flow readily in the dies and fill up the impressions better than any of the higher carbon or alloy steels. Aside from instances where especially severe service is required, this grade of carbon steel is usually used, being properly heat-treated before being put into service. Greater difficulty is experienced in drop-forging high-carbon and alloy steels, and more caution must be employed in designing the dies so that there will be a minimum of sharp projections and deep impressions. Failure to fill the die impressions fully, which is likely to occur with certain grades of high-carbon and alloy steels, entails subsequent work and additional expense. Such forgings, at times, can be salvaged by building up the defect with the acetylene torch and restriking in the drop-hammer. This involves, besides the extra labor, the trouble of transporting the work to the welding department.

Among the many alloy steels which are commonly used for drop-forgings may be mentioned straight nickel, chrome-nickel and chrome-vanadium. Nickel steels must be carefully watched when being worked and treated. Chrome-nickel steel is probably the most difficult alloy to work under the hammer, and in addition to the special heat-treatment which this steel must receive, there are certain other precautions that must be taken. Steel forgings containing nickel should have large fillets, and should be worked fairly hot and not be permitted to cool rapidly by being thrown on a damp cold floor, or put out of doors where the cold air can quickly chill them. Large fillets reduce the possibility of cracks starting, and check the development of fatigue fractures in the work. Sudden cooling is injurious to the structure of those alloy steels in which nickel is an ingredient, and is also liable to cause distortion.

It is good practice to take a rough cut from forgings made from chrome-nickel steel before the final heat-treatment occurs. This will remove any

The process of drop-forging has been developed to a point where thousands of pieces are practically completed under the drop-hammer and require little or no further machining operations. As a cost-reducing method, drop-forging ranks high among metal-working processes. In the drop-forging plant itself, costs may be reduced by applying certain principles and methods making for economy—by selecting steel of the right quality, and by keeping dies and stock in such a manner that they are readily accessible and the required die and the right size and kind of steel may be easily located. Drop-forgings, when used in quantity, can sometimes be made as cheaply as castings, and are superior in strength. Actual costs are then reduced by employing them, because of the improved quality obtained at an equal price. Furthermore, a saving is usually made in the cost of machining, due to the fact that a drop-forging generally requires less finishing than a casting.

surface seams or laps, and will prevent the development of cracks which otherwise might be developed during the final heating. Generally, alloy steels are more sensitive and require far more care in working and in heating than straight carbon steels, and consequently the output is correspondingly reduced. A detailed account of the method of heat-treating drop-forgings of different analyses will be given in a subsequent article in this series.

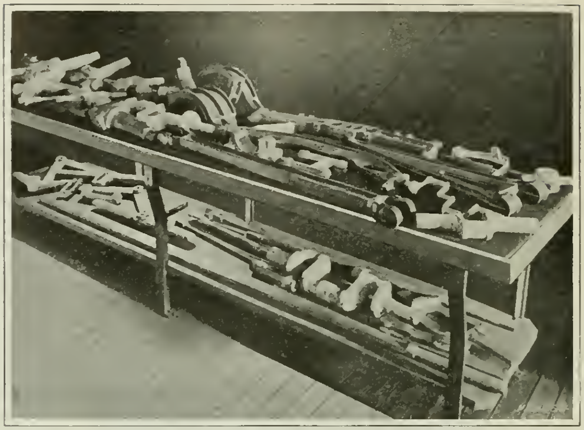


Fig. 1. Examples of Drop-forgings, showing Variety of Size and Design

Tungsten steel may be drop-forged, although a high forging heat is required. Of the non-ferrous materials, copper alloys, such as tobin, naval, and manganese bronze, can be readily forged, and aluminum can also be forged if it is handled with care, but the die impressions must be exceptionally well finished. No success has been met with in drop-forging phosphor-bronze or any composition of brass, although brass forgings can be produced by means of dies and applied pressure, which is a distinctly different process from drop-forging.

Selection of Drop-forging Steel

A great deal of care is usually taken in modern drop-forging plants in purchasing forging steel. The material is ordered from the steel mill in accordance with certain definite standards. Assurance that these have been maintained by the steel manufacturers is obtained by physical and chemical tests in the laboratories of the drop-forging plant, which test the material when received. Some concerns follow the practice of putting an inspector in the steel mill, and he sends a sample of the steel to the laboratory of the drop-forge plant to have its chemical analysis checked before the steel is shipped. After this sample has passed the exhaustive laboratory tests to which it is subjected, the process is repeated on a piece of steel cropped from the end of a bar as soon as the shipment arrives from the mill. When desirable, photomicrographs are made of these two pieces, so that a permanent record may be kept of the exact appearance of their structure. The filing cabinet shown in Fig. 2 is located in the laboratory of a large drop-forging concern and contains fractured test pieces, suitably marked. Record sheets, shown at the left of the cabinet, contain the data obtained by the various tests; and these furnish a permanent record of what each grade of steel is capable of withstanding in the way of tension, compression, impact, bending, wear, etc.

Suitable laboratory equipment for conducting these physical tests may consist of one transverse testing machine, one Brinell hardness testing machine, one impact testing ma-

Fig. 4. Horizontal Storage Rack in which Special Grades of Drop-forging Steel are stored

chine, one tensile testing machine, and the necessary number and types of machine tools for cutting the metal into the sizes and shapes desired for test pieces. The apparatus used for making photomicrographs of the fractured test pieces shown in Fig. 2 is the product of the Bausch & Lomb Optical Co. of Rochester, N. Y., and is standard for this kind of work.

After the steel has been unloaded from the cars, it should be stored in suitable bins or racks and labeled, or marked by the color system. Figs. 3 and 4 show vertical and horizontal storage racks, respectively, which greatly facilitate the handling of stock, and which are in use in one modern drop-forging plant. Various sizes of bars have separate compartments, as shown in Fig. 3, while special grades where the quantities are small are placed horizontally, as in Fig. 4. The largest sizes are stored horizontally on floor stands.

Drop-hammers for Different Classes of Work

In the early development of the process, the size of drop-forgings and the material from which they were made, called for board drop-hammers of not more than 2000 pounds falling weight; in fact, at the present time where concerns are engaged in the manufacture of drop-forgings such as the smaller wrenches, eyebolts, chain ends and similar parts, hammers of this style and capacity are adequate. In the modern commercial drop-forge plant, however, there must be facilities for handling everything from small work up to heavy forgings of 350 to 400 pounds in weight, such as motor truck axles; consequently the range in hammer sizes must necessarily be such as will also conveniently handle this large class of work. The typical drop-forge plant, therefore, should be equipped with a much wider variety of apparatus than was formerly needed, but practice is so varied that standard requirements are very difficult to state. (See "Drop-forge Plant Lay-out and Equipment" in MACHINERY, July, 1921.)

In selecting the drop-hammer to use for producing a particular drop-forging, it does not necessarily follow that the size of the work regulates the size of hammer to use, although, of course, there is a certain relationship between the two. If the metal is hard to work, as for example chrome-nickel, it is always desirable to produce the forging with as few blows as possible; consequently the heavier drop-hammers will give the best results. If the forging is bulky, a hammer should be selected which will have enough falling weight to deliver blows that will penetrate to the center of the forging. As a general rule, it is better to select a drop-hammer which is too large for the job than one that is under weight. The greatest cross-section area of the forging must always be considered when selecting a hammer. The heavier drop-forgings are commonly produced on steam drop-hammers rather than on board hammers, and the inclination is, especially in the automobile industry, toward the use of steam drop-hammers, in a ratio of about two to one.

The depth of impression and the direction and distance the heated metal must be forced to flow in order to fill the die, the forging heat which must be used on the steel, and the intricacy of design, must each be given due consideration in the selection of the hammer. The sizes of hammers most suitable for different types of parts will best be learned by following the practice employed in the actual production of a number of drop-forgings to be described in the next article, which will appear in December MACHINERY.

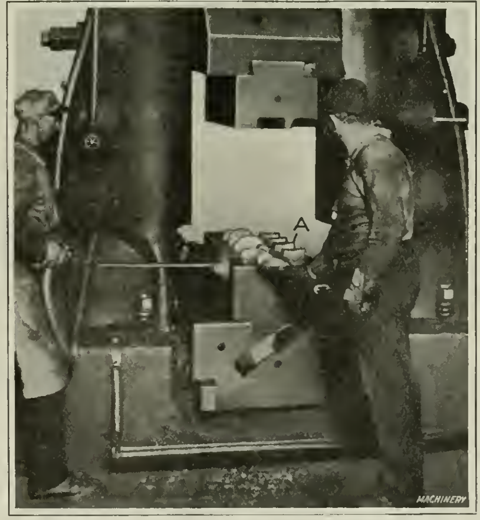

Fig. 5. Forging a Crankshaft

General Procedure

Starting with the smallest sizes of drop-forgings, the usual practice is to work from short bar lengths, rather than to cut the stock up into blanks, continuing this practice as long as it is practicable to do so. These bars are about 3 to 5 feet long, which is a convenient length for handling. They are placed in the furnace, and after being properly heated at one end, transferred to the dies and the forgings produced, this practice being continued until the bar is too short to be handled with tongs. The work is much easier to handle in this way than if individual blanks were used. On the very small sizes it is often possible to produce two drop-forgings with one heating of the bar, provided too many blows are not required to produce each piece. In other words, by working from the bar, full advantage is taken of the heat retained in the bar after one drop-forging has been made, for of course, the bars are heated beyond the length required for the actual production of the drop-forging. The drop-hammers, which for small work are invariably of the board type, range in size from 300 pounds falling weight up to 2500 or 3000 pounds, which is the maximum efficient size for this type.

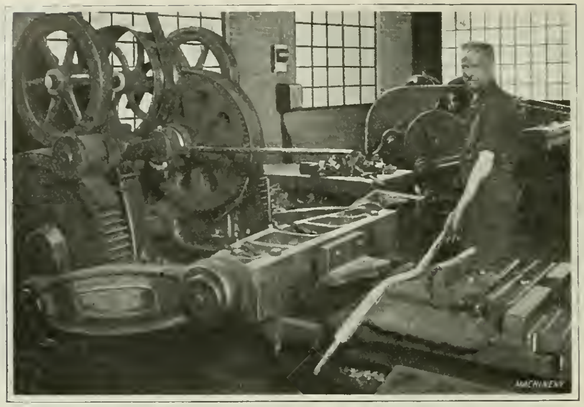

Fig. 6. Using Bulldozer for Preliminary Bending Operations on Large Work

Frequently the forger works with a helper who passes the heated bars to him and receives in return from the hammer man the end of the bar from which the forging has just been made, which he places back in the furnace fire. The hammer man usually works from left to right, first scraping the scale from the heated bar before fullering out his stock (the fuller being located conveniently on the side of the die as described in detail in the article "Design and Manufacture of Drop-forging Dies" published in August MACHINERY), and then transposing the drawn-out metal to the edger which is cut into the dies on the side opposite the fuller, and finally into the die impression. If two die impressions are required—a breakdown and a finishing impression—the breakdown is usually located next to the edger and the finisher between the breakdown and the fuller.

One blow is all that is usually needed to edge the drawn-out stock. For average work only a few blows (perhaps three or four) are required in either the breakdown die or the finisher die. Between each of these blows the hammer man slightly lifts or tilts the partially forged end of the bar so that it will not "freeze" in the impression. This tilting also allows the surface scale to be removed by air or a steam blast. When working from the bar, a cut-off is attached to the smaller hammers on whichever side is most convenient for the operator. For larger work, the cut-off is attached to the press on the hammer side. When the blanks are cold-sheared to the proper forging size before heating, instead of being cut off from the bar during the forging operation, the hammer cut-off is not used—in fact no cut-off is provided on the larger sizes of hammers.

When working from blanks of a predetermined size, the work must be handled with tongs, the dies being so designed that a sprue or "tong-hold" is left for convenience in handling the hot forgings. This practice is always followed in making heavy parts. On this class of work a steam drop-hammer is preferable, because the blow delivered is firmer and drives the greater mass of metal contained in the blank into the impression more completely.

It should be borne in mind that under-cuts and transverse holes which can be produced in castings by means of cores are out of the question when it comes to making parts under the drop-hammer. The movement of the dies is limited to a vertical direction, and attempts to produce intricately shaped cavities by the use of mandrels, although often made, have never been successful. Although the drop-forging process has certain limitations, quite intricate pieces can be produced by the use of properly designed dies and by the application of only vertical blows, as some of the examples to be discussed in the next installment of this article will show.

It has been mentioned that the practice followed in various drop-forging plants conforms to the facilities for handling the work. For example, in breaking down a crankshaft blank, an edger may be used such as shown in Fig. 5 at *A* attached to the die, or, if more convenient, a bulldozer, Fig. 6, equipped with suitable bending dies, may be employed. Probably the best machine for bending a crankshaft blank, however, is a hydraulic press equipped for the

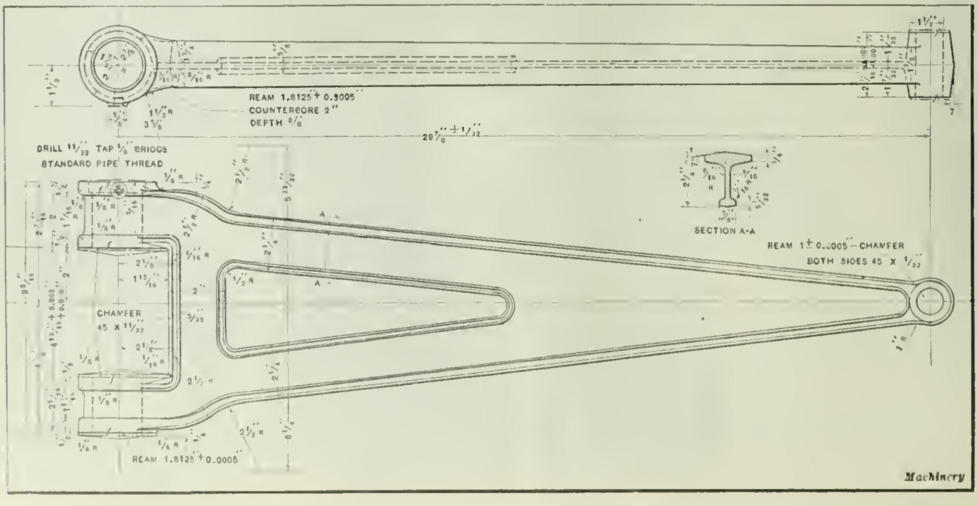

Fig. 7. Rear Axle Torque Arm drop-forged in the Dies shown in Fig. 8

purpose. Particular care must be exercised when using bending dies, to see that the benders are not of a design which is likely to cause rupture of the structure of the steel; for example, they should not be narrow and comparatively sharp.

In connection with the general reference to crankshafts for gasoline engines, it may be mentioned that the drop-forging of these pieces preserves a uniform fiber structure throughout all sections of the crankshaft, whereas if these shafts are hand-forged in the steam hammer the continuous grain structure is not obtained, because in hand-forging the arms and wrist-pins are machined from a solid slab of roughly forged metal. After the arms have been produced by cutting out the metal, the grain of the arms will be seen to extend transversely in relation to that in the drawn-out end bearings, and as a result the strength and the stability of the entire crankshaft are considerably lessened.

Variations in Size of Forgings

Although the die impressions may be accurately laid out, sunk, and carefully finished, as explained in the article "Design and Making of Drop-forging Dies," which was published in August and September MACHINERY, a certain amount of variation from the required sizes is unavoidable in drop-forging practice. The variation is due partly to wear and partly to unevenly distributed shrinkage resulting from peculiarities in design. Wear, of course, depends directly on the hardness of the steel being drop-forged. Tool steel (0.70 per cent carbon and over), must be worked at a lower forging heat than is advisable for an 0.20 to 0.30 per cent carbon mild steel, and this lower forging temperature in combination with the increased hardness of the steel causes au appreciable increase in the rate at which the die deteriorates. The allowance for wear, therefore, for hard, dense steels must be greater than for the low-carbon steels.

An example where the length of a forging is considerably affected due to excessive shrinkage is that of a gasoline engine connecting-rod. The typical connecting-rod design embodies two rather bulky bosses connected by a thin I-beam section. This unequal distribution of metal permits the large amount of flash on both sides of the I-beam section to cool quickly, which tends to draw the ends together, producing greater shrinkage than would otherwise result. On parts such as this, where the metal is unevenly distributed, the total shrinkage will be at least 5/32 inch in a center-to-center distance of 10 inches. Forgings such as these, however, do not shrink equal amounts. On a lot of 10-inch connecting-rods this variation will amount to as much as 1/32 inch, while for longer forgings such as crankshafts the shrinkage allowed when laying out the dies will vary in proportion to the length. For example, in a four-throw crankshaft having an over-all length of 43 inches, a variation of 1/16 inch or more from the intended length will probably occur. Such variation is, of course, unavoidable on parts that cool unevenly.

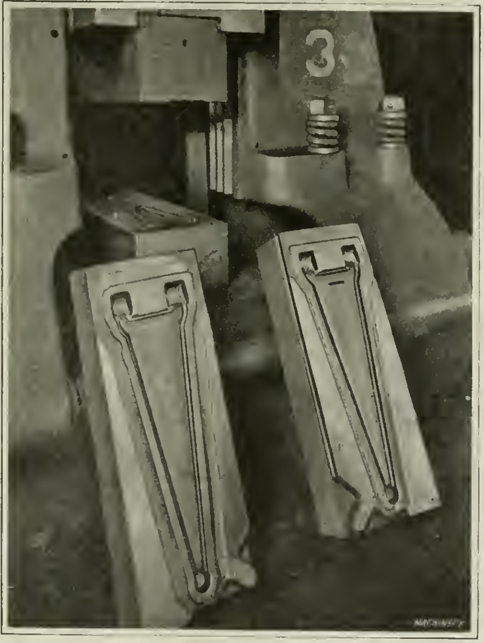

Fig. 8. Steam Drop-hammer and Dies for producing the Torque Arm in Fig. 7

The variation in thickness will depend somewhat on the shape and size of the piece, but will not ordinarily vary more than 1/32 inch and usually less in the smaller forgings. If greater accuracy than this is required, the impressions may be made over size, and the forgings restruck cold to size them after they have been trimmed. Often, no special dies will be needed for this sizing operation, the regular drop-forging dies being suitable. Type-bars for typewriters are usually sized in this manner and may be produced so that there will not be a variation in thickness of more than a few thousandths inch.

Another common cause for variation in size of drop-forgings is due to the metal not being worked fast enough, so that it has a chance to cool before the size of hammer employed can break it down and force the forging to shape. The result is that the dies do not come together as they should, and consequently the thickness or diameter is increased. This will also occur if there has been too great an allowance of metal in shearing the blank. Over-size blanks are also likely to produce cold-shuts by the metal being lapped over on the forging by the first blow or two of the hammer, and then being hammered in on subsequent blows. This trouble may be experienced if the blanks are under size, for in that case there is the probability of laps and seams showing at the parting line where the metal fails to fill the impression.

Bending, Drawing out, and Heading Work

The bulldozer is useful in a forge plant, for bending large work such as motor truck axles, etc. Preliminary bending operations of this kind can be handled on the bulldozer to advantage. The hydraulic press is also a valuable machine in the drop-forge plant, and is used for drawing out long tapered parts, such as the rear axle torque arm for a motor truck shown in Fig. 7. The forging is made from a piece of 0.20 to 0.25 per cent carbon steel, 3 inches thick, 6 inches wide, and 12¾ inches long. It is first drawn out to the approximate length and taper on a hydraulic press, and forged in a 5000-pound steam drop-hammer. The first operation is that of breaking down the drawn out blank and hot-trimming the flash from the outside of the forging. In the second operation the forging is reheated, finished, and the flash removed hot from the outside and from the triangular hole in the web, both the trimming operations being performed simultaneously by the use of a combination trimming die and punch. Fig. 8 shows an Erie 5000-pound steam drop-hammer set up for producing the finished drop-forging. The first-operation dies used in breaking down the drawn out blank are shown resting against the machine. The forging weighs 37 pounds.

The upsetter, variously termed a header and forging machine, is of vital importance for the production of numerous designs of drop-forgings. One of the most common uses for an upsetter is that of heading the end of a crankshaft to produce the flywheel flange. For such work, as well as for bending heavy hooks, the upsetter is commonly used, subsequent to the drop-forging operation.

How To Reduce Production Costs ?

Drawing Dies for Manufacturing a Carburetor Bowl

By N. T. THURSTON, The Acklin Stamping Co., Toledo, Ohio

An interesting series of operations was performed in the manufacture of the carburetor cup or bowl illustrated in Fig. 1. By drawing and forming this part on power presses, a substantial saving was effected over the previous method of casting the part. The later method of manufacture eliminated all cleaning and machining necessary when a casting was used. In addition, tolerances on the various dimensions were actually decreased, because it was possible to secure more accurate work and at a lower cost than when the part was cast. The appearance and dimensions of the part after each of the operations are shown in Fig. 2. One apparent obstacle to the successful drawing and forming of the part was the fact that a metal thickness sufficient to permit the drilling and tapping of a hole for a standard 1/8-inch pipe was required at the bottom of the boss. This difficulty was successfully overcome, however, by filling the inside of the boss with spelter as shown at *H*. All the operations on the part were performed on single-action straight-sided power presses.

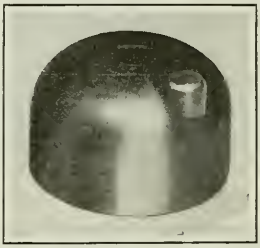

Fig. 1. Carburetor Bowl

The design adopted for dies used for drawing operations may make the difference between a substantial profit and a serious loss in the manufacture of an article. The study of successful die designs is therefore of the greatest value to the designer of press tools. By a slight modification in the design, an extra operation may be saved; and the quality of the product depends greatly upon the right proportioning of the successive operations. A press-tool designer can reduce the cost of manufacture to a great extent, and he is aided in so doing by studying designs that have proved successful elsewhere.

The material used in manufacturing this bowl was 0.050-inch hot-rolled strip steel of a good drawing quality. The strips were purchased from the mill in sizes 5 5/8 inches wide by 60 inches long, and before being used, they were well coated with slushing oil in a machine designed for this purpose. This oiling process was sufficient to permit the work to be put through the first three operations; it was then annealed and dipped in slushing oil prior to the fourth operation. The eight operations required to complete the part, and the dies used are described in the following.

Cutting the Blank and Drawing it to a Varied Depth

The combination die used to blank the part and draw it to the dimensions shown at *A*, Fig. 2, is illustrated in Fig. 3. It will be readily seen that the height of the shell varies around its periphery, the greatest difference being 11/32 inch, at points diametrically opposite. This result was effected by placing the draw-ring *A*, Fig. 3, eccentrically in relation to the die plug *B*, so that dimension *R* in the sectional view *X-Y* is greater than dimension *S*. This difference is not apparent on account of the great reduction necessary in making the illustration. If the draw-ring were concentric with the die plug, a shell of one depth would, of course, have resulted. Although there is a difference of 11/32 inch in the height of the shell, the difference between dimensions *R* and *S* only amounts to 7/32 inch. The extra 1/8 inch of height is produced by the stretching of the metal due to its being held more firmly on the side where the draw-ring is wider, than on the narrower side of the die.

Prior to a descent of the punch, the top of the draw-ring is on a level with the top of die part *D*, and as punch *E* enters the latter, the blank is cut and held firmly against the punch by the draw-ring during the remainder of the operation. Pins *C* are, of course, pushed down on the rubber buffers supporting them, and on the ascent of the punch, these buffers expand, forcing the draw-ring to follow the punch upward and thus stripping the shell from plug *B*. At the end of the upward stroke, the knock-out device *F* forces the shell from the punch, and as the shell falls on

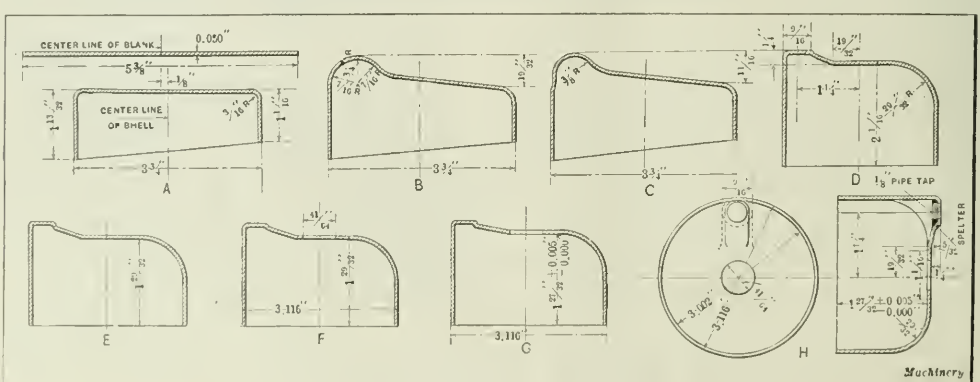

Fig. 2. Appearance and Dimensions of the Shell after Each Successive Operation

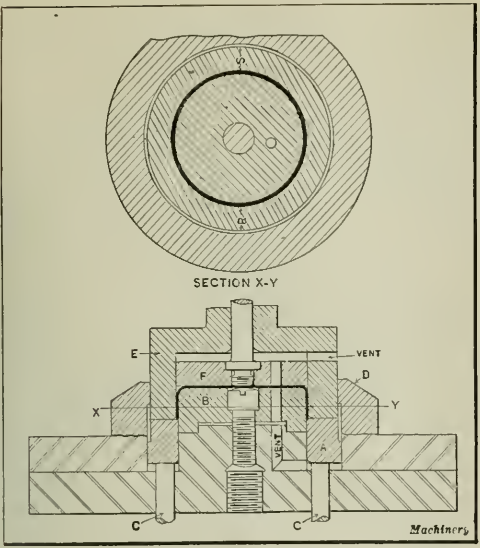

Fig. 3. Combination Die with Eccentric Draw-ring

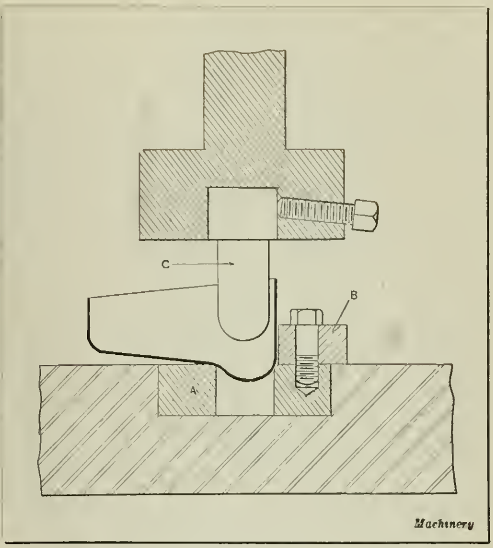

Fig. 4. First Embossing Operation on the Shell

top of the die, it is removed by the operator. Die part *D* consists of a machine steel base on which is forged a ring of tool steel. Punch *E* and plug *B* are also made of tool steel. Vents are provided in the punch and die to allow confined air to escape when the punch descends. A No. 57 Toledo press was used for this operation, and a production of about 4000 pieces per day was maintained.

Forming the Boss on the Shell

The second operation was an embossing one, the boss at the bottom of the bowl being made to the dimensions shown at *B*, Fig. 2. The construction of the die for this operation is shown in Fig. 4. The work is placed over the hole in the tool-steel ring *A* of the die, being located properly by means of stop-gage *B*, which is curved on the inside to correspond with the periphery of the shell. The die ring is mounted in a cast-iron base. The punch-holder is also made of cast iron and is carried in stock. Punch *C* is made of tool steel, so that all parts of the die which actually come in contact with the shell during the forming operation are made of tool steel. The punch is held in the holder by means of a set-screw inclined at an angle of about 2 degrees from the horizontal, which is a simple but satisfactory arrangement for keeping such a member in place. This operation was accomplished on a No. 5 Toledo press, and the production was about 6000 pieces per day.

The die for the next operation is shown in Fig. 5; this die increases the depth of the boss, and forms it to a smaller inside radius, as shown at *C*, Fig. 2. The construction of the die is very similar to the one for the preceding operation, with the exception that a stop-gage is not required. The shell is placed with the boss in the opening of the die ring and the die ring serves as a stop gage. The shell is held in place during this operation by the operator,

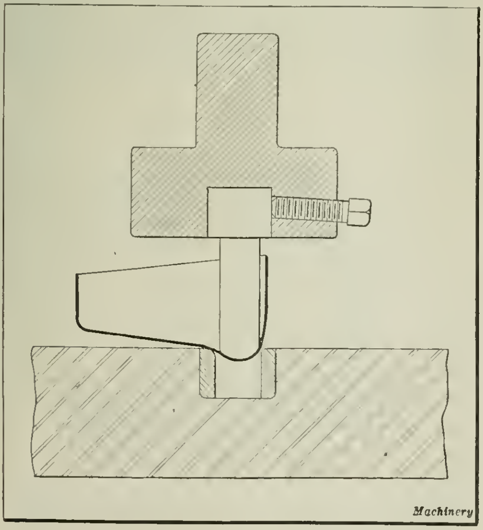

Fig. 5. Second Embossing Operation

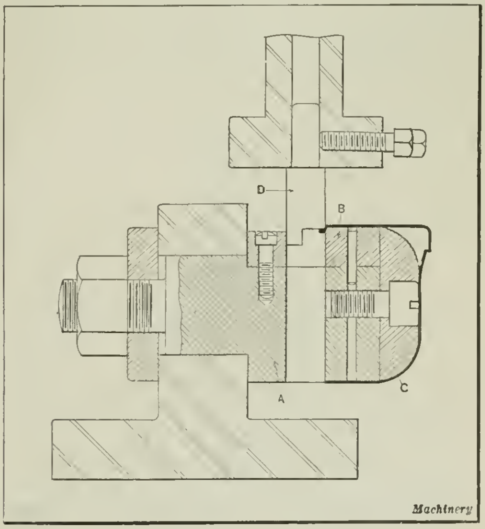

Fig. 6. Rough-trimming the Open End

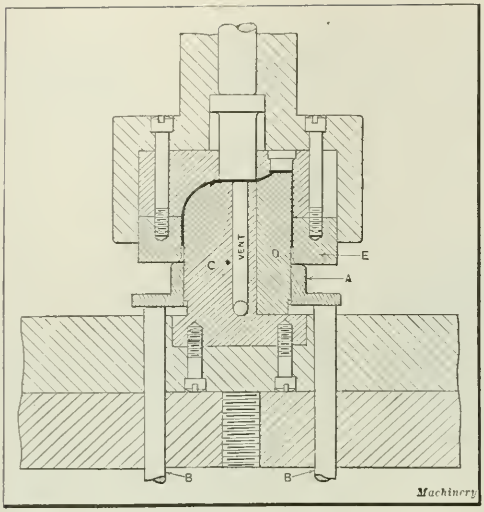

Fig. 7. Die used in drawing the Part to the Final Shape

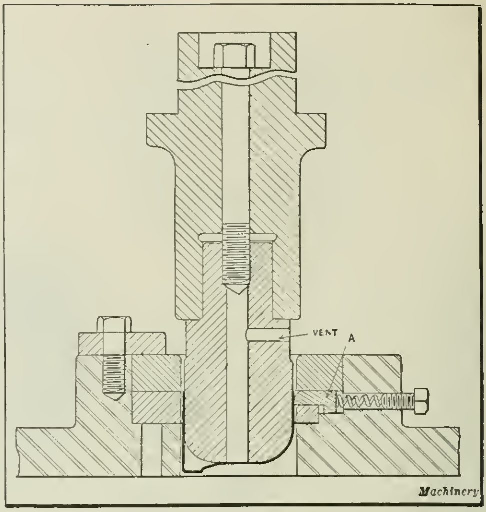

Fig. 8. Push-through Die used in sizing the Open End of the Part

who holds it at a point diametrically opposite the boss. The punch and die ring are made of tool steel, and the die base and punch-holder of cast iron. This die was also mounted on a No. 5 Toledo press, and the production was approximately 6000 pieces per day.

Final Drawing Operation

Prior to the fourth operation, it was necessary to anneal the shell thoroughly. The shell was heated to a cherry red, and the annealing was performed in a gas furnace after the shell had been dipped in a solution of one part of muriatic acid to five parts of water. This solution had no direct effect upon the annealing, but was applied for the purpose of loosening scale formed by the oxidation of the hot steel. When a part is annealed after being wet with such a solution, the scale which invariably forms can easily be removed by tumbling.

In the fourth operation the shell was brought to the final shape shown at *D*, Fig. 2; the die used for this operation is shown in Fig. 7. As in the case of the first die described, the draw-ring *A* is in a raised position before the punch begins to descend, due to the action of the rubber buffers upon which pins *B* rest. The work is then located by slipping it over the draw-ring, and is drawn on plugs *C* and *D* as the punch descends and draws the metal between the draw-ring and face *E* of the punch. The rubber buffers again expand as the punch ascends, causing the draw-ring to follow the punch and strip the shell from plugs *C* and *D*. The knock-out arrangement in the punch ejects the shell when the punch reaches the conclusion of its upward movement, and the work is caught on the end of a wooden paddle by the operator as it drops.

Die plugs *C* and *D* are mounted on a machine steel base, and the punch-holder is made of the same metal. All forming parts of the punch and die are made of hardened tool steel. A vent is provided through plug *C* for the escape of confined air during the operation. It will be noticed that two plugs are placed in the punch; one of these flattens the top of the boss, while the other flattens the closed end of the shell at the center. The view of the completed shell at *H*, Fig. 2, shows that a flat space 1 1/16 inch in diameter is required at this point.

This specification caused some difficulty when the dies for this operation were first tried out, the trouble being that the thickness of the metal at the bottom of the boss became several thousandths of an inch thinner than the thickness

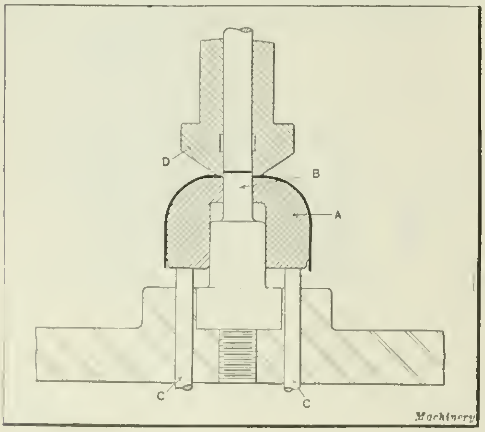

Fig. 9. Piercing a Hole through the Closed End

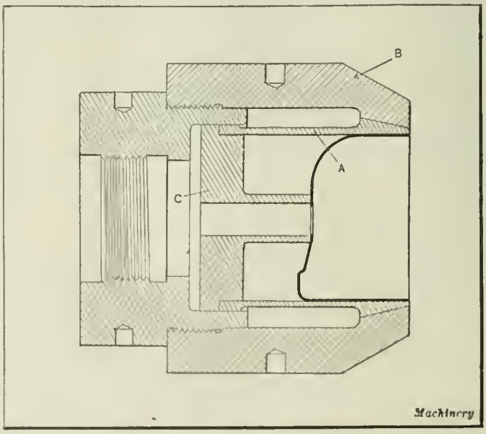

Fig. 10. Chuck used in finish-trimming the Open End

at the center of the closed end. While this condition had been anticipated, the exact thickness at the two points had not been estimated correctly. The result was that the bottom of the boss was not entirely flat. However, the condition was quickly remedied by grinding down the shoulder of the small plug placed in the punch above the boss, and thus lowering the plug several thousandths of an inch. The thickness at the center of the closed end and at the bottom of the boss as the shell was finally produced differed from 0.003 to 0.004 inch, the bottom of the boss being the thinner. The production of this part on a No. 57 Toledo press averaged 5000 pieces per day.

Rough-trimming, Piercing, and Sizing Dies

The fifth operation consisted of roughly trimming the open end of the shell, thus reducing its height to the dimension given at *E*, Fig. 2. This operation was accomplished by the die illustrated in Fig. 6. The base of this die and plug *A* are made of machine steel, but the plug is fitted with a hardened tool-steel block *B* which serves as a cutting edge. End *C* of the plug is also made of machine steel. Punch *D* is a hardened tool-steel piece, held in a machine-steel punch-holder of standard construction. In this operation, the shell is slipped over the plug and turned slowly by the operator while the punch is kept moving up and down, until the entire periphery of the shell has been trimmed. A production of about 2500 pieces was obtained with this die on a No. 3½ Toledo press. A far more efficient die for this sort of operation is a type known as the "Brehm," which is provided with cams that give it a rotary motion around its perpendicular axis. The expense of a die of this design, however, did not warrant its use in the production of the limited number of shells made.

The sixth operation sized the open end of the shell to the dimension shown at *F*, Fig. 2. This was found necessary, because, while the final drawing operation brought the top of the shell to size, it did not bring the open end to the proper dimension. The operation was performed on the push-through die shown in Fig. 8. This die is constructed in a manner assuring that the shell will pass through the die and not stick to the punch upon its upward stroke. The stripping of the shell is accomplished by means of three spring-plungers *A* which protrude into the opening of the die when the punch is in a raised position. These plungers are beveled at the top so that they are forced back flush with the internal surface of the die as the shell is pushed against them on the downward stroke of the punch. However, the pressures of the springs hold them against the outside of the shell, and as the open end passes them, the plungers are forced against the punch, thus enabling them to strip the shell from the punch when it ascends. The work is forced through the die by the next shell being sized. It will be seen that this punch is also provided with a vent. The die is mounted on a cast-iron circular base, and all parts coming in contact with the work are made of tool steel. A production of about 5000 pieces per day was obtained on a No. 55 Toledo press.

The diameter of the hole next punched at the center of the closed end of the shell is indicated at *F*, Fig. 2, and this operation is done by the piercing die shown in Fig. 9. It will be noted that the hole is pierced from the inside rather than from the outside. This method made it easy to dispose of the slugs punched from the shell, and permitted a simpler construction. The work is slipped over the machine-steel work-holder *A*, the top surface of which is on a level with the top of the tool-steel plug *B* when the punch is in the raised position, due to the action of pins *C*, which rest on rubber buffers. The hole is punched through the part as the tool-steel punch *D* descends and forces the work and holder *A* downward while plug *B* remains stationary. Each slug is knocked out of the punch at the end of the return stroke by the knock-out rod at the center of the punch. This piercing operation was performed on a No. 3½ Toledo press. The production was about 5000 pieces per day.

Final Trimming Operation

The shell was finish-trimmed to the height indicated at *G*, Fig. 2, in an operation performed on a small screw machine. The height of the shell was measured from the inside, and it will be seen that a tolerance of only 0.005 inch was allowed. If it had not been for the close limits, the shell could have been satisfactorily trimmed on a press equipped with a die similar to that used in the rough-trimming operation previously mentioned.

The chuck illustrated in Fig. 10 was made especially for this finish-trimming operation. Collet *A* is slit at four points for almost the entire length, so that it contracts when pushed against the inside tapered surface of sleeve *B*, thus securely holding work which has been inserted in the chuck. The collet is advanced by operating a lever on the side of the machine, which gives a horizontal movement to a sleeve bearing against the rear end of the collet member *C*. A knock-out rod extends through the hole at the center of member *C*, and forces the part from the chuck at the completion of an operation. Parts *A* and *C* are made of tool steel, while sleeve *B* is made of machine steel. This was the slowest operation of the series, but the production per day was about 900 pieces.

The spelter shown in the view of the shell at *H*, Fig. 2, was, as previously mentioned, placed in the bottom of the boss to give the latter sufficient thickness to permit the

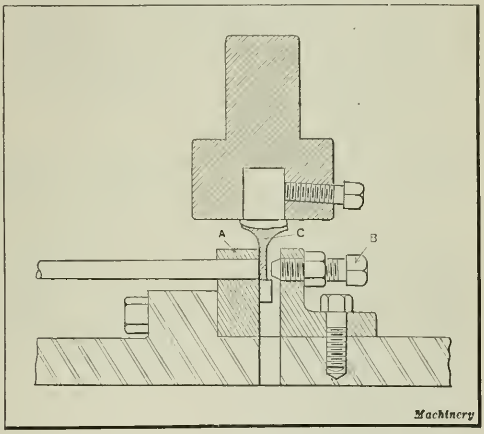

Fig. 11. Cutting the Spelter to the Proper Length

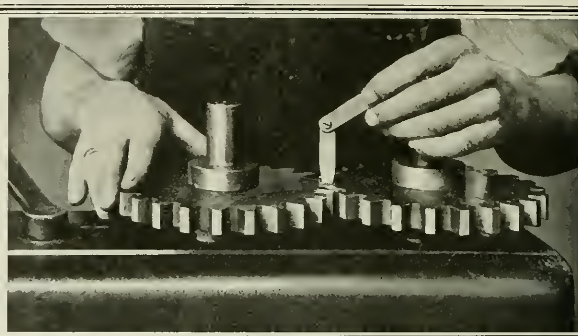
drilling and tapping of a hole to accommodate a pipe. The spelter was bought in rods ⅜ inch in diameter and 30 inches in length, and in order to cut the rod into small pieces of the proper size to fill the boss, the die shown in Fig. 11 was employed. The rod is fed through the tool-steel support *A* until it strikes the end of set-screw *B*, which serves as a stop-gage. The press is then tripped, and the descending punch *C* shears the spelter to the proper size. The die was mounted on a No. 3½ Toledo press, and the production was about 12,000 pieces per day. Punch *C* was, of course, made of tool steel.

The method used to fuse the spelter in the boss was simple, yet quite effective. The shell was placed on a small furnace with the open end upward, and the boss projecting through the top of the furnace into the flames. The work was kept in this position until the boss reached a red heat. A piece of spelter and a small amount of powdered borax were then placed in the boss and melted and fused in the steel shell. The latter when cooled was placed in a jig and a hole drilled through the boss. This operation was performed from the inside in order to prevent any danger of the spelter becoming loosened. The hole was finally tapped. All the dies described were designed, built, and operated in the shops of the Acklin Stamping Co., Toledo, Ohio.

Backlash in Hobbed Spur Gears



Amount of Backlash Recommended to Provide for Unavoidable Inaccuracies in Machining and Heat-treatment

By CARL G. OLSON, Chief Engineer, Illinois Tool Works, Chicago, Ill.

In cutting gears, it is often required to make the teeth slightly thinner than the spaces between the teeth measured on the pitch circle. The backlash thus produced provides freedom between the involute curves to accommodate any slight inaccuracy produced in machining, heat-treating, and assembling. The backlash should be in proportion to the pitch, and it should also be governed by the accuracy of the process used for cutting the gears. Because of the continuous generating action of the process of hobbing, the highest accuracy can be obtained in spacing the teeth and in their concentricity; and this will permit a minimum amount of backlash to be used in hobbed gears. The backlash is usually obtained by cutting the teeth deeper than standard depth. In using the standard involute hob, this method is satisfactory in most cases, but it is not generally recommended on account of a slight increase in the under-cutting of the teeth of small gears and pinions.

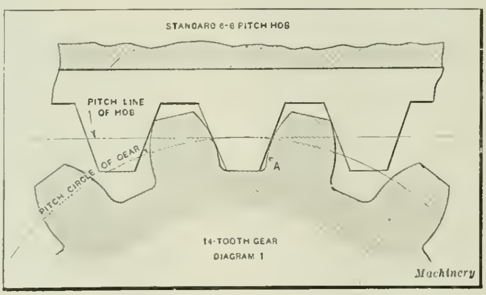


Fig. 1. Cutting Fourteen-tooth Gear of Standard Depth without Backlash

Special hobs formed to avoid under-cutting the teeth in the pinions should never be used to cut deeper than standard, but should be made with thick teeth to produce the desired backlash. The accompanying diagrams illustrate more clearly the reason for these recommendations. Fig. 1 represents a 6-8 pitch standard hob generating a fourteen-tooth gear having teeth of standard depth, and with no correction in the involute curve. The pitch line of the hob is tangent to the pitch circle of the gear, and the under-cut shown at *A* is very slight. This gear will have no backlash when running at the standard center distance with another gear having teeth cut to the same depth with the same hob.

For example, the recommended backlash for 6-8 pitch gears is 0.008 inch, and in order to produce this, it is necessary to feed the hob into each gear 0.0055 inch deeper than standard. The result is shown in Fig. 2, where the pitch line of the hob has been brought inside the pitch circle of the gear. However, it will be seen that the generating pitch line still remains tangent to the pitch circle of the gear and becomes a new pitch line, parallel to the measured or actual pitch line in the hob. The relation between the cutting edges of the teeth and the new generating pitch line remains the same, due to the fact that these cutting edges are straight lines and will still produce teeth with true involute curves. However, the added depth has increased the under-cut *A*, but this increase is very slight.

In Fig. 3 are shown two gears in mesh on standard center distances. These gears were hobbed 0.0055 inch deeper than standard, as previously recommended, and the backlash measured by the thickness gage inserted between the teeth

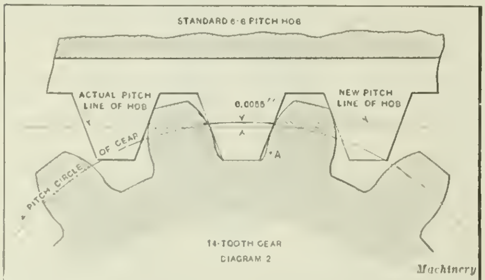

Fig. 2. Cutting Fourteen-tooth Gear Deeper than Standard to give Backlash between the Gears

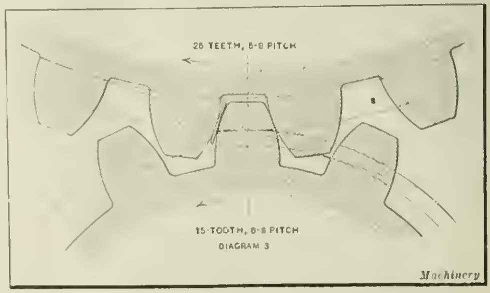

Fig. 3. Gears which have been cut Deeper than Standard to give Backlash

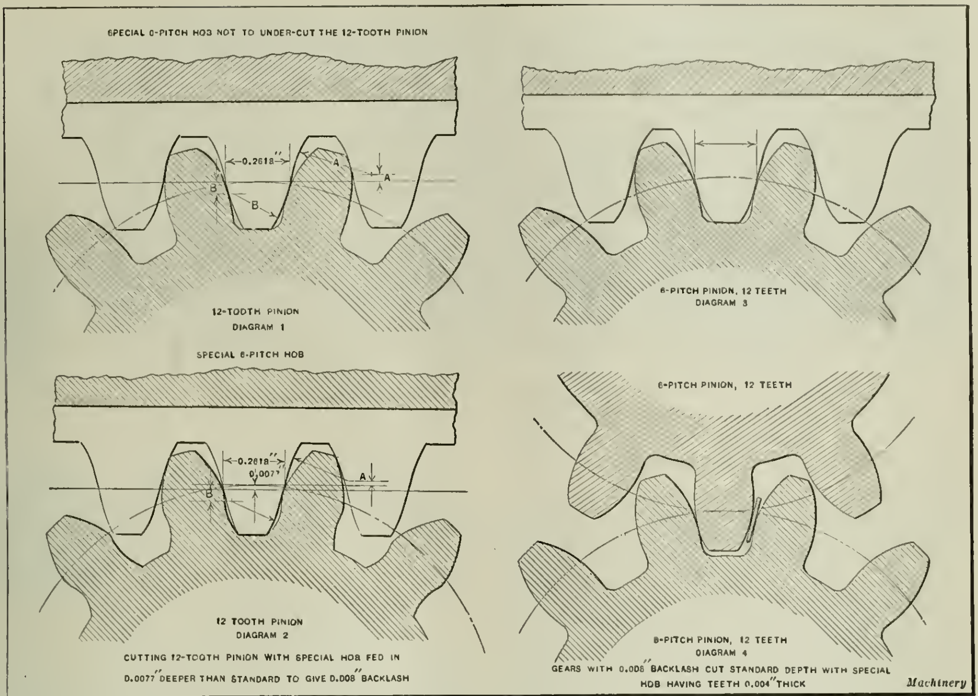

Fig. 4. (Diagram 1) Cutting Twelve-tooth Pinion without Backlash by the Use of Special Hob. (Diagram 2) Cutting Twelve-tooth Pinion with Special Hob Deeper than Standard to give Backlash. (Diagram 3) Cutting Twelve-tooth Pinion with Special Hob having Teeth Thicker than Standard to give Backlash. (Diagram 4) Gears with Backlash, cut to Standard Depth with Special Hob having Teeth Thicker than Standard

is found to be 0.008 inch. Fig. 4, Diagram 1, shows a hob designed not to under-cut the twelve-tooth pinion. The form of the teeth has been modified in fixed relation to the pitch line of the hob, as seen at *A* and *B*, and this will produce a corresponding modification in the fixed relation to the pitch circle of the gear. If it were attempted to cut deeper than standard with this hob, in order to produce backlash, we would have the condition shown in Diagram 2, Fig. 4. The recommended backlash is 0.008 inch, and as this hob has a 14½-degree pressure angle, it must be fed in 0.0077 inch deeper than standard. The relation of the modification has here been changed in relation to the new generating pitch line in the hob, and will no longer be correctly reproduced in the gear. The under-cut is more pronounced in this case, due to the fact that there is a 14½-degree pressure angle and a twelve-tooth pinion.

Diagram 3, Fig. 4, shows a 6-pitch hob made with teeth 0.004 inch thicker than standard, cutting a pinion with 0.008 inch backlash. This is the correct method, the appearance of the gear and pinion being shown in Diagram 4. This illustration also shows a gage placed between the teeth for measuring the backlash; this is done while the gears are held on studs of the correct center distance, as may be seen by reference to the heading illustration of this article.

A fixture for rapidly and accurately testing the backlash of gears is shown in Fig. 5. The gears are mounted on studs *A* and *B* which may be adjusted on base *C* to any desired center distance within the capacity of the fixture. The center distance may be measured over the studs with a vernier caliper or a micrometer. Half of the sum of the diameters of the plugs should be added to the correct center distance for this measurement. A swinging arm *D* hinged to bracket *E* carries a stop *F* and a dial indicator *G*, both of which may

Machinery

be adjusted to correspond with the center distance of the gears to be tested. The bracket E can also be adjusted to hold arm D in the correct relation to gears of differing diameters.

In using this fixture, the operator, with his left hand on the handle of arm D holds the stop tightly in contact with the teeth of the gear on stud A and with his right hand rocks the gear on stud B. As the indicator G is in contact with this gear, a direct reading may be obtained, showing the exact amount of backlash between the teeth of the gears. The test can be taken in several places to insure the uniformity of the gears. Table 1 gives the recommended backlash for hobbed gears of common pitches, and Table 2 gives the amount to feed the hob in deeper than the standard depth to get the required backlash. Table 2 is based on a table published in *Automotive Industries*, May 6, 1920. The added depth may be expressed by the following formula:

$$A = \frac{B}{4} \times \cot \alpha$$

where

A = added depth;
B = backlash; and
α = pressure angle

Gears cut with backlash may be brought closer together than the standard center distance. The difference is given in Column 3, Table 2, and this will be also found convenient for measuring.

CONGRESSIONAL HEARINGS ON THE METRIC SYSTEM

The congressional sub-committee of the Senate Committee on Manufactures, composed of Senator McNary, of Oregon, as chairman, and Senators Weller, of Maryland, and Jones, of New Mexico, will conduct hearings on the bill introduced in Congress providing for the compulsory adoption of the metric system. This bill provides that after a period of ten years, goods, wares, and merchandise, except for export, must be sold in accordance with the metric system, and that charges for transportation must also be made in accordance with this system. It is the intention of the sub-committee to have limited hearings at this time, so that those in favor of and opposed to this legislation may each state their cases. It is then intended to circulate as widely as possible a record of the hearing, with the idea of acquainting the public with the problems involved. Later, during the regular session of Congress beginning next December, it is planned to have further hearings, after which the committee will take action upon the bill. American manufacturers and business men are opposed to the introduction of the metric system into the United States because of the expense that a change would involve and the confusion that would necessarily follow. MACHINERY has repeatedly pointed out that the industries of the country are most vitally interested in the system of weights and measures used, and that it should be left to the industries themselves to determine what system they are to employ. Congress should not by compulsory legislation introduce a system that the industrial leaders, business men, and engineers of the country, do not want.

COOPERATION BETWEEN BRITISH AND AMERICAN ENGINEERS

Several hundred American engineers gathered with representatives of the principal engineering societies of Great Britain and France at a dinner at the Engineers' Club, New York City, on the evening of October 10. The event formally celebrated the homecoming of the distinguished American engineers who went abroad to confer the John Fritz medal upon Sir Robert Hadfield of London and Eugene Schneider of Paris. Heading this deputation, which in addition to the foreign representatives constituted the guests of honor, was Ambrose Swasey of the Warner & Swasey Co., Cleveland, Ohio, founder of the Engineering Foundation and past president of the American Society of Mechanical Engineers.

British organizations whose representatives were guests were the Institution of Civil Engineers, the Institution of Mechanical Engineers, the Institution of Mining Engineers, the Institution of Mining and Metallurgy, the Iron and Steel Institute, the Institution of Electrical Engineers, and the Royal Society of London. France was represented by La Société des Ingenieurs Civils de France.

Close cooperation between British and American engineers already exists as the result of the visit abroad of the mission. Communication is now in progress as to the method of engineering organization in the United Kingdom and the Dominions. British engineers are planning a federation of the British societies, and are closely studying the developments in America which resulted in the formation of the Federated American Engineering Societies.

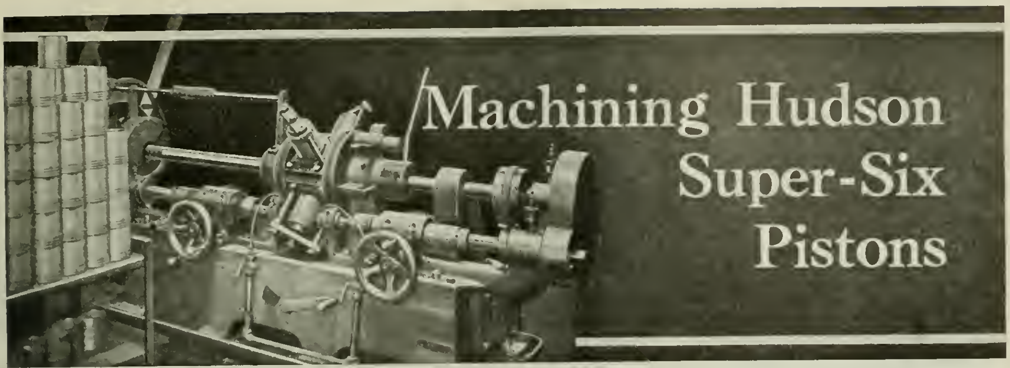
SAFETY CODE FOR COMPRESSED AIR MACHINERY

The American Society of Safety Engineers has been designated as sponsor for a safety code for compressed air machinery by the American Engineering Standards Committee. The code will include rules for the construction and use of compressors, tanks, pipe lines, and the use of apparatus where compressed air is the active agent. In accordance with the usual procedure, the code will be formulated by a sectional committee composed of representatives designated by the various bodies interested in this phase of safety work.



Methods Used by the Hudson Motor Car Co. in Producing Pistons with High-production Machinery at Low Cost

How To Reduce Production Costs ?

THE pistons for the "Super-six" engines for automobiles built by the Hudson Motor Car Co., of Detroit, Mich., are made of cast iron. Many interesting methods have been developed for the machining of these parts, and excellent results are obtained through the application of automatic machines for performing certain operations.

As the castings are delivered to the machine shop, they are first subjected to a rough inspection; and they are then sent to a Gridley automatic on which the outside diameter is rough-turned, the closed end of the piston rough-faced, and the ring grooves rough-turned, the time per piece being about three and a half minutes. On this machine the turning tool *A*, Fig. 1, is carried by the back-rest, on which are also mounted two supporting rollers *B*. The closed end of the piston is faced by a tool *C*, mounted on the front slide; and the three tools which cut the piston-ring grooves are also carried on this slide, although they cannot be seen in the illustration.

In designing the cams, provision has been made for feeding the turning tool *A* from right to left, and at the same time when this tool begins its cut, the facing tool *C* also comes into action. The opposed position of these tools enables each to assist in preventing the pressure exerted by the other to spring the work out of place. As the turning tool *A* progresses toward the left-hand end of the work, facing tool *C* is also approaching the center of the piston; and toward the completion of the operation, the three piston-ring groove-turning tools come into operation. These tools greatly increase the pressure applied at the front of the work, and the tendency to throw the piston casting out of place is overcome by the two rollers *B* which are now in contact with the right-hand end of the work.

Rough-boring and Facing the Open End

After this preliminary operation, the castings are sent to a Fay automatic lathe on which the open end is rough-bored and rough-faced to the required length at a rate of about forty-five seconds per piece. These bored and faced surfaces are then used as locating points in setting up the work for subsequent operations.

Rough-drilling the Wrist-pin Holes

After the work on the castings has progressed to this point, they are delivered to a special drilling machine built by the Hoefer Mfg. Co., on which they are set up for rough-drilling the wrist-pin holes. This machine is shown in operation in Fig. 3. It consists of a turret *A* that carries castings *B* into position between two opposed spindles *C*; these spindles feed the drills in from opposite sides of the work, thus simultaneously drilling the holes through the two wrist-pin bosses. The spindles hold the twist drills in accurate alignment, so that the holes are drilled straight and in line with each other.

Each face of the turret is provided with a pilot that enters the previously bored and faced open end of the work, and there is a yoke over the casting, by means of which it is secured in place. The cross-bar *D* on the yoke has a C-slot in one end, which enables it to be pivoted about one of the side bolts *E*, so that the bar is brought into position over the casting to allow a nut on the second side bolt *F* to be tightened. The final clamping action is obtained by tightening the bolt *G* at the center, which forces a pressure pad down on the top of the work. The design of this machine is such that the drills *H* are automatically fed into the work, and the feed is tripped as soon as they have passed through the inner ends of the wrist-pin bosses. The spindles are then returned to their starting positions by turning handwheels *I* at each side of the machine; and the turret is indexed by hand to bring a fresh casting into the operating position.

After the operator has brought a new piece into place to be drilled, he occupies his time in removing the drilled casting which has made a complete circuit on the work-holding turret, and in setting up a fresh piece of work in its place. In this way, one drilled piston casting is secured for each index movement of the work-holding fixture, and the operator is kept busy unloading and reloading the machine while the drilling spindles are working on the holes in a piston casting which is in the operating position. As a result, the average time is only forty seconds per piece, and the idle time of both the machine and the operator is reduced to a minimum.

In this article attention is called to the number of automatic machines and lathes that are employed for machining the pistons for Hudson "Super-six" engines. It is apparent that the equipment used aids in greatly increasing the rate of production and thereby decreasing costs; and in the present instance this is especially true because the machines have been equipped with an unusually large number of tools that are simultaneously engaged in turning, facing, boring, and other operations. With automatic lathes used in this way, it is safe to assume that the cost of machining these pistons is very close to the minimum attainable through the use of any available types of machine shop equipment.

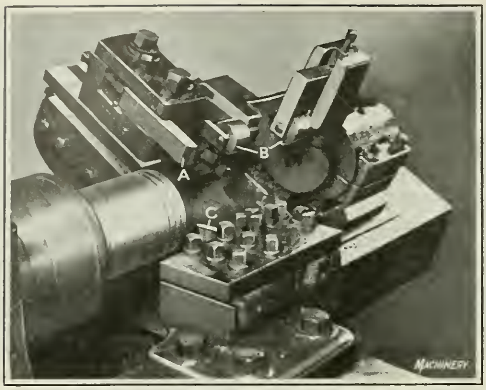


Fig. 1. Gridley Automatic equipped for rough-turning Outside Diameter, facing Closed End, and rough-turning Ring Grooves

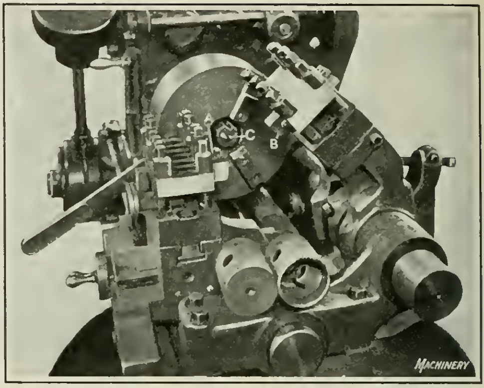

Fig. 2. Fay Automatic Lathe tooled up for finish-boring and facing the Open End, and centering the Closed End of the Piston

Finish-boring and Finish-facing Open End and Centering Boss on Closed End

After drilling, the castings are sent to the heat-treating department, where they are carefully annealed to remove strains that have been produced in machining; they are then sand-blasted on the inside to remove scale before being returned to the machine shop. This work is done in a Pangborn sand-blasting machine.

Next in the order of machining operations comes the finish-boring and finish-facing of the open end of the work, while the boss cast on the other end is centered and counterbored. This work is done on a Fay automatic lathe, equipped as illustrated in Fig. 2, at the rate of about forty seconds per piece. In this machine the boring is done by a tool *A* carried at the front of the cross-slide, while the facing operation is performed by a pivoted tool *B* at the rear. The centering and counterboring of the boss cast at the top or closed end of the casting is done by means of a tool *C* carried by a rod extending through the hollow spindle and actuated from the bar feed mechanism.

Another Fay automatic lathe, shown in Fig. 4, is then employed for finish-turning the outside diameter of the castings, taking a second roughing cut and a finishing cut in the ring grooves, and a finish-facing cut over the closed end of each casting, all of which requires about two minutes per piece. Referring to the illustration of the machine used for this purpose, it will be seen that on the front slide there are three tools *A* by which the finish-turning operation is performed on the outside diameter of the piston casting. For the intermediate- and the finish-turning operations in the piston-ring grooves, two sets of tools are provided, one of which will be seen at *B*. These tools are of somewhat the same form as the so-called "hob" used on a thread-milling machine of the type where the work makes one complete revolution in contact with a rotating cutter to complete an internal or an external thread-cutting operation. But in the present case the cutter does not revolve, the purpose of having a number of sets of teeth being to enable the tool to be loosened and reset with another set of teeth in the operating position. In this way, the cutter can be reset a number of times, as the teeth become dull, and it need only be sent to the tool-room for grinding when all of the teeth are dull. The tool that performs the final facing operation on the closed end of the piston will be seen at *C*, and it will be evident from the illustration that this tool is carried on the back-rest.

Recentering the Work Preparatory to Grinding

After the preceding turning and facing operations have been finished, the castings are sent to a special centering machine that is employed to recenter the open end of each piston, so that the work may be set up between centers for grinding. A special grinding machine was designed and built for this centering operation. In Fig. 5 a plug *A* with a knurled handle is slipped through the wrist-pin hole in the piston, to hold the center hole in the closed end of the work in contact with a center carried by the post *B*. Then, the formed grinding wheel *C*, which is mounted on a sliding spindle, is pulled forward into contact with the open end of the work by means of a handle *D* that has a yoke at its lower end, connected with a collar on the spindle. This is a very simple machine and one that gives entirely satisfactory results. After being recentered,

ORDER OF MACHINING OPERATIONS ON HUDSON "SUPER-SIX" PISTONS

Operation Number	Name of Operation	Type of Equipment Used
1	Rough-inspect	Bench
2	Rough-turn outside diameter, face closed end, and rough-turn ring grooves	Gridley automatic
3	Rough-bore open end and face to length	Fay automatic
4	Rough-drill wrist-pin holes	Special Hoefer drilling machine
5	Heat-treat	Gas furnace
6	Sand-blast inside	Pangborn sand-blasting machine
7	Finish-bore and face open end, and center closed end	Fay automatic
8	Finish-turn outside diameter, rough- and finish-turn ring grooves a second time, and face closed end	Fay automatic
9	Recenter open end	Special center-grinding machine
10	Rough-grind outside diameter	Fitchburg grinder
11	Rough- and finish-bore and ream wrist-pin hole	Warner & Swasey hand screw machine
12	Hand-ream wrist-pin hole	Bench
13	Face wrist-pin bosses	Whitney hand milling machine
14	Mill oil-grooves in wrist-pin holes	Sipp drilling machine with National oil-grooving tool
15	Grind clearance on sides	Norton cam-grinding machine
16	Drill six oil-holes through ring grooves	Avey sensitive drilling machine
17	Hand-ream wrist-pin hole to remove burrs	Bench
18	Rough- and finish-grind outside diameter	Norton cylindrical grinding machine
19	Inspect	Bench

Machinery

the castings go to a cylindrical grinder built by the Fitchburg Grinding Machine Co., which is used for grinding the outside diameter, the time required for the operation being approximately one and one-third minutes per piston.

Boring and Reaming the Wrist-pin Hole

Next in the order of machining operations comes the rough- and finish-boring and the reaming of the wrist-pin hole in the piston. For this purpose, the castings are sent to a Warner & Swasey hand screw machine which is equipped with a core-drill, a boring-bar, and a reamer to handle the required sequence of operations. The operation requires less than one and one-half minutes per piece. From this machine, the castings are sent to a bench where the wrist-pin hole is hand-reamed to assure obtaining accurate alignment.

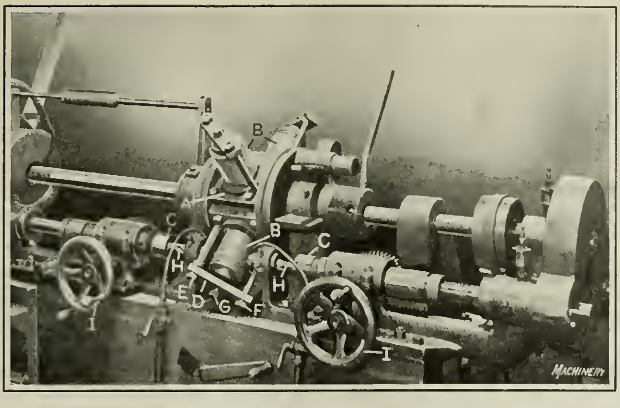

Fig. 3. Hoefer Special Opposed-spindle Duplex Drilling Machine for simultaneously drilling the Wrist-pin Bearing Holes in Piston Castings

Facing Wrist-pin Bearing Bosses, and Drilling Oil-holes

After this operation has been completed, the castings are sent to a hand milling machine built by the Whitney Mfg. Co., which is equipped with a work-holding fixture in which the castings can be located from the reamed wrist-pin holes; in this machine the inner ends of the wrist-pin bosses are milled by means of an offset attachment at the rate of nearly two a minute. Oil-grooves are then milled in the wrist-pin holes, at the rate of over three pistons a minute, with one of the No. 2 oil-grooving tools made by the National Machine Tool Co., carried in the spindle of an upright drilling machine built by the Sipp Machine Co.

Grinding Clearance at Sides of Piston

For grinding the clearance required at each side of the piston, at points where the wrist-pin holes come through, use is made of a Norton cam-grinding machine which is equipped with master cams of the same form as the cross-sectional area of the finished piston on a plane through the wrist-pin holes. Each piston requires about forty-five seconds for grinding. Next, six oil-holes are drilled through the piston in the ring grooves, using an indexing fixture on an upright drilling machine built by the Avey Drilling Machine Co. After this, the wrist-pin hole is hand-reamed to remove all burrs.

Rough- and Finish-grinding the Outside Diameter

The castings are next sent to a Norton cylindrical grinding machine, on which the outside diameter is rough- and finish-ground, one and one-half minutes per piece being the average time required. The pistons are then ready for assembly into engines as required.

* * *

WASTE BY FIRE LOSS

Carelessness is the main cause of the enormous loss due to fires in the United States. Our fire loss per capita is several times greater than that of any other civilized country in the world, and amounts now to about $300,000,000 a year —an amount almost sufficient to have provided for the building of the Panama Canal. Property loss is only one item. The human lives lost by fire amount, on an average, to 18,000 annually, while about 60,000 persons are injured by fire. Ultimately, the property loss is shared by every citizen of the country. Everyone has to help pay the $300,000,000 annually going up in smoke. Manufacturers should take active steps to impress upon employes the need for greater care in order to prevent fires, not only in the factories but around their homes as well. An educational campaign along these lines is of national importance.

Production Work in the Locomotive Shop

Application of the Bullard Vertical Turret Lathe in Locomotive Shop Practice
Second of Two Articles

The high cost of production in railroad shops has been the subject of many comments in both the daily and the technical press, in public speeches, and in governmental reports. Costs can be reduced in railroad shops in three ways—by capable management; by the efficiency of labor; and by the employment of labor-saving and cost-reducing machines and methods. The present article deals with the last phase, and shows a number of examples of economical production by the use of the vertical turret lathe in combination with carefully laid out tooling equipments.

In the first installment of this article, published in October MACHINERY, the machining of piston-heads and rings and cylinder heads was described. In the present installment the tooling up for machining cross-heads, main throttle valves and piston-heads will be dealt with.

Tooling up for Machining Cross-heads

The machining of locomotive cross-heads involves a number of special tooling and chucking arrangements. A complete lay-out showing each operation in the three chuckings required to finish a cross-head of typical design is shown in Fig. 11. The first point of interest is the method of presenting the work to be machined. It is located between suitable jaws, and is supported by wooden blocks from the bottom, and by a screw-jack between the two sides, to prevent the upper side from springing while being machined.

In the second chucking, it is not practical to use jaws to hold the work, so a special fixture is employed. A tapered bushing *B*, which fits the central stud of the fixture closely, is placed in the previously machined hole of the cross-head, and the work is clamped in the position shown in the lay-out by means of a nut and washer *A* seating against the inner surface of the cross-head. This securely anchors the work in the proper position on the fixture. A driver *C* is clamped in a slot of the machine table so that the work will revolve positively with the table.

In the third chucking, another special method of holding the work is required; in this case a special fixture is used, which is provided with the same means for securing

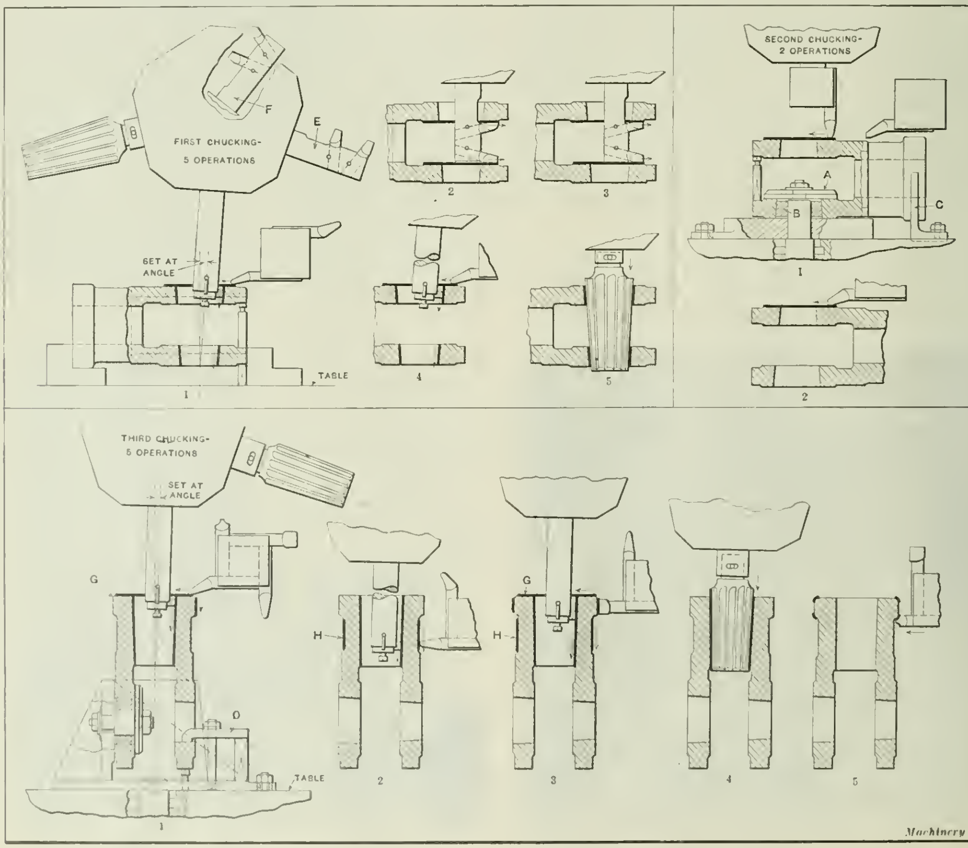

Fig. 11. Machining a Locomotive Cross-head in Three Chuckings on the Vertical Turret Lathe

the cross-head in position as was used in holding the work during the second chucking. Attention is also called to the use of a blocked-up strap *D*, which engages the small end of the tapered hole and binds the work down against an adjusting screw in the base of the fixture.

In machining the cross-head, the main turret is set at the desired angle, and in the first chucking, a combination boring-bar, equipped with a roughing cutter, rough-bores the tapered hole while the surrounding surface of this hole is rough-faced with a side-head turret roughing tool. The second and third operations are straddle-facing operations in which the special bars *E* and *F* are employed. The cutters are properly set in the bars, it being preferable to use two separate bars, one for roughing and one for finishing, rather than to change the cutters after the roughing operation. In the fourth operation, the tapered hole is trued up and the top surface finished by the tool in the side-head turret, as the lay-out indicates, while in the last operation of the first chucking, the hole is finished with a floating taper-reamer, by a method similar to the one employed in finishing the piston-heads, previously described. The second chucking consists of two operations, performed on the opposite side of the work. These operations are simply those of roughing and finishing the surface surrounding the tapered hole.

The cross-head is held in a vertical position during the third chucking, in which the piston-rod end of the cross-head is machined. In order to finish the tapered hole for the end of the piston-rod, the main turret is set at the required angle, while the hole is first rough-bored by a cutter carried in the boring-bar, and the surfaces of the head *G* are rough-faced and rough-turned with a side-head turret tool, as indicated by the arrows in the diagram. A second tool carried in the side-head turret is used in the next operation to rough-turn neck *H* while the remainder of the tapered hole is being rough-bored. The third operation is truing up the tapered hole by substituting another cutter for the roughing cutter in the boring-bar, and finish-facing and finish-turning the head *G*, and finish-turning neck *H* with a special tool carried in the side-head turret. A floating reamer is used in the fourth operation to finish the piston-rod hole, while in the fifth operation a double-radius formed tool carried in the side-head turret, is employed to form the radii of head *G*. This completes the machining of the cross-head, the total time being from 1½ to 1¾ hours.

Machining Locomotive Main Throttle Valves

The machining of locomotive throttle valves on vertical turret lathes is of interest principally as regards the holding method. Referring to Fig. 12, it will be seen that a special plate *A* is attached to the machine table, in which a tie-rod is carried. The work is located centrally in a special fixture by providing an extension *B* which is cast to the lower part of the valve stem and which fits into a hole in the fixture. By dropping a ring *C* into the upper end of the valve, provision is made for holding the work down by means of the tie-rods passed between the radial vanes, a positive driving arrangement being thus secured.

The machining of this valve requires two chuckings, as illustrated in the tooling lay-out. In the first chucking, the stem of the valve is rough-turned, and then the end of this stem is rough-faced with a special long-shank tool carried in the main turret tool-holder, this operation being performed simultaneously with the forming of the bevel and the roughing of the outside cylindrical surface by a tool carried in the side-head turret. The second operation finish-turns the outside of the stem and the shoulder at its upper end, while a special tool in the side-head turret is finishing the bevel at the top and finish-turning the outer surfaces which were roughed in the first operation. The position of the tool at the end of the finish-turning operation, when it reaches the lower flange of the casting, is indicated in the illustration. The third operation consists of finishing the angular surface at the lower part of the valve.

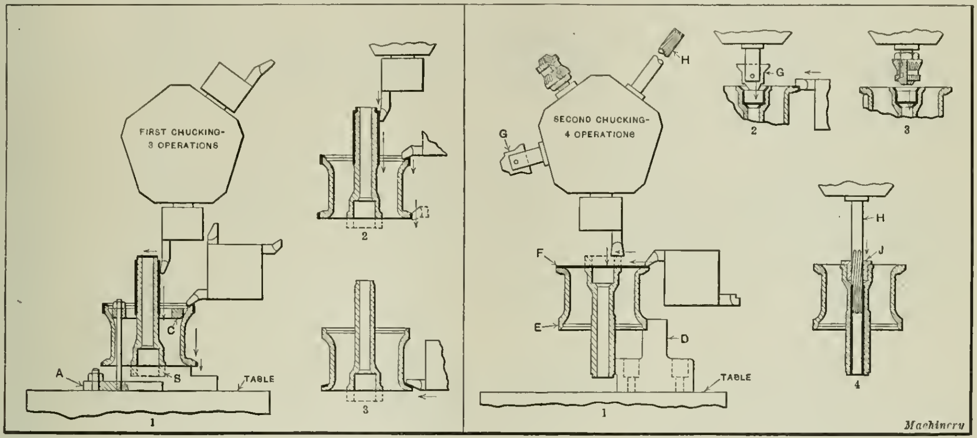

Fig. 12. Tooling Lay-out of the Two Chuckings required to machine a Main Throttle Valve for a Locomotive

In the second chucking, the work is secured by special soft jaws *D* which are so designed as to engage the work on the previously machined diameter *E* and on the extending end of the stem. The auxiliary boss which was cast on the valve stem for the purpose of locating the work in the first chucking, is turned off in the first operation by a tool carried in the main turret tool-holder. At the same time, the surface of flange *F* is faced by a tool carried in the side-head turret. As soon as the boss has been turned off, the same tool is used to face this end of the stem. During the second operation a special formed boring-bar *G*, rough-bores the counterbored hole in the end of the stem. This boring-bar is carried in the main turret, and while it is in operation, a radius-forming tool in the side-head turret forms the radius at the top of the flange. In the third operation a special reamer is employed to complete the machining of this counterbored hole. Finally, the central hole which passes entirely through the stem is reamed with a special length core-drill *H*, used in connection with a bushing *J* which fits into the counterbored hole as a means of securing perfect concentricity of this hole with the previously counterbored hole. These cast-iron throttle valves are about 18 inches in diameter, and are machined complete in from forty to forty-five minutes.

Compound Feed Gearing for Machining Angular Surfaces of Locomotive Piston-head

The tooling lay-out, Fig. 13, shows each operation in the two chuckings required to finish a locomotive piston-head all over, the special point of interest being the machining of the angular surfaces. Standard jaws and buttons are employed to chuck the work during each series of operations. Tools carried in the two turrets simultaneously rough-face surface *A* and rough-turn diameters *B* and *C*. In finishing the angular surface *D* during the second operation, a compound gear combination between the cross and vertical feeds of the machine is employed to traverse the main turret at the proper angle for machining the surface. While the angular surface is being machined, tool *C* of the side-head turret rough-faces the surface indicated by the position of the tool in the lay-out and also rough-faces the flange. For machining the tapered hole, the turret is set at the desired angle, and the boring-bar furnished with proper roughing and truing cutters, is employed. Simultaneously with the performance of this operation, a special hooked tool carried in the side-head turret finish-faces the top surface of the flange and finish-turns the adjacent shoulder, as indicated. The fourth operation consists of finishing the taper hole with a floating reamer while the bevel on the flange is being turned with a tool carried in the side-head turret. In the fifth and sixth operations, special formed tools, carried in the main turret, are used for rounding the edge of the hole and for blending the two curved surfaces.

The machining of more angular surfaces is involved in the second chucking, in which four operations are required to complete the machining of the work. With the feed gears properly compounded, the hub is rough-turned and rough-faced by the special tool *E*, carried in the main turret. While this tool is at work, the bottom flat surface of the flange is rough-faced and the outside diameter rough-turned by a tool in the side-head turret. Another angular setting of the main turret is employed in the second operation for finishing the angular surface *F*, while a hook-forming tool is carried in the side-head turret for finishing the radius. In the third step of the second chucking, the end of the piston-head hub is finish-faced while the end flat surface of the flange is being similarly machined with a hook tool carried in the side-head turret. The last operation required to complete the machining of this part employs a forming tool in the main turret to form the end of the hub and the same tool that was used in the third operation to finish-face the outside diameter of the flange. These heads are about 30 inches in diameter, and the total time required to perform the operations in which the parts are machined all over is from 1½ to 2 hours per casting.

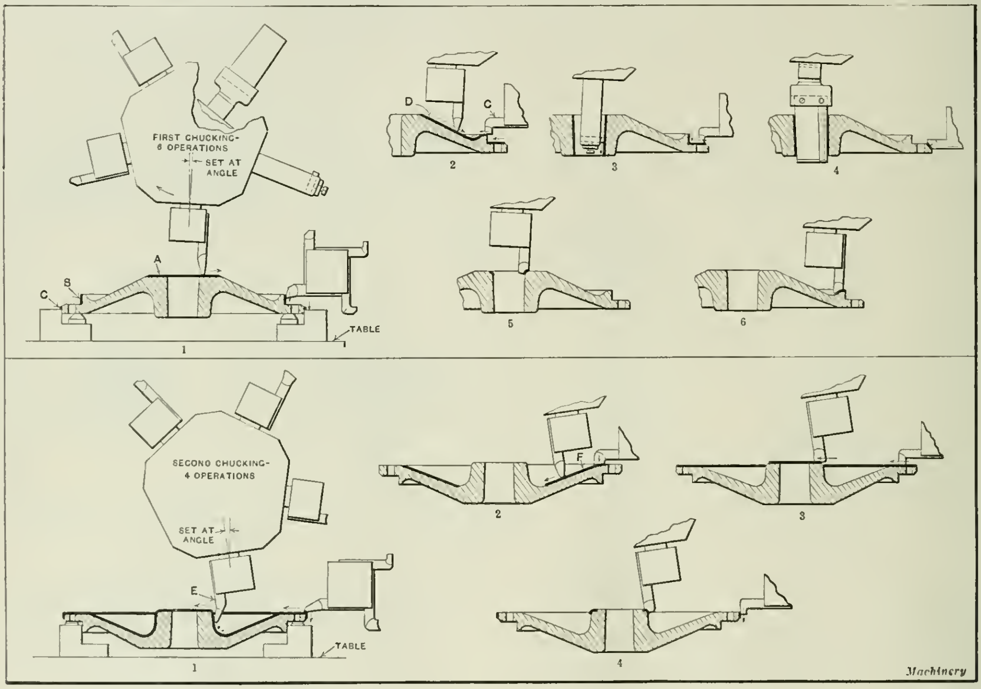

Fig. 13. Tooling Lay-out for machining a Locomotive Piston-head of the Mallet Type, showing the Method of machining Angular Surfaces

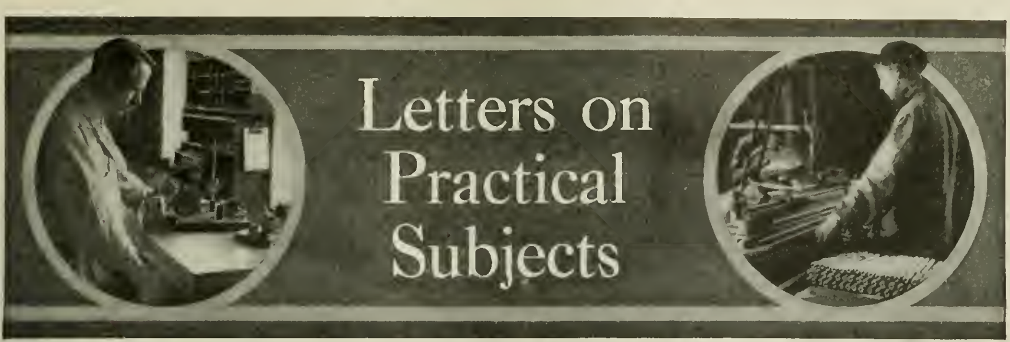
BELGIAN MACHINE TOOL INDUSTRY

A report originally published by the Bureau of Foreign and Domestic Commerce relating to Belgian machine tool trade was referred to in August MACHINERY, page 1113. We are informed by a correspondent who has specialized for twenty-five years in the manufacturing and selling of machine tools in Belgium that several of the statements made in this report are erroneous. While it is true that there are only four important Belgian plants for machine tool manufacture, two of these are located at Brussels and two in Liége, and there is none at Bruges. There are also a few other firms of lesser importance making special machine tools. In addition to the plants manufacturing machine tools there are two factories engaged in the production of wood-working machinery.

Our correspondent states that modern Belgian wheel lathes are quite equal to the best American machines, and that Belgian manufacturers do not only imitate, but have also done a great deal of development work in machine tool manufacture. Some German machine tools are said to be quite equal to those built in America, and one of the largest dealers in Liége has sold Swiss, German, French, and Belgian machine tools to the entire satisfaction of his customers.



ADJUSTABLE REAMER BLADE FOR LARGE HOLES

The machining of two large holes in revolving-frame steel castings used in the construction of steam-shovels, resulted in the development of the floating reamer blade described and illustrated herewith. One hole was required to be reamed to 9⅞ inches in diameter and was to be a press fit for a bushing. This hole was 8⅞ inches long and extended through the casting. The other hole was 10 inches in diameter, reamed for a bushing, and 13 inches long. The holes were first bored on a large radial drilling machine, using a boring-bar and an inserted-blade cutter-head. This type of tool permitted the amount of adjustment required, and the boring operation caused no difficulty. Before the adjustable blade illustrated in Fig. 1 was used, the reaming was done with a single blade placed loosely in the boring head and permitted to float during the operation. Considerable difficulty was experienced, in that the blade had to be reground with every hole in which it was used, necessitating the re-hardening and redrawing of the blade each time it was reground. In addition to this extra work, the repeated heat-treatments often resulted in checks in the finished tool at the cutting edge, rendering it useless and requiring the making of a new blade.

These difficulties were overcome in the design of the blade illustrated in Fig. 1. This one blade, by its special adjustable feature, was also used for reaming both the 9⅞-inch and 10-inch diameter holes. It will be seen that the tool consists of two members, the male half *A* and the female half *B*, which are adjusted by a suitable screw and which are fastened together by a taper pin that fits in one of the two holes *C*. The two members are fitted together by a dovetail slide to produce a fairly good push fit, and a standard No. 8 taper pin secures the two members together and makes a rigid solid tool. The construction and dimensions of the fitted members are shown in Fig. 2. It will be seen that the tapered holes for the pin are located ⅛ inch closer together in one member than those in the other half, so that by the proper selection of holes the tool is made available for either of the two diameter holes in the work to be reamed.

In regrinding this blade it is simply necessary to remove the taper pin, disassembling the two members, and replace the pin in the male member *A*. By slightly relieving the extending portion of the pin by filing, as indicated in the illustration, the tool may be lengthened the same amount, or enough to allow for regrinding. It will be understood that as soon as the two members are re-assembled and the adjusting screw brought to bear against the end of the male member, a slight elongation of the tool is accomplished. It will be seen that this device eliminates all heat-treatment after the first hardening and makes it possible if the filing of the pin is carefully done, to oftentimes put the blade into proper shape by simply slightly honing the cutting edges. The blade does not work loose under the cut and causes no trouble. It is made of high-speed steel, the taper pins are of drill rod, and the set-screw is made from machine steel. The device described in the foregoing was designed by F. Springer. L. O. K.

CARE NEEDED IN USE OF MURIATIC ACID

A cup of muriatic acid, employed as a flux for soldering, was recently left over night on the tool-room bench near a new lathe, where it had been used by the writer. In the morning it was found that the lathe ways, and other scraped or polished parts, instead of being bright and shiny, were a dull brownish color. Investigation showed that other polished iron surfaces near the cup of acid were similarly affected, evidently by the acid fumes. The writer hopes that this will serve as a warning to others against leaving muriatic acid in an open receptacle near machinery having polished surfaces, as it requires considerable polishing to remove the rust caused by the fumes of this acid.

Boston, Mass. Homer S. Tregartin

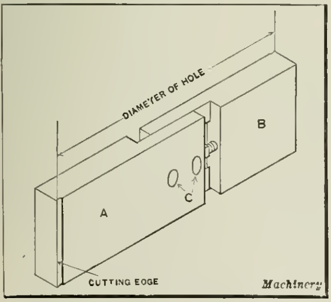


Fig. 1. Assembled Two-piece Reamer Blade

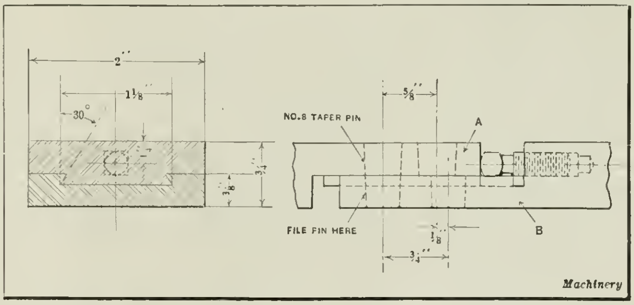

Fig. 2. Showing how Members are fastened together and adjusted

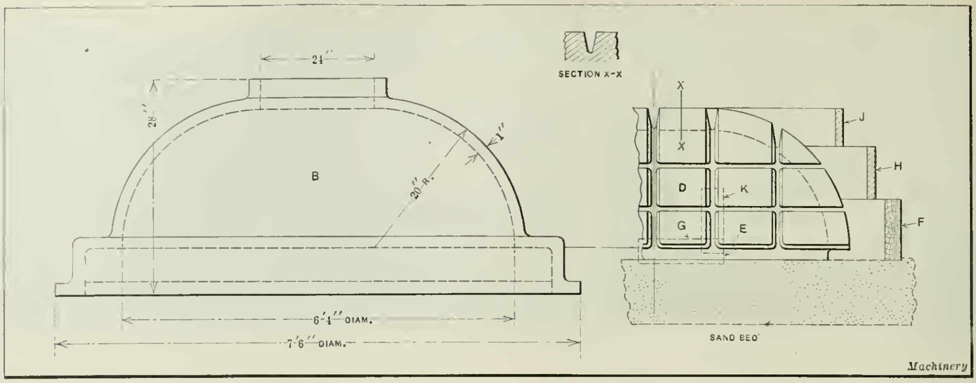

Fig. 1. Tank-head Casting and Method of molding Arbor or Sand-bar for Cope

MOLDING AN ARBOR OR SAND-BAR FOR A COPE MOLD

While on a visit to a foundry recently, the writer's attention was directed to the method employed in molding and casting the arbor or sand-bar *A*, shown in Fig. 2. This arbor was used in making the cope mold required in the production of the large tank-head casting shown at *B*, Fig. 1. The arbor was made without the use of a pattern other than that furnished for the tank-head casting. The pattern for this casting was of the simple built-up type, and was the same shape and approximately the same size as the casting to be produced, proper allowance, of course, being made to compensate for shrinkage. The molder, after looking the pattern over, decided that a very strong and rigid cope flask was required. He accordingly made a flask of steel which is shown at *C*, Fig. 2. The arbor or sand-bar *A*, required to support the heavy body of hanging sand that was to form the cope mold was next made. Ordinarily the maker of the pattern would be requested to furnish a pattern for the sand-bar, but as the casting was needed at once, the method of molding described in the following paragraphs was employed:

The pattern for the tank head shown in Fig. 1 was placed on a bed of molding sand, and the inside filled in with molding sand through the 24-inch hole at the top. When this molding operation was completed, the pattern was lifted, leaving a sand mold *D* of the form indicated at the right. At this stage there were not, of course, any grooves in the mold. With a piece of tin bent to the shape of the sand-bar, a cross-sectional view of which is shown at *X-X*, this body of sand was sectioned off by the eye, and at each section or division the sand was cut or gouged out as shown. The sand was next cut away at *E*, in order to form a flange ring at this point. When the gouging or cutting away of the mold that was to form the sand-bar had been completed, the wooden flask *F* was placed on the bed of sand. Small strips of tin, 4 inches wide and any convenient length, were placed on the mold over the grooves or slots.

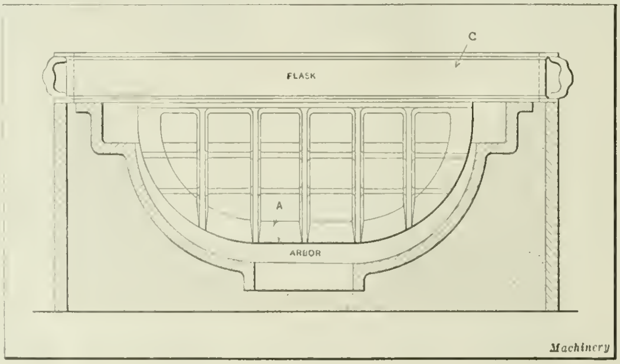

Fig. 2. Mold with Sand-bar or Arbor in Place

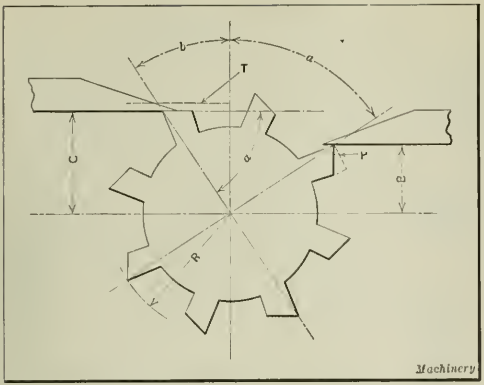
The first strips were placed over the flange-ring groove, as indicated by the dotted lines at *G*. The grooves at right angles with the horizontal grooves were also covered over with tin strips, the position of one of these strips being indicated by dotted lines at *K*. The sand was then filled in as in the making of a regular mold. Steel flasks *H* and *J* were stacked up as shown, pieces of tin being placed over the slots as the filling in and tamping progressed. When the sand had been filled in up to a level with the top of flask *J*, a pouring basin was formed at the top of the mold. This completed the mold, ready for pouring. The time required by the molder and his helper for making the mold was fourteen hours. The arbor or sand-bar casting *A* made from this mold was bolted securely to the flask, as shown in Fig. 2. The making of the mold for the tank-head casting then proceeded in the usual manner.

Kenosha, Wis. M. E. Duggan

MILLING TEETH OF ESCAPEMENT WHEEL

The following method of locating the work when milling the teeth of an escapement wheel was used by the writer with excellent results. A simple adaptation of this method also proved to be the best means of inspecting the work, as the faces of the teeth were so narrow that a sine bar could not easily be employed. The procedure followed in locating and milling the teeth was as follows: The recesses or spaces between the teeth were first milled, then the tops of the teeth, as shown by dotted lines *P*, were milled to radius *R*. The work can also be turned to diameter before milling.

The locating of the work for the operation was the difficult part of the job. After carefully removing the burrs from the work, leaving the corners sharp (although a slight rounding at the points of the teeth would probably affect the accuracy but little), the work was mounted on the dividing head and was rotated until measurement *B* was made to equal $R \times \sin b$. After clamping the work in this position, a trial cut was taken at the approximate height indicated by dotted line *T*. The height of *T* above the center



Method of setting up Escapement Wheel to obtain Correct Tooth Angle

line of the wheel was next measured by the use of a height gage, and the depth of cut required to finish the milling operation was obtained by subtracting dimension *C* from this measurement.

As an example showing how the calculations are performed let angle $a = 60$ degrees; $b = 30$ degrees; $a + b = 90$ degrees; and $R = 0.375$ inch. Then

$$B = R \times \sin b = 0.375 \times 0.5 = 0.1875 \text{ inch}$$

and

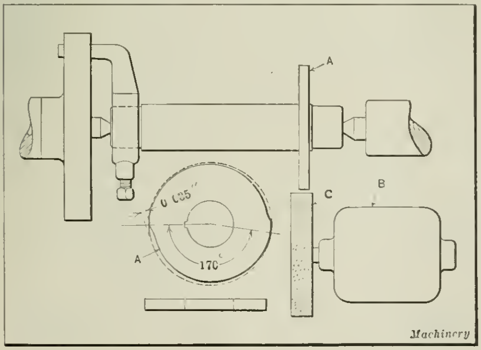
$$C = R \times \cos b = 0.375 \times 0.8660 = 0.3247 \text{ inch}$$

Cincinnati, Ohio J. F. Thornton

GRINDING A SPECIAL CAM

The special cam shown at *A* in the accompanying illustration was ground on a lathe by the use of a portable motor-driven grinder and a taper-turning attachment. The cam is about 3 inches in diameter, ¼ inch thick, and is of hardened steel. The edge or the contour is in the form of a double spiral, and the high degree of accuracy required made it necessary to use considerable care in grinding this edge. The piece was mounted on an arbor held between the lathe centers as shown, and the spiral ground by using a taper attachment and gearing the lathe as for screw cutting.

The 0.035-inch rise in the 170-degree sector was obtained by gearing the lathe for 2 threads per inch or, in other words, advancing the carriage ½ inch for each revolution of the work, and setting the taper-turning attachment to give a taper of 0.074 inch per inch, which is the rise or pitch in one complete revolution required to give a rise of 0.035 inch when the work is rotated through an arc of 170 degrees. The lathe can be geared for a finer pitch or lead,



Method of grinding a Special Cam

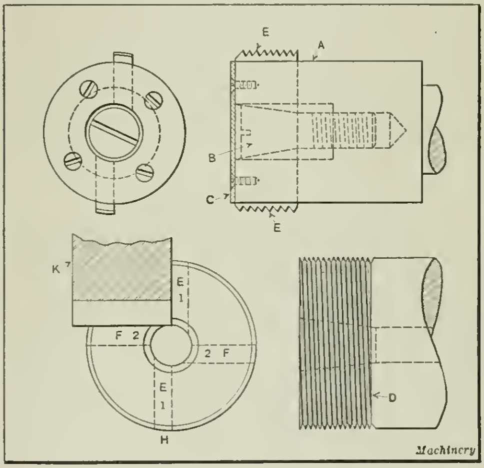
but this would necessitate setting the taper attachment to an angle which would be rather steep. The motor of the portable grinder employed is shown at *B* and the grinding wheel at *C*. The carriage on which the motor is mounted (not shown in the illustration) is run back and forth the same as in screw cutting. The compound rest is employed to feed the grinding wheel to the work.

A lathe without a taper attachment was used in a similar manner for grinding a small cam by setting the tailstock over, as in turning tapers. In this case the compound rest was set in line with the arbor. If it were necessary to grind a sharp corner at the point of drop in the cam, this could be accomplished by setting the grinding wheel in such a position that its face would cut at the upper corner only.

Providence, R. I. John T. Slocomb

ADJUSTABLE TAP

The adjustable tap shown in the upper view of the accompanying illustration was designed for tapping brass elbows to be assembled on pipes. The diameter of the threads on different lots, or orders of pipe, varied to such an extent that it was necessary to increase or decrease the diameter of the threads in the elbows to obtain the proper fit. Accordingly, the tap shown was provided with means of making sufficient adjustment to compensate for the maximum variation in the diameters of the pipe threads.



Adjustable Tap, and Blank from which Chasers are made

The tap consists of body *A*, a cone-shaped adjusting screw *B*, chasers *E*, and a cover plate *C*. The chasers were made from a piece of tool steel *D* which was threaded in a lathe to correspond with the nominal pitch and size of the required thread. Before removing this piece from the lathe, a tapered hole was bored to fit the taper of the adjusting screw *B*. After completing the threading and boring operation, piece *D* was placed on a milling machine and four cuts were taken. A section of the milling cutter is shown at *K* in the position which it occupied when taking the first milling cut. By properly indexing the work after each cut the metal was finally cut away so that only the four chasers *E* and *F* remained. These chasers were stamped with the numbers 1 and 2, as indicated in the view at *H*, after which they were hardened. It will be noted that two sets of cutters were obtained from one piece *D*, but of course only two chasers having corresponding numbers were used in the tap at the same time.

Rosemount, Montreal, Canada Harry Moore

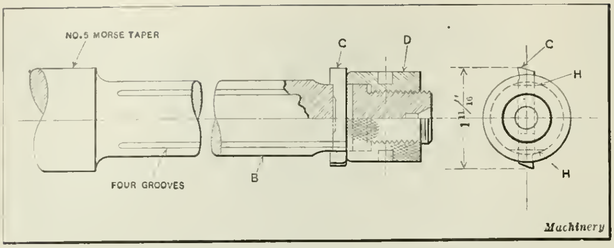


Fig. 1. Boring-bar used in boring Piston-pin Hole in Connecting-rods

FORGING LEAD MODELS FOR PRACTICE

Lead has proved to be an excellent metal for use in teaching forging practice. It requires no heating, and small models of various tools or articles can be readily forged or formed to the desired shape while cold. This is an advantage in schools or colleges when a considerable number of students are under instruction and the equipment is limited. Models for lathe and planer tools, for instance, may be formed from pieces of lead about 4 inches long, and 3/8 inch thick, by 3/4 inch wide, or 1/4 inch thick by 1/2 inch wide.

New Britain, Conn. WILLIAM C. BETZ

CONNECTING-ROD BORING-BARS

Two boring-bars used for boring the small and large bearing holes in Fiat automobile engine connecting-rods are shown in Figs. 1 and 2. These boring-bars are of the inserted-blade type, and are provided with cutter-locking features of an unusual type. In performing the boring operations, the connecting-rod is held in a horizontal position in a heavy jig. This jig is first placed on the table of a drilling machine, where the small end of the connecting-rod is drilled, bored with the boring-bar shown in Fig. 1, and reamed to fit the piston-pin. After finish-boring and reaming the piston-pin hole, the jig with the connecting-rod still in place is transferred to another drilling machine where the large, or crankshaft bearing, hole is drilled, bored with the boring-bar shown in Fig. 2, and then reamed to size.

The small boring-bar shown in Fig. 1 is made of a solid bar with the end tapered to fit the taper in the spindle of the drilling machine. A bearing *B* is ground to fit a bushing in the jig which serves to guide and support the tool. At the end of this bearing is the inserted cutter *C*, which is held in a rectangular hole in the bar. The cutter is notched to fit the dimension across flats *H*, milled in the bar at each end of the rectangular hole. This arrangement enables the cutter to be accurately located and held in place by nut *D*. Nut *D* has right-hand threads, so that any chatter of the tool will only screw the nut up tighter.

The larger bar shown in Fig. 2 is provided with a front pilot *C* which insures greater rigidity. Small cutter blades *E* inserted in holder *F* are employed, as solid cutters would be too expensive. In this design the clamping nut *A* is placed behind the cutter. Left-hand threads are used in order to keep the cutters or cutter-block tight. The inserted piece *F* is located in the rectangular hole, and has flats at *H*. The two cutter blades *E* are held securely in the slots in *F* by means of taper pins *D*. Pins *B* serve to locate and take the thrust of cutters *E*. The boring-bars described are not expensive to make and can be kept supplied with fresh cutter blades at a small cost.

Irvington, N. J. C. H. DENGLER

MEASURING DISTANCE BETWEEN CENTER-PUNCH MARKS

The device illustrated is designed for accurately spacing center-punch marks when laying out work, and for measuring or checking the distance between center marks already made in the work. The main body *A* is made of machine or tool steel, the latter being preferable. The micrometer head support *B* and the stop support *C* are made of machine steel. The measuring or marking centers *D* and *E* are made of tool steel, and are hardened and ground to a conical point having a 60-degree angle. The head support *B* should be a good sliding fit in the elongated slot in body *A*, and no up-and-down or sidewise play should be allowed. The stop support *C* is stationary in the main body, and is provided with an adjustable stop-screw *F*, which is locked in place by screw *G*. Center *D* moves with the micrometer head support *B* into which it is screwed.

Center *E* should have no play in any of the equally spaced holes in which it is inserted. The holes for center *E* are spaced exactly one inch apart, and the number of holes depends on the purpose for which the device is to be used. In this particular case centers *D* and *E* can be brought to within 2 inches of each other. In making a device of this kind, it is best to machine and assemble all the parts before boring the holes for center *E*. By bringing the spindle of the micrometer head up against the stop, it is a simple matter to locate the first hole for center *E* at a distance of 2 inches from center *D*. The positions of the succeeding holes may then be laid out and accurately machined—preferably in a milling machine.

In using this device for measuring the distance between any two center marks, it is only necessary to move center *E* to the proper hole in body *A*, and adjust the micrometer head support which carries center *D* until both points or centers are located in the punch-marks. Next

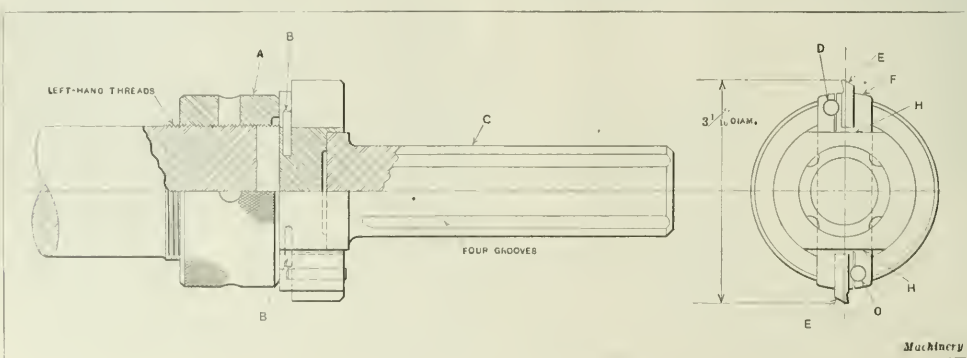

Fig. 2. Boring-bar for boring Crankshaft Hole in Connecting-rods

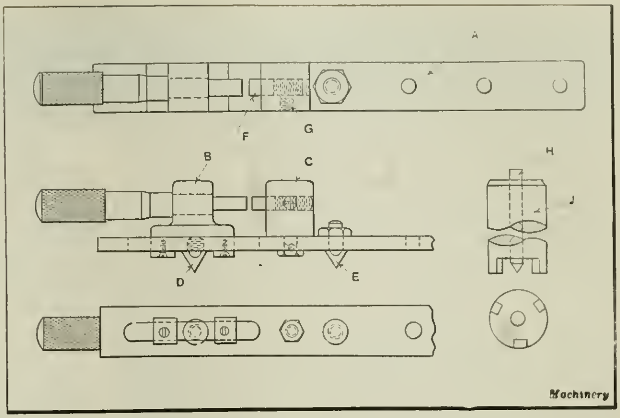
turn the micrometer head up until the spindle strikes stop F and take the micrometer reading, which will enable the distance between the center-punch marks to be accurately determined.

To lay out dimensions, centers D and E are moved to the correct positions, and a light hammer blow is given to the device above each of the centers in order to make slight impressions in the work, which may be enlarged by using the center-punch and holder shown in the lower right-hand corner of the illustration. Referring to this view, punch H is a piece of hardened drill rod ground to a conical point having an angle of 60 degrees. This punch is a sliding fit in block J which holds it in a vertical position when delivering the hammer blow.



Device for measuring Distance between Center-punch Marks

If the distance between the center-punch marks is found to be incorrect, one of the punch marks can be shifted by using an ordinary center-punch held at an angle with the face of the work. After the center mark has been moved in this way, the punch shown can be used to straighten up the center before again measuring the distance between the marks. This measuring device has proved very handy for laying out work on jigs, fixtures, and dies and it is also very dependable for measuring lengths. The writer has found that spacings aggregating many feet show a variation of but a few thousandths inch in total length when this device is used.

Ilion, N. Y. D. R. GALLAGHER

RELIEVING WORN TWIST DRILLS

Twist drills that have the lands worn down until there is insufficient relief back of the cutting edges of the flutes, or drills that have been ground down for special work, may be put into serviceable condition by regrinding in the following manner. The drill should first be trued up in the chuck of a cylindrical grinder, after which the periphery should be ground to clean up all worn portions and bring the drill down to a size, or diameter, that is commonly employed in the shop. In performing this grinding operation, care must be taken to back-taper the drill from 0.003 to 0.006 inch per foot, the amount depending on the size of the drill. This grinding should be done with a hard and comparatively fine-grained wheel. On small machines a No. 60 J alundum wheel has been found to give good results. As the cut is intermittent, on account of the flutes, and as no support is provided on the outer or cutting end of the drill, the depth of cut or feed should be light.

The drill is next placed in the V-block fixture shown in Fig. 1. This V-block and an additional block for supporting the shank of the drill are then placed on the magnetic chuck of the surface grinder in an angular position relative to the wheel, as shown in Fig. 2. After locating in this position, the drill is drawn past or under the grinding wheel, the V-block being set at an angle of about 20 degrees from the center line of the grinding machine spindle. The spring-plunger finger A, Fig. 1, guides the drill as it is pushed or drawn past the wheel, imparting a rotary or spiral motion to it. The plunger is left soft to prevent roughing or scratching the cutting edge of the drill flute. The platen of the machine, of course, remains stationary while the drill is being fed back and forth past the grinding wheel.

The amount of clearance can be regulated by adjusting the platen in relation to the wheel. In passing the drill through the V-blocks, a rotary motion is given to the work, which results in a clean-cut spiral relief back of the cutting edge of the flute. The width or amount of land may be regulated to suit the conditions of service. For the relieving operation, a No. 46 I Norton wheel is satisfactory.

New Britain, Conn. WILLIAM C. BETZ

INDUSTRIAL CONDITIONS IN RUSSIA

An almost inconceivable slump in Russian industries is indicated by the following figures compiled by the Department of Commerce from various reliable sources, showing the production of different industrial products during 1920, as compared with the production of the same products in Russia annually previous to the war: Pig iron, 2 per cent; copper ore, 0.6 per cent; rubber industry, 5 per cent; sugar industry, 5 per cent; cotton industry, 3 per cent; woolen industry, 4 per cent; coal production, 20 per cent. An average for all industries indicates that the production was less than 10 per cent of the pre-war production. The number of railway cars in running order is about one-half the number in use previous to the war. The road-beds are reported in very bad condition, and if extensive repairs are not made within the next few months, some sections of the railroads will have to be entirely closed to traffic. According to the latest estimate, at least 25,000,000 ties must be replaced. A considerable mileage of branch lines has been removed, the material being used for repairs on the main lines.

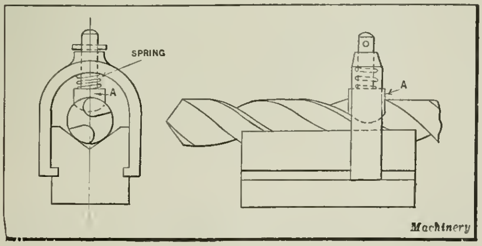

Fig. 1. V-block provided with Spiraling Device

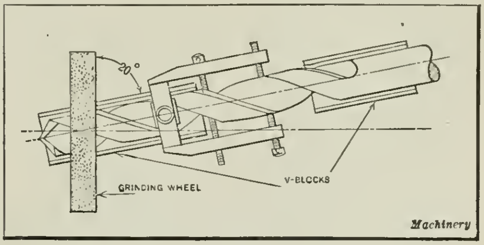

Fig. 2. Set-up for relieving Twist Drills

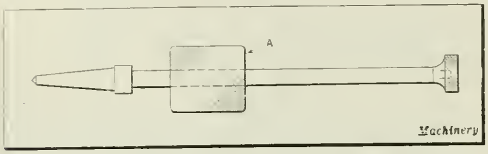
SHOP AND DRAFTING-ROOM KINKS

PRICK-PUNCH FOR ACCURATE WORK

The illustration shows a prick-punch having a long shank upon which a weight *A* may readily be slid. When desiring to produce a mark on a piece of work, the punch shank is held perpendicular to the work, after which the weight is lifted and allowed to drop on the shoulder of the punch. This tool is especially useful in laying out fine work, it being possible to produce a punch mark in much less time than with an ordinary punch and hammer. A small knurled head is attached to the upper end of the shank to prevent removal of the weight from the tool.



Prick-punch provided with Weight to facilitate the Marking of Work

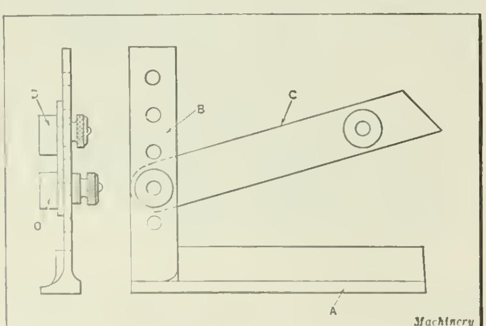
Rosemount, Montreal, Canada — STANLEY ALMOND

SINE-BAR TAPER GAGE

In turning or grinding tapers, it often happens that no suitable gage is available, and the only recourse is to gage the piece being ground by inserting it in the machine spindle or part in which it is to be used. The sine-bar taper gage shown in the accompanying illustration is designed to facilitate the gaging of the taper when performing this class of work. The simplicity of the design permits this device to be made by any skilled mechanic. The base *A* should be square with the sides and outer edge of the vertical blade section *B*. The holes in the blade must be accurately located from the bottom of the base or beam *A* and at an even distance from the outer edge of the blade. The adjustable blade *C* should be ground square, and so that its sides are parallel. The two holes for buttons *D* must be the same distance from one edge and have a given center distance, which in the case of the gage shown is 3 inches.

The procedure in setting the tool is practically the same as for a regular sine bar. It will be noted that the bottom of the beam projects the same distance as the buttons, so that micrometers may be used for setting. With this device, tapers and angles within the range of the instrument can be accurately measured.

New Britain, Conn. — WILLIAM C. BETZ



Sine-bar Taper Gage

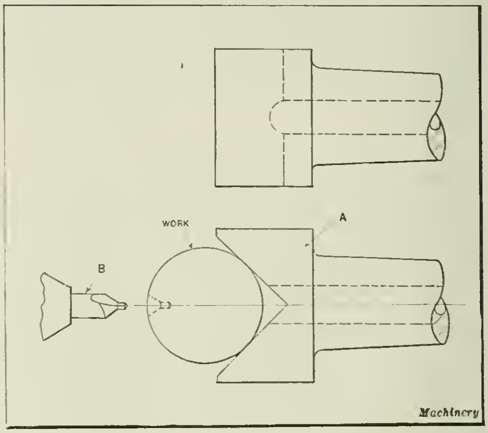
ENLARGING A REAMED HOLE

It sometimes happens that a hole is to be produced in a piece a few thousandths inch larger than the reamer will normally cut. This may be done by placing wires in two adjacent flutes of the reamer so that one side of the reamer rides on the wires, which should not project over 0.002 inch beyond the cutting edges.

New Britain, Conn. — WILLIAM C. BETZ

VEE FOR LATHE TAILSTOCK

The lathe tailstock vee shown at *A* in the accompanying illustration is intended for use in drilling small holes through round stock or such small parts as wrench handles, etc. The taper shank fits the hole in the tailstock, and has a hole drilled through the center as indicated. By placing the work in the vee as shown, then employing a center drill *B*, and afterward the size drill required, a hole can be drilled through the work that will be accurately centered.



Vee used in drilling Round Stock

Ontario, Cal. — J. HOMEWOOD

RENEWING WORN CORNERS OF DRAFTING-BOARD

The following method can be used to prevent the surface of a drawing-board from being damaged by the insertion of thumb-tacks. With a wood bit about ¾ inch in diameter, bore holes through the board near the corners where the thumb-tacks are to be inserted. Carefully measure the diameter of the hole in the board (as all bits do not bore to size) and have a hole drilled in a piece of iron plate the size of the hole in the board. Next, obtain a piece of white pine, poplar or similar wood, shave it down almost to size, and drive it through the hole drilled in the iron plate. Then, using a miter box, cut this piece into sections equal in length to the thickness of the board. Drive four of these sections or pieces into the holes in the drawing-board so that their ends will be flush with the upper surface of the board. When these pieces have become worn, it is a simple matter to reverse them in the board or insert new ones. For some work such as free-hand drawing, an ordinary cork can be used in place of the wooden plugs.

Fort Wayne, Ind. — NELSON HALL

HOW AND WHY

QUESTIONS ON PRACTICAL SUBJECTS OF GENERAL INTEREST

STANDARDS FOR COMPOSITION GEARING

W. E. G.—Have any standards been adopted for rawhide and other non-metallic gearing?

A.—Standards for composition gearing were adopted by the American Gear Manufacturers Association in 1919. An abstract of the specifications adopted was published in MACHINERY, January, 1920, page 476.

FORMING DIE PROBLEM

ANSWERED BY J. F. THORNTON, CINCINNATI, OHIO

The following method of forming a shell of the shape shown at *A*, Fig. 1, is proposed as a solution for the problem submitted by R. A. B. in April MACHINERY, page 792. The writer wishes to state that the extrusion-by-oil principle incorporated in the method to be described has proved practical for the production of similarly shaped shells of lighter material. Some experimental work, however, is necessary to obtain satisfactory results. In the problem as submitted some of the work had already been performed on the shell, and for such partially completed work the writer can offer no solution. However, it is assumed that it is not necessary to carry out the forming operations in any particular order. In producing the shell the writer would first form a straight tube having an inside diameter of 1 1/16 inches as shown at *A*, Fig. 2. The length of this tube can best be determined by experiment. After forming the straight tube, the open end should be curled in to the shape shown at *B*.

The extruding operation, which completes the forming of the shell, should be performed in a split die consisting of two members *C* and *D*, Fig. 1. One half *D* of the die is hinged, which permits the die to open on center line *X–X*. After filling the closed-in shell with an oil of low compressibility, it is inserted in the extruding die. In descending, the plunger *E* first effectually closes the vent *F*, and then as it continues on its downward stroke it compresses the oil so that it will flow to the points of least resistance as indicated by the arrows. This action forces the metal into the crevices of the die, thus giving the shell the desired form.

The writer would make the capacity of the first trial tube, as shown at *B*, Fig. 2, about 1¼ times the capacity of the finished piece. If the cubical contents of this shell are too great, the plunger cannot be forced deep enough, and if the capacity of the shell is too small, the corners of the shell will not be square. A number of small vent holes, as shown in Fig. 1, should be drilled in the hinged die member *D* to release the air which would otherwise be trapped in the corners of the die. These holes must be small or the metal will be extruded at the points where they enter the die cavity.

Some slight difficulty may be encountered in preventing the spherical form at the top of the tube shown at *B*, Fig. 2, from becoming wrinkled. It should be borne in mind that the smaller the hole at the top of the spherical end of the tube, the better will be the results obtained in the final forming operation. As a last resort, hole *F* might be closed by soldering after the tube has been filled with oil. After the last forming operation, the holes at the top and bottom of the shell may be finished by drilling.

INTERNATIONAL PATENT PROTECTION

H. A. F.—Is there such a thing as an "international patent," that is, some kind of patent that, under an agreement between various countries, will protect an inventor in a number of countries by the making of a single application? In that case, does such a patent protect a foreign inventor in the United States for a given time, and if so, for how long?

A.—There is no such thing as an international patent. Under the International Convention for the Protection of Industrial Property, inventors may file applications in the countries that have agreed to this convention at any time within twelve months from the filing of the application on which a patent would be issued in any one of the countries; but in order to obtain patent protection in the different countries, separate applications must be filed in each.

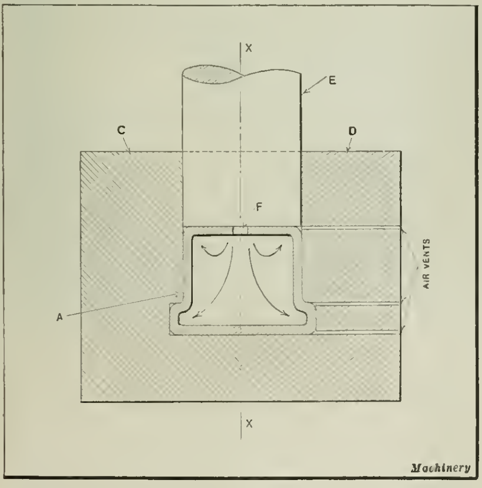


Fig. 1. Sectional View of "Oil Extrusion" Die for Final Forming Operation on Shell A

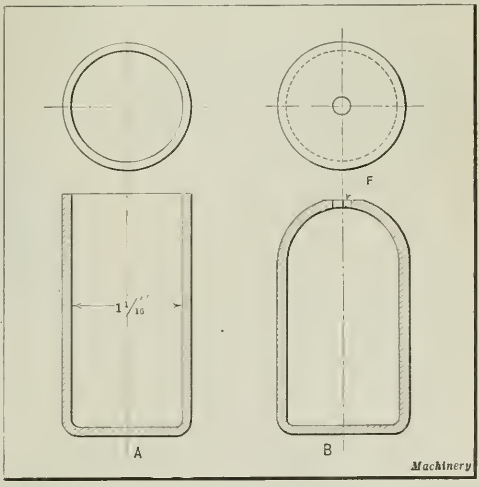

Fig. 2. Shell after First and Second Operations preparatory to forming in Die shown in Fig. 1

PROBLEM IN GAGE DESIGN

H. A. B.—In designing the gage shown in Fig. 1, a mathematical problem is involved which requires the solution of angle β. How can the magnitude of this angle be found?

ANSWERED BY W. W. JOHNSON, CLEVELAND, OHIO

A.—With the values for a, b, h, and r given in Fig. 1, the magnitude of angle β can be calculated as follows (see Fig. 2):

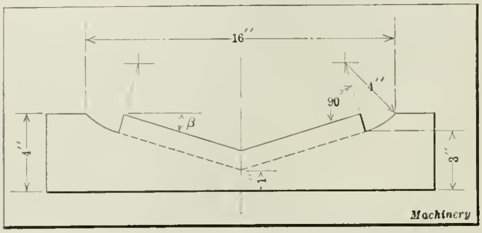

Fig. 1. Gage having Angular Surface, involving Mathematical Calculations

$$z = h \cot \beta; \text{ also } z - x = r \sin \beta$$

Then

$$x = h \cot \beta - r \sin \beta \quad (1) \qquad y = h + r \cos \beta \quad (2)$$

$$r^2 = (y - a)^2 + (b - x)^2 \quad (3)$$

Substituting (1) and (2) in (3),

$$r^2 = (h + r \cos \beta - a)^2 + (b + r \sin \beta - h \cot \beta)^2$$

Expanding and combining,

$$(a - h)^2 + b^2 - 2ar \cos \beta + 2br \sin \beta - 2bh \cot \beta + h^2 \cot^2 \beta = 0$$

But

$$\sqrt{1 - \sin^2\beta} = \cos \beta \text{ and } \frac{\sqrt{1 - \sin^2\beta}}{\sin \beta} = \cot \beta$$

Then

$$(a - h)^2 + b^2 - 2ar\sqrt{1 - \sin^2\beta} + 2br \sin \beta - \frac{2bh\sqrt{1 - \sin^2\beta}}{\sin \beta} + \frac{h^2(1 - \sin^2\beta)}{\sin^2\beta} = 0$$

Clearing of fractions, factoring, and transposing,

$$(a^2 + b^2 - 2ah) \sin^2\beta + 2br \sin^3\beta + h^2 = 2 \sin \beta \times (ar \sin \beta + bh) \sqrt{1 - \sin^2\beta}$$

Squaring both sides of the equation, combining, and arranging terms with reference to sin β, we get

$$4r^2(a^2 + b^2) \sin^6\beta + 4br(a^2 + b^2) \sin^5\beta + [(a^2 + b^2 - 2ah)^2 + 4(b^2h^2 - a^2r^2)] \sin^4\beta - 4bhr(2a - h) \sin^3\beta + 2h^2(a^2 - b^2 - 2ah) \sin^2\beta + h^4 = 0 \quad (4)$$

Substituting the known values in Equation (4) we obtain

$$4672 \sin^6\beta + 9344 \sin^5\beta + 4169 \sin^4\beta - 1024 \sin^3\beta - 536 \sin^2\beta + 16 = 0$$

Solving this equation by Horner's method, we find Sin β = 0.3000244, and angle β = 17 deg. 27 min. 33 sec.

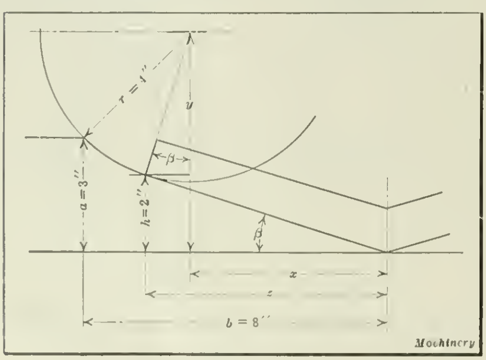

Fig. 2. Diagram used in the Solution of the Gage Angle

COST OF CYLINDER REGRINDING EQUIPMENT

H. E. W.—Will you please tell me what equipment is required for handling a small gas engine cylinder regrinding business and what would be the approximate initial expenditure?

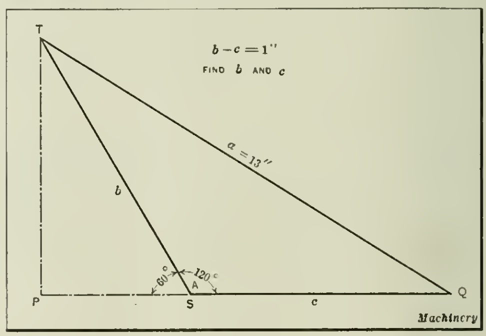
A.—It would be necessary to have a fully equipped bore-grinder, costing about \$2500 when new; a small lathe which can be bought for about \$200; a drilling machine costing about \$125; a supply of over-size pistons costing \$2.60 each, say half a dozen sizes in sets of four, representing \$62.40; piston-rings for the pistons at 30 cents a piece, \$7.20; wrist-pins, \$15; small tools, not over \$100; making a total of slightly over \$3000. If a small cylindrical grinder for external work is included (or a grinding attachment for the lathe), over-size pistons could be ground to size from the semi-finished state and their cost correspondingly lowered, resulting in ultimate economy.

DETERMINING THE LENGTHS OF TWO SIDES OF AN OBLIQUE TRIANGLE

H. W. P.—The accompanying illustration shows an oblique triangle in which the difference between the lengths of sides b and c = 1 inch; the length of side a = 13 inches; and angle A = 120 degrees. How can the lengths of sides b and c be found?

ANSWERED BY C. N. PICKWORTH, MANCHESTER, ENGLAND

In the following is given a solution to this problem which is believed by the writer to be simpler and more direct than that presented on page 580 of February MACHINERY. Referring to the accompanying illustration, continue QS to



Oblique Triangle of which the Lengths of Sides b and c are to be found

P and draw TP at right angles to PQ. It will be obvious that angle TSP = 60 degrees. Then, PS = ½ ST and PT = $\sqrt{3}$ × ½ ST. Also, if $b - c = 1$, $b = c + 1$. Therefore,

$$QP = c + \frac{c + 1}{2} \text{ and } PT = \sqrt{3} \times \frac{c + 1}{2}$$

Hence

$$\left(c + \frac{c + 1}{2}\right)^2 + \left(\sqrt{3} \times \frac{c + 1}{2}\right)^2 = 13^2 = 169$$

$$\frac{9c^2 + 6c + 1}{4} + \frac{3c^2 + 6c + 3}{4} = \frac{12c^2 + 12c + 4}{4} = 169$$

$$3c^2 + 3c + 1 = 169$$

$$3c^2 + 3c = 168$$

$$c^2 + c = 56$$

Then

$$c^2 + c + 0.25 = 56.25$$

$$c + 0.5 = 7.5$$

and

$$c = 7.5 - 0.5 = 7 \text{ inches}$$

Finally, as

$$b = c + 1$$

$$b = 7 + 1 = 8 \text{ inches}$$

DUPLEX MULTI-SPINDLE TURRET MACHINE

The machine shown in the accompanying illustrations, which is built by the Blomquist-Eck Machine Co., Cleveland, Ohio, is intended for work that is to be machined from both ends simultaneously and on which a number of turning, boring, facing, drilling, and threading operations have to be performed. The machine is entirely automatic, except that it is loaded and unloaded by the operator. It consists mainly of a revolving turret for holding the work and six work-spindles operating upon the work, three from each side, two of these being roughing spindles, two finishing spindles, and two drilling and threading spindles. The turret has eight flat faces, each with a groove in the center to receive the tongue of the work-holding fixture. While the work is being performed, the turret and the work being actuated upon remain stationary and the spindles holding the cutting tools rotate. These spindles are fed in to the work automatically by means of cams, after which they return rapidly to the outward position, when the work-holding turret is automatically unlocked, the index-plunger released, and the turret automatically indexed to the next station, at which time the index-plunger drops into the next index-hole in the turret. The turret is then automatically locked, after which the same cycle is repeated.

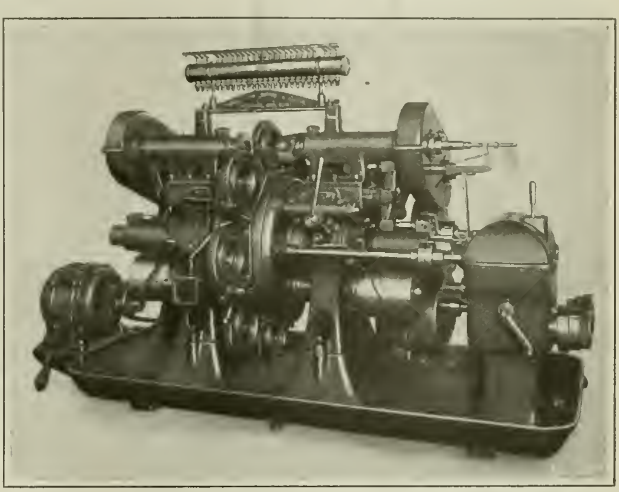


Fig. 1. Duplex Multi-spindle Turret Machine made by the Blomquist-Eck Machine Co.

The machine is motor-driven. Power is transmitted from the motor to a jack-shaft at the rear of the machine by means of a chain drive, and from the jack-shaft another chain drive transmits power to the finishing spindles; from these, in turn, power is transmitted by a chain drive to the roughing spindles. There is also a separate chain drive from the jack-shaft to the die-head and drilling spindles. These chain drives are duplicated at each end of the machine.

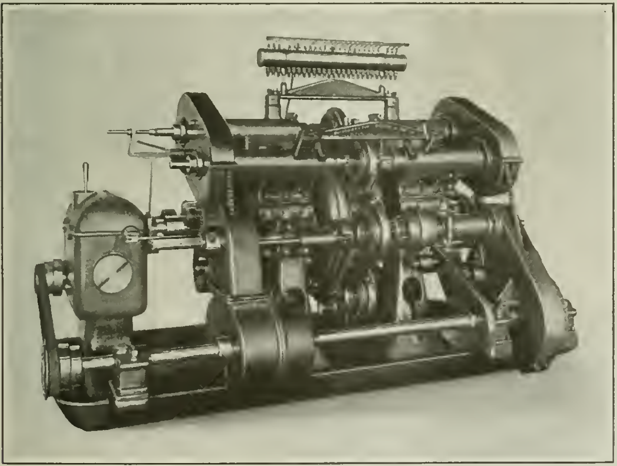

Fig. 2. Rear View of Blomquist-Eck Duplex Multi-spindle Turret Machine

The feed to the spindles is actuated from the jack-shaft through a gear-box. The drive from the jack-shaft to the gear-box is by a belt on a three-step cone pulley, from which the motion is transmitted by a pair of helical gears, and a worm and worm-wheel to a shaft geared to the shafts on which the cams are mounted. The indexing is also controlled by the mechanism in the gear-box, which is so arranged that the feed motion is temporarily disengaged while the indexing takes place. At the front of the gear-box a crank is provided for hand adjustment and for setting the spindles when setting up the machine. The gear-box runs in a bath of oil. The sub-base and pan of the machine are cast hollow and act as a reservoir for holding the oil, a pump being provided for the circulation of the lubricant.

The main advantage of the machine is its capacity for machining pieces from both ends at one setting, assuring on the one hand concentricity and accuracy in the product, and on the other, increased production because of the reduced amount of handling. The machine was originally designed for the machining of Studebaker automobile front and rear stamped steel hubs, of which a production of 520 hubs in ten hours was obtained.

The large production required in the automobile field has paved the way for special automatic machinery of the type described. The necessity for reducing manufacturing costs to meet present prices in the automobile field makes the need for labor saving machinery all the more urgent.

* * *

LABOR AND READJUSTMENT

Large classes of labor have taken their losses by severe wage cuts. Among those that have accepted them have been many skilled crafts which have seen that in the long run wages on the new basis will have a purchasing power equivalent to that when wages were higher.

Certain classes of labor contrast unfavorably, however, with labor as a whole. The time is not far distant when not only that uncertain group known as the "general public" but those sections of it consisting of other classes of workers and farmers will have come to a realization that labor pays its own wages, which are ultimately measured, not in money, but in goods. The money wage only measures the estimated worth to other consumers of the goods produced by the wage earner. When any class of labor attempts to force its wages out of line with other wages and the price level, that group endeavors primarily to take advantage, not of capital, but of other workers, who must suffer as others gain.—*National Bank of Commerce*

The Metal-working Industries

NOTWITHSTANDING present conditions in the machine tool industry, which, regarded by themselves would offer but little encouragement to those engaged in this basic field, it is not impossible, in surveying the entire metal-working field, to share the belief that a change for the better is in sight. It is natural that the machine tool industry should be in a state of depression when the iron and steel industry as a whole is declining or remaining stationary at a point of low activity. But when iron and steel show definite signs of renewed activity, there is every reason to believe that a demand for machine tools will make itself felt within a reasonable time. It has been aptly said that "the only use for machine tools is to cut up iron and steel," and unless there is some iron and steel to be cut up, there can be no demand for machine tools.

Everyone engaged directly or indirectly in the machine tool field should therefore note that all reports from the iron and steel industry confirm a continued improvement in orders, operation, and inquiries. There is slow but steady improvement in the entire iron and steel trade, from pig iron to finished products. The United States Steel Corporation, as a whole, is operating at about 35 per cent capacity, as against 25 per cent a few weeks ago, and the operation for the entire industry is placed at about 40 per cent, with 50 per cent in sight. Tin plate mills are working at considerably more than 50 per cent, and sheet mills at nearly 85 per cent of their capacity. As a consequence, prices of sheet steel have advanced $5 a ton, and prices on bars, shapes, and plates have been advanced by some companies from $1 to $3 a ton. The demand for pipe and wire is also stronger, and the market for structural materials is more active.

General Conditions in the Machine-building Field

Another indication of a slow but definite improvement in the metal-working industries is reported from the small tool manufacturers, who, in general, found the lowest point of their business reached in June or July, with a gradual gain since that time. Isolated cases of great activity in the machine-building field may also be mentioned. One large Pennsylvania engine builder operates day and night in the building of steam shovels for construction work, and another large Pennsylvania shop keeps its plant occupied on nail-making machinery. In the northern Ohio district, in and adjacent to Akron, the tire mold business shows activity. In the gear-cutting field, where the depression was felt much later than in the machine tool field, there has been considerable reduction in activity, and many plants are running at greatly reduced capacity; yet in the case of manufacturers engaged in cutting automobile service gears, very active business is reported, one manufacturer, at least, running two shifts.

Some of the gray iron foundries are running full time with full force, but prices on castings have been reduced to such a point that practically all profit has been wiped out and just the bare costs are covered. In many lines of machine tools, so substantial have been the reductions that further price cuts cannot be expected.

The Railroad Situation

Most manufacturers of medium and heavy machine tools, as well as dealers handling these lines, agree that unless the railroads are in a position to buy within the near future, there is no immediate prospect for any considerable business in this class of machines. At the present writing, just when the constantly increasing operating income of the railroads might have placed them in a position to rehabilitate their shop equipment and rolling stock, comes the threat of a nation-wide railroad strike against accepting the 12 per cent wage reduction which became effective July 1. It is most unfortunate that at the very moment when the railroads were in a position to buy shop equipment, the unions should deal them another blow from which it may take them a long time to recover.

The net railway operating income in August amounted to over $85,000,000, contrasted with the deficit of $150,000,000 in the same month a year ago; and this in the face of the fact that the railroads will pay labor in 1921, on the basis of the wages paid in the first six months of the year, $1,175,000,000 more than in 1917. Furthermore, the railroads have been seriously contemplating the reduction of freight rates, and in some instances such reductions have already taken place. All these steps toward more favorable industrial conditions may now be frustrated by the action of the railroad unions. It has been estimated that $1,600,000,000 is needed to bring the railroads of the country back to the standard of 1911. If the railroads continue to pay excessive wages, there will be nothing left for necessary improvements and equipment, and sooner or later they will have to pass into receiverships.

The Automobile Industry

The reports from different automobile manufacturers vary considerably. On the whole, automobile production is decreasing for the moment, this being the usual seasonal falling off, and the output in October is estimated to be 20 per cent less than during the previous month. Ford production, which has been at high tide for the last five months, each month breaking the record of the previous one, has dropped off from 10 to 15 per cent. On the other hand, there is an increasing demand for some of the higher priced cars, and the Cadillac and Packard plants are reported to be operating at a higher capacity than at any time during the past year. More Franklin cars were also shipped in September than during August, and in the trade this is interpreted as indicating that the purchasers of higher grade cars are convinced that industrially the country has now turned the corner. Another sign of increased activity is the report of the Motor and Accessory Manufacturers' Association, that purchases of parts have somewhat increased, and that there are fewer unpaid accounts and notes outstanding.

Labor Conditions

During the month of September, according to the statistics of the Department of Labor, there was an increase of 1.2 per cent in the number of men employed in the plants included in the Department's survey, the increases being mainly in the textile and iron and steel industry and in the railroad field. The influence of the labor unions in retarding the return of industrial activity by refusing to accept reasonable wage reductions is indicated in a statement by George E. Roberts of the National City Bank of New York, who says:

"One-half of our population is engaged in producing foodstuffs and raw materials, a considerable share of which must be exported and sold in world markets. These products have fallen almost to the pre-war level, while the products of urban industries, held up by labor costs and understandings of various kinds, have undergone comparatively slight reductions. The result is that the producers of the former goods can buy but one-half as much of the products of urban industries as formerly. There can be no revival of prosperity until a readjustment of these relations is accomplished."

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

The New Tool descriptions in MACHINERY are restricted to the special field the journal covers—machine tools and accessories and other machine shop equipment. The editorial policy is to describe the machine or accessory so as to give the technical reader a definite idea of the design, construction, and function of the machine, of the mechanical principles involved, and of its application.

How To Reduce Production Costs ?

Davis-Bournonville Tube Manufacturing Equipment

A COMPLETE line of equipment for the oxy-acetylene welding and fabricating of tubing for use in the construction of automobiles, bicycles, motorcycles, furniture, office appliances and machinery, in which strength combined with lightness is a prime requisite, has been developed by the Davis-Bournonville Co., Jersey City, N. J. This line includes gang-slitting, tube-forming, welding, straightening, seam-grinding, cutting-off, swaging and bending machines and draw-benches.

Manufacturing plants which are equipped with this line of machinery have the means for producing tubes of any common diameter and gage on short notice. Commercial steel sheets of any gage between Nos. 10 and 22 may be cut into strips, formed into tubes from 5/8 to 4 inches in diameter, and welded. Thus it is unnecessary to carry in stock tubes of many diameters and gages to meet anticipated uses, but instead, commercial sheets may be bought in the open market, as required, or sheet stock in few gages may be kept on hand ready for slitting, forming, welding and subsequent fabrication. It is generally found advantageous to purchase tube stock in strips trimmed to the required widths, as this practice results in comparatively little waste.

Slitting and Tube-forming Machines

When tubing is made from commercial sheets, slitting machines are required to cut the sheets into strips suitable for the forming operation. The lengths of tubing before drawing are limited to the length of the sheets used. If tubing is produced from strip stock, a slitter is not required unless it is necessary to trim the strips to width, in order to insure uniformity and smooth edges. A gang slitter is shown in Fig. 1. The shafts of this machine are made of alloy steel, ground and fitted with keys for the entire working length. Provision is made for simultaneous adjustment of the bearings, thus maintaining accurate alignment. The cutters are made from steel forgings, accurately ground, and are resharpened by face-grinding, which results in the original settings being maintained. The cutters are used in opposed pairs and are set up by means of wide and narrow ring spacers.

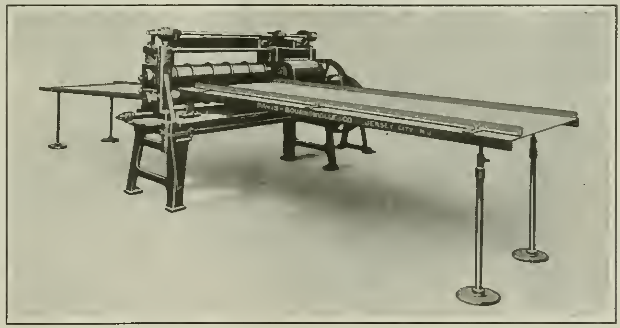

Fig. 1. Machine for slitting Commercial Steel Sheets, which is built by the Davis-Bournonville Co.

One end-bearing housing may be drawn off the shafts through the operation of a screw, and then swung out of position to permit the removal of cutters and spacers. The latter can be changed in a few minutes. Tables having a width equal to that of the widest sheet which can be accommodated by the machine are placed on each side of the cutters, the feed table being equipped with adjustable guides. The power is conveyed to the machine through a friction clutch, and the normal cutting speed is 50 feet per minute. Gang slitters are built by this company in various styles and sizes for cutting steel sheets ranging from 18 to 52 inches in width and up to No. 10 gage in thickness.

Tube stock, whether cut from mill sheets or supplied in rolled strips, must be form-rolled preparatory to welding. The Davis-Bournonville tube-forming mills are of the two- and three-roll stand types, the former being illustrated in Fig. 2. It comprises a break-down and finishing roll stand. The machine is operated by one man who handles both the strips and the formed tubes. A

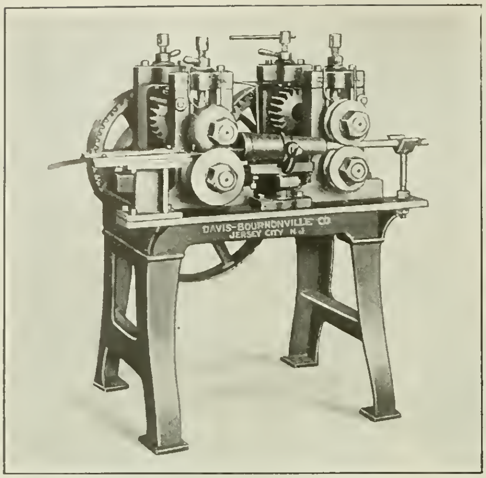

Fig. 2. Two-roll Stand Type of Tube-forming Mill

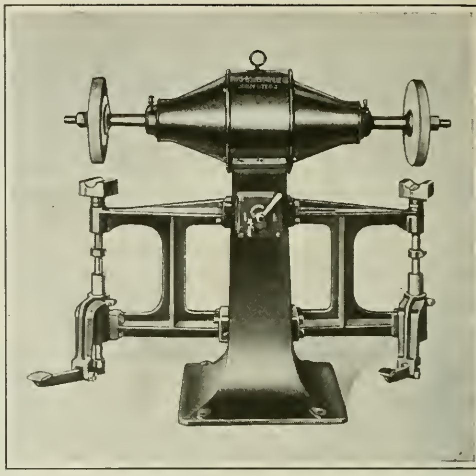

Fig. 3. Machine for grinding off Ridge produced in Welding

hollow conical conductor between the roll stands completes the forming started by the first pair of rolls, and the second pair compresses the formed tube into a truly circular shape. Adjustments of the tube-forming rolls may be made while the machine is in operation. The speeds are from 50 to 100 feet per minute, depending on the diameter and gage of the material being operated upon. The three-roll stand tube-forming mill is similar in construction and arrangement to the two-roll type, except that it is provided with an extra stand of rolls.

Tube-welding Machines

From the tube-forming machine the tubing goes to a welding machine and thence to an inspector's station at which unwelded spots are welded by means of hand torches. The No. 1 tube-welding machines illustrated in Fig. 4 are built for right- or left-hand operation, and with or without a motor drive and push-button control. The usual power equipment comprises a 230-volt adjustable-speed direct-current motor, field rheostat, magnetic control panel and push-botton station, with reverse. There are thirty-six different speeds, which is ample for all gages of metal and diameters of tubing within the capacity of the machine. The motor drives through a belt, and dynamic braking gives instant control. Starting, stopping, and reversing of the machine are effected without shock. The rolls are individually adjustable for alignment, and the guide rolls are adjustable relative to the welding rolls. The welding rolls are vertically adjustable to compensate for the stresses produced by the contraction of the cooling metal.

The welding torches used on these tube-welding machines are of the multiple-flame type, the number and arrangement of flames varying with the gage and diameter of the tubing, speed of welding, and kind of metal. The larger tips are

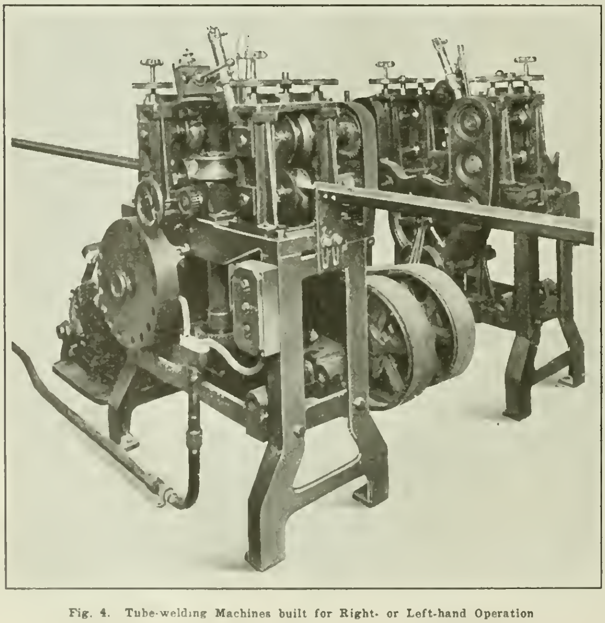

Fig. 4. Tube-welding Machines built for Right- or Left-hand Operation

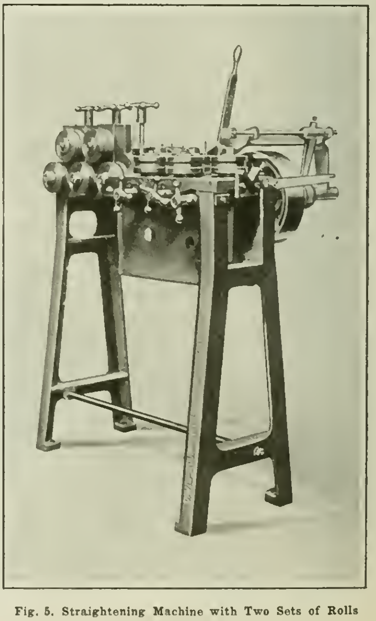

Fig. 5. Straightening Machine with Two Sets of Rolls

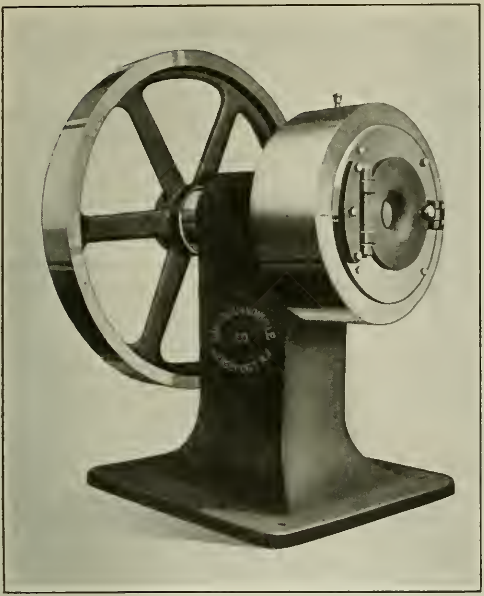

Fig. 6. Rotary Swaging Machine with Ten or More Rolls in the Head

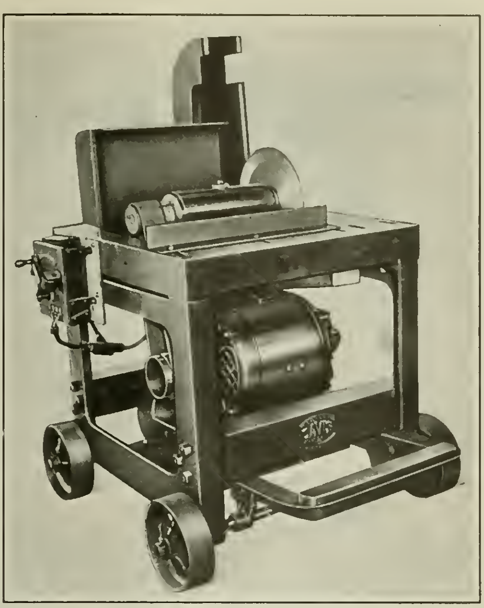

Fig. 7. Motor-driven Tube-cutting Machine having an Oscillating Head

water-cooled in order to maintain uniform heating conditions, the cooling water being circulated through the tip and then into the barrel of the torch. Rolls are furnished for any diameter of tube from ½ to 3 inches, inclusive, and the welding speeds vary between 36 and 72 inches per minute. Conductors are placed between the welding and finishing rolls for tubes 1¼ inches and smaller in diameter. A universal torch-adjusting arm is supplied with these machines when required.

An important feature of the No. 2 tube-welding machine is the overhung mounting of the rolls, which facilitates changes. This machine is supplied for right-hand operations only. A two-speed gear change in the base, together with an adjustable-speed motor, provides variations in welding speeds ranging from 24 to 168 inches per minute. The bearings subjected to heat are cooled by the circulation of water through cored spaces in the housings. Welding at the higher speeds is facilitated by the provision of two sets of following rolls. The No. 2 welding machine has a capacity for welding tubes ranging in size from 1¼ to 4 inches diameter, and up to No. 10 gage.

Straightening Machine

The next machine used in the process of tube manufacture is the straightening machine shown in Fig. 5. This machine is built in three sizes, all of which are of the ten-roll type having rolls arranged in two sets of five each, the axes of the rolls in one set being placed in a horizontal plane, while those of the other set are placed in a vertical plane. Three rolls of each set are power driven, and the last roll in each set is adjustable. The two idler rolls are mounted on studs attached to cross-slides provided with a screw adjustment. The No. 1 machine has a capacity for straightening tubes up to 1 inch in diameter; the No. 2 machine, up to 2 inches in diameter; and the No. 3 machine, from 1½ to 3 inches in diameter.

Seam Grinding Machine

From the straightening machine, the tubes go to a seam-grinding machine for the removal of the slight ridge produced in the welding operation, or else they go to a draw-bench. When the tubes are finished by drawing, it is unnecessary to grind off the flash, as this is smoothed out in the drawing process. The grinding machine shown in Fig. 3 is designed to grind off the flash rapidly and to provide for uniform wear of the grinding wheels across the face. The tube passes under the wheel at an angle while supported in a formed rest elevated by foot pressure. The machine is driven by a 7½-horsepower alternating-current ball bearing motor having a large-diameter armature shaft that extends at each end, on which the grinding wheels are mounted. The foot-control pressure mechanism and the tube guides are arranged to enable the grinding of tubes at any desired angle. As the wheel faces wear concave, the grinding of flat spots is obviated. The machine is so designed that two operators may work simultaneously, one on each end of the machine. The motor has an integral starting device and is of any standard voltage and frequency.

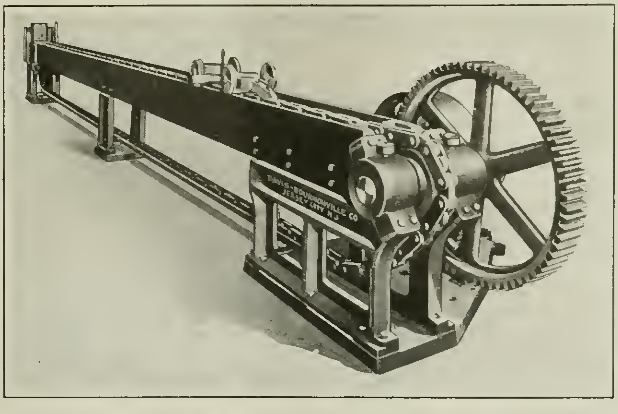

Fig. 8. No. 1 Draw-bench which has a Capacity for Tubes up to 2 Inches in Diameter and No. 14 Gage

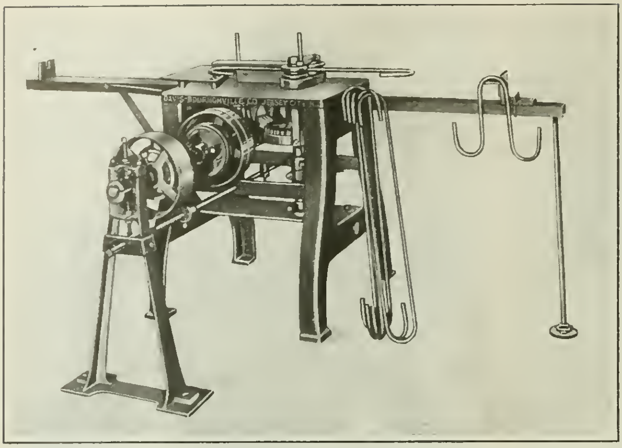

Fig. 9. One Style of Tube-bending Machine developed by the Davis-Bournonville Co.

Swaging and Cutting-off Machines

Tapered tubes and a great variety of shapes are produced by swaging. A swaging machine of the rotary type, using ten or more rolls in the head, and so designed and constructed that its operation is practically noiseless, is shown in Fig. 6. The dies have cam surfaces that engage the rollers easily, and produce a smooth acceleration. This machine is made in three sizes, each of which may be fitted with dies of different lengths, but the swaging is not limited by the length of the dies. Mechanical feeding devices are furnished when required, as well as equipment for special work. The roll cages and shafts are made from forgings machined all over, and the rolls, dies, and hammers are made from special alloy steel, hardened and heat-treated. The maximum die dimensions on the No. 1 machine are 1 3/8 inches in diameter and 2 1/4 inches in length; on the No. 2 machine, 2 inches in diameter and 4 inches in length; and on the No. 3 machine, 3 inches in diameter and 5 inches in length.

A motor-driven machine designed for the rapid cutting of tubes is shown in Fig. 7. The motor is mounted on the base of an oscillating cutting head which carries the saw arbor. The cutting head is held back against a stop by means of a coil spring, and is actuated by a foot-treadle through a mechanism which enables the operator to exert the required pressure of the saw on the tube without undue fatigue. The saw is usually 14 inches in diameter and from 3/32 to 1/8 inch thick. A 5-horsepower motor of any suitable type drives the saw at speeds of from 3000 to 4000 revolutions per minute. All exposed working parts are guarded by hinged covers.

Draw-benches and Bending Machines

The No. 1 draw-bench, which has a capacity for drawing tubes up to 2 inches in diameter and up to No. 14 gage, is illustrated in Fig. 8. The No. 2 draw-bench has a capacity up to 3 inches in diameter and up to No. 14 gage. The machines are made in various lengths, and their construction embodies a single heavy steel H-section bolted between head and transmission castings. The chain is of the usual construction, and runs over a steel sprocket driven through double reduction gearing. It is adjusted by a grooved idler wheel, the bearings of which slide in slots in the head casting. The dog is made of steel castings mounted on rollers running on the beam flanges. The dog jaws are machined to accommodate removable grips which may be serrated or machined to grip round tubing without marring it. The draw-benches are equipped with back benches for drawing tubes over a plug or mandrel, when necessary. The driving clutch is operated through a shaft running the length of the bed and having a lever at the head of the bench.

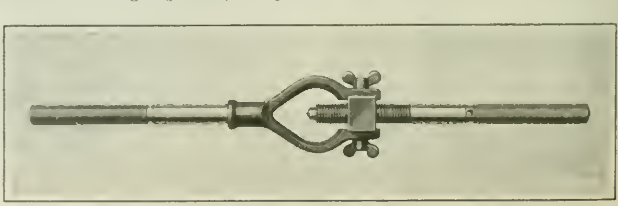
Three regular styles of tube-bending machines are also made. The No. 1 machine illustrated in Fig. 9 has a maximum bending radius of 8 inches; the No. 2 machine, of 12 inches; and the No. 3. of 35 inches. A special No. 2 machine will bend to a radius of 25 inches, while a special No. 3 machine can also be built for bending to a larger radius than the regular type. The standard machines are equipped with double clutch pulleys for operation in either direction. The Nos. 2 and 3 machines are provided with power attachments and a back bench when required. The power attachments are made in various forms suited to the class of work to be done, and operate a rack to which is attached a plug that gives internal support when bending. The rack that controls the plug may be operated by power in either direction.

The main drive of the machines is through reduction gearing and a steel worm which drives a bronze worm-wheel, or a cast-iron worm-wheel provided with a bronze band for the teeth, the construction depending on the work for which the machine is employed. The oscillating tube carriage, carrying the roll, vise, and other parts, is mounted on the same shaft as the worm-wheel. The carriage is so designed as to enable tools for any diameter of tube and bending radius to be readily mounted in place. A stationary half-die furnished with the oscillating members is actuated by a cam, screw, or in conjunction with a follower.

The construction of the bending mechanism makes possible the bending of light-walled tubing without wrinkling or distortion. A dog directly beneath the worm-wheel, which operates on adjustable knock-outs, limits the angle to which a bend is made. These bending machines are suitable for bending tubes of all kinds of metal, of any shape, and to angles not exceeding 180 degrees. The operating levers are so located that a machine is readily controlled by one operator. The number of bends made per hour vary with the length, diameter, and angle, and is usually between 60 and 120.

MARTIN DIE-STOCK

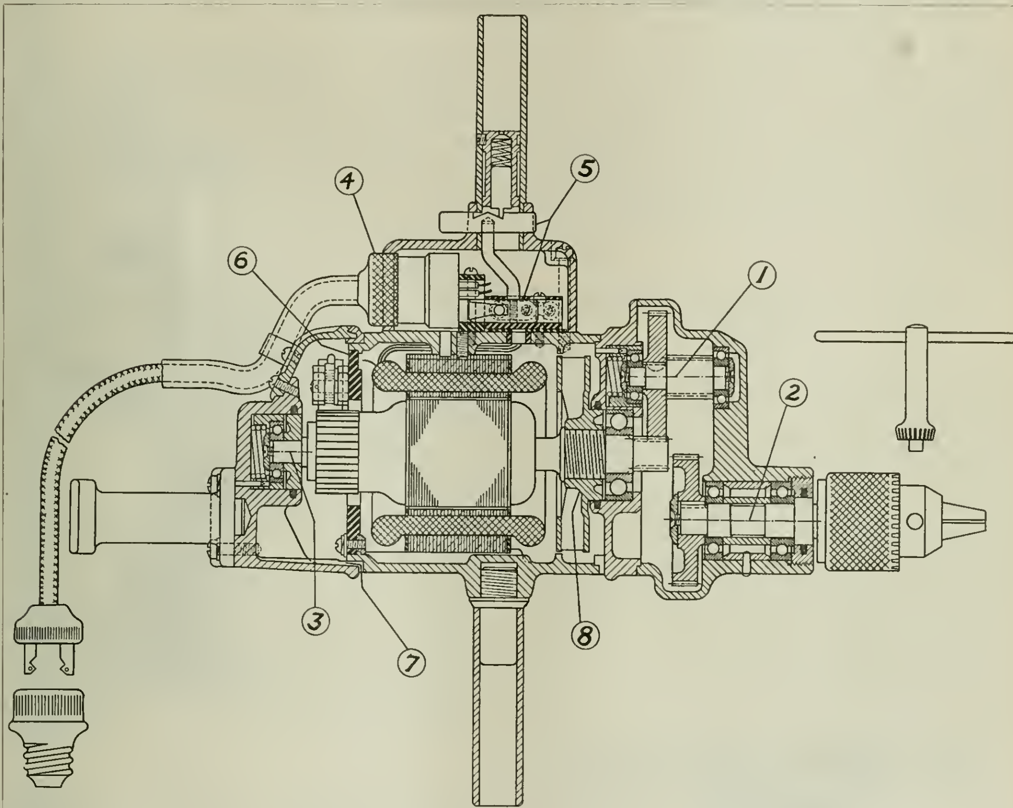
The No. 8 "All-In-One" die-stock shown in the accompanying illustration has just been placed on the market by the Martin Machine Co., Inc., Turner Falls, Mass. This stock will take round dies ranging from 5/8 to 2 1/4 inches in outside diameter. The loose handle of the stock may be quickly adjusted to line up with a spot hole in the side of a die by means of a sliding block, which is then held firmly in place by tightening two thumb-screws. The point of the die-stock which engages the spot hole of the die is made of hardened tool steel to withstand wear. The advantage of this tool is the possibility of using one stock for dies of various diameters. It is especially intended for the use of machinists, garage men, and plumbers.



No. 8 "All-In-One" Die-stock made by the Martin Machine Co., Inc.

HISEY-WOLF PORTABLE ELECTRIC DRILL

Two sizes of a universal portable electric drill equipped with ball bearings throughout have lately been brought out by the Hisey-Wolf Machine Co., Cincinnati, Ohio, under the trade name of "Super." The Type 38 KU has a capacity for drilling holes up to 3/8 inch in diameter, while the Type 50 KU drills holes up to 1/2 inch in diameter. The distinctive features of this drill may be seen in the accompanying illustration, which shows a sectional view. The motor is built by the Hisey-Wolf Machine Co., and patents are pending for its design. All revolving spindles, three of which are shown at 1, 2, and 3, are fitted with ball bearings. Coil springs are also provided at the bearings to allow expansion and contraction of shafts to take place without resulting in distortion, which is likely to occur with fixed bearings. The quick cable connector 4 permits cable repairs and renewals to be made without dismantling the drill; hence such repairs can be accomplished with a minimum loss of time. Switch 5 is patented and, although externally mounted, is protected by a removable handle cover.



Cross-sectional View of "Super" Universal Portable Electric Drill made by the Hisey-Wolf Machine Co.

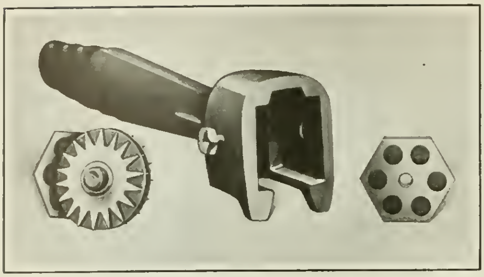
The brush-holder yoke 6 is made of bakelite, and is not affected by oil, moisture, or atmospheric conditions. The complete yoke is adjustable and the brushes can be shifted without dismantling the equipment. Forced ventilation is obtained through vents such as shown at 7, which are so designed that all cool incoming air must pass over the commutator and brushes before being drawn through the motor and expelled. The fan, which is shown at 8, is so designed and mounted as to prevent the lubricating grease in the gear head from working into the motor parts.

LOSHBOUGH-JORDAN INCLINABLE PRESSES

Two recent additions to the line of inclinable presses built by the Loshbough-Jordan Tool & Machine Co., Elkhart, Ind., are known as the "No. 5 Special" and the "No. 0." The No. 5 special press is identical with the regular No. 5 machine described on page 1155 of August, 1918, MACHINERY, except that the die space is 12 inches, whereas on the regular machine it is only 7 inches. The No. 0 press is similar in design to standard presses of the inclinable type built by this concern, but it is of smaller dimensions, some of which are as follows: Opening in bed, 3 by 5 inches; opening through back, 5 1/2 inches; depth of throat, 3 1/2 inches; adjustment of stroke, 4 1/2 inches; and standard stroke, 1 inch. The pressure exerted by the slide is between 5 and 7 tons, for which approximately 1/2 horsepower is required. The weight of the machine is about 300 pounds, and when supplied with a floor stand, 475 pounds.

"DESMOND-HEX" GRINDING WHEEL DRESSER

The accompanying illustration shows the disassembled parts of the "Desmond-Hex" grinding wheel dresser which has just been placed on the market by the Desmond-Stephan Mfg. Co., Urbana, Ohio. An important feature of this dresser is that the parts subject to wear can be readily replaced. The inside of the handle jaws are machined to accommodate hexagonal members having a tapped hole at the center to receive a set-screw, by means of which they are secured to



New Design of Grinding Wheel Dresser made by the Desmond-Stephen Mfg. Co.

the handle. These hexagonal members are provided with six circular recesses, any of which may serve as a bearing for the spindle carrying the cutters. Wear during use will be on these recesses, and as a set becomes worn, the hexagonal members are given a sixth turn and the spindle of the cutters advanced to the next set. When all the recesses have been worn out, new hexagonal members may be substituted. The dresser is made in two sizes, one for cutters 1½ inches in diameter, the other for cutters 2⅜ inches in diameter. The small cutter is intended for use on ordinary grinding wheels, while the other size is for large and coarse wheels.

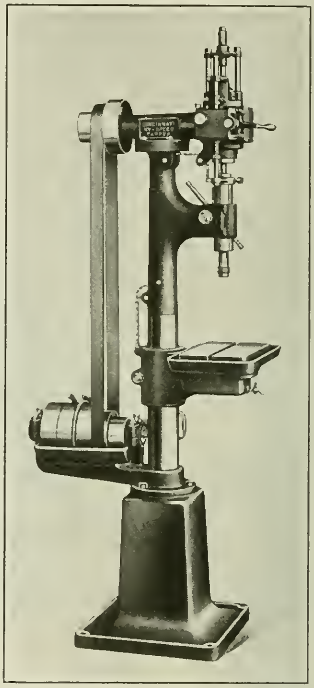
BLOUNT BALL-BEARING BUFFING MACHINES

The J. G. Blount Co., Everett, Mass., has just placed on the market a line of ball-bearing buffing machines consisting of three sizes. The No. 5 machine illustrated is the medium size. The design of these machines is very similar to that of the regular buffing machines manufactured by this concern, but an added feature is the S K F ball bearings contained in dustproof mountings, with which they are equipped. The bearings are secured to the spindle by a light driving fit and lock-nuts. The spindles are made of a high-carbon steel, ground to size, and carefully balanced before fitting to the head. A taper point is fitted to the right-hand end of the spindle to accommodate small wheels. The contact surfaces of all parts bolted together are planed or milled to insure a rigid unit. The head can be furnished separate, for mounting on a bench. The countershaft may be of a self-oiling type or equipped with Hyatt roller bearings.

No. 5 Ball-bearing Buffing Machine built by the J. G. Blount Co.

CINCINNATI HY-SPEED AUTOMATIC TAPPING MACHINE

The Cincinnati Hy-Speed Machine Co., Cincinnati, Ohio, has recently developed and placed on the market a line of tapping machines, the operation of which may be semi- or full-automatic. One of these machines is shown in the accompanying illustration. Among the features of these machines are a patented spindle lead and an automatic reversing mechanism. Through the use of the spindle lead device, the tap is fed and returned in a positive way entirely independent of the operator, it being stated that holes are tapped accurately without danger of threads being stripped or taps broken. By giving the stop-plunger at the side of the control handle a half turn, the machine is changed from semi- to full-automatic, or vice versa. When set for semi-automatic operation, the spindle feeds downward, reverses automatically, and stops at the end of the return stroke. To cause the spindle to feed again, the operator merely pulls down on the control lever.



Semi- and Full-automatic Tapping Machine placed on the Market by the Cincinnati Hy-Speed Machine Co.

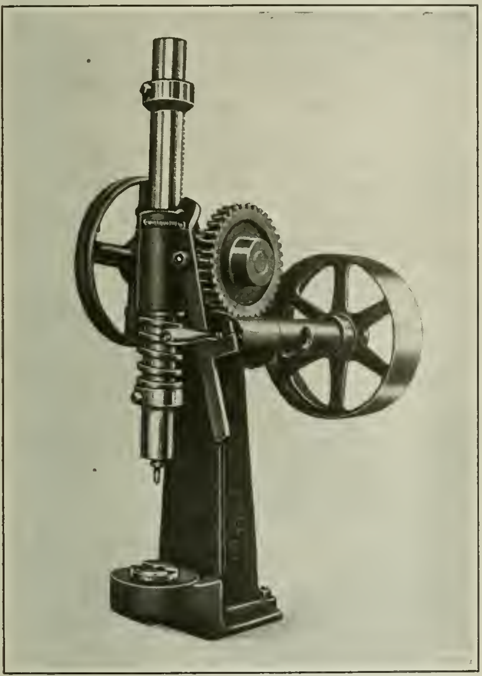
When set for full-automatic operation, the stop-plunger is withdrawn, and the spindle then reverses automatically at each end of its travel. The spindle can be stopped at any point, reversed and fed again, through the operation of the control lever. Adjustable dogs with limit stops on a trip-rod regulate the depth to be tapped. The chuck is driven by a clutch-end on the spindle, and is locked in position. The machines are equipped with S K F ball bearings throughout, and are regularly furnished for right-hand tapping, but an attachment is included to enable left-hand tapping operations to be performed, this attachment being quickly secured to the end of the rack sleeve. The machines are built in styles having from one to three spindles, and in two sizes of which the maximum tapping capacities are ½ and ⅞ inch diameter in steel, respectively. The ½-inch machine is equipped with tight and loose pulleys, while the ⅞-inch machine is equipped with a single-pulley direct overhead drive. In addition to the type illustrated, the machines are also built in bench and belted motor-drive styles.

THREE- AND FOUR-WAY INDEX-BASES

In July, 1920, a description appeared in MACHINERY of a two-way index-base for milling and drilling machines, etc., which had been brought out by the Industrial Engineering Co., 407-425 E. Fort St., Detroit, Mich. By means of this index-base, work can be placed on one side of the fixture table while another part is being machined diametrically opposite. Then when the operation on one piece has been completed, the table can be indexed 180 degrees to bring the unfinished part in line with the cutters. The same company has now placed on the market two more styles of bases which can be indexed to three and four positions, respectively. These bases are made the same dimensions as the original style, 10 and 16 inches in diameter, and the mechanism is based on the same principle.

AMERICAN BENCH BROACH PRESS

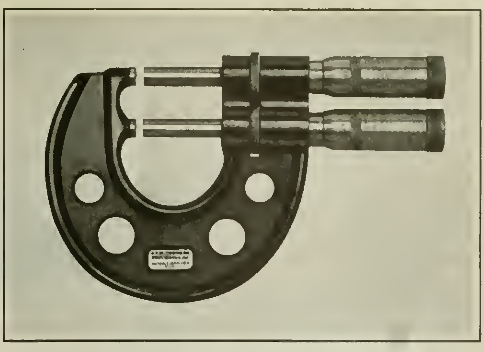
A power broach press of a bench type which is being placed on the market by the American Broach & Machine Co., Ann Arbor, Mich., is here illustrated. This machine is intended not only for push broaching operations, but also for pressing into place or removing mandrels, bushings, etc. The machine is driven through a pulley 10 inches in diameter, having a face width suitable for a 2½-inch belt. Power from the driving shaft is transmitted through worm-gearing to a steel pinion that engages rack teeth cut directly on the ram. The worm-gearing has a 30 to 1 reduction. The worm is arranged to disengage automatically at the end of a predetermined stroke, through the medium of a collar at the upper end of the ram. Automatic return of the ram is effected through a weight and cord, the rack being wound in a groove around the handwheel. The machine has a stroke of 14 inches, and the bore in the table is 2½ inches in diameter.



Combination Broaching and Assembling Press developed by the American Broach & Machine Co.

SLOCOMB SNAP GAGE MICROMETER

In order to eliminate the necessity of having a large number of snap or limit gages on hand, the J. T. Slocomb Co., Providence, R. I., has brought out a duplex micrometer intended for use as an adjustable limit snap gage. The gaging surfaces are the anvils and spindles of two micrometers, which are set in the frame of the instrument. The construction will be apparent by reference to the illustration. This design enables any dimension within the range of the micrometers to be gaged by merely setting one spindle to the "Go" dimension and the other to the "Not Go" dimension. Provision is made for locking the spindles after they have been set. Application has been made for a patent covering this instrument.

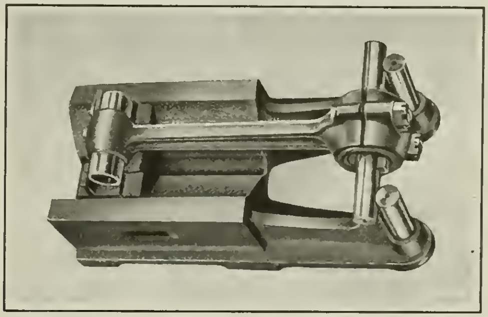


Micrometer Snap Gage produced by the J. T. Slocomb Co.

ALLEN CONNECTING-ROD ALIGNING FIXTURE

A fixture for testing the parallelism of holes and the twist in automobile engine connecting-rods is now being manufactured by the Allen Wrench & Tool Co., Public St., corner of Eddy St., Providence, R. I. From the illustration it will be seen that the base of the fixture is a heavy iron casting having a 45-degree scraped V-bearing for the accommodation of a sliding member. This slide has horizontal and vertical surfaces on which the projecting ends of the wrist-pin in one end of a rod are seated while the rod is being tested. A special arbor is inserted in the crankshaft bearing of the connecting-rod; this arbor rests on two horizontal seats and makes contact with two vertical posts secured to the base. It is held in the bearing by means of a sliding key tapered on the under side to fit a keyway on the arbor, and an eccentrically bored steel bushing that is slotted to receive the projecting tapered key. This construction enables the upper side of the key to bind against the bearing cap as the key is advanced by lightly tapping on its end.

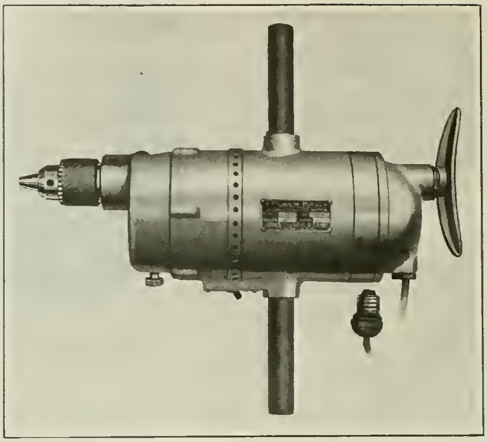
By the use of the eccentric bushing and sliding key it is possible for the outside diameter of the bushing to be slightly less than the diameter of the crankshaft bearing, and so the bushing makes contact on one side of the hole and the taper key diametrically opposite. This feature eliminates the necessity of pressing the bushing into place, and greatly facilitate its removal. The wrist-pin, arbor, and vertical



Fixture made by the Allen Wrench & Tool Co. for detecting Inaccuracies in Conneoting-rods posts are made of steel, hardened and ground to size. By placing a connecting-rod on the fixture in the manner illustrated, and bearing down on the wrist-pin to produce an even contact on the slide, the twist in the rod can be readily detected either by sight or by placing feelers between the under side of one end of the arbor and the seat upon which it is intended to rest. Similarly, if the wrist-pin is held securely against the vertical faces of the slide, deviation from parallelism of the two holes is shown by a space between a post and the corresponding end of the arbor.

The accuracy with which the wrist-pin holes are machined in the piston may be checked by assembling the piston on the connecting-rod and then placing the entire unit on the fixture after the slide has been removed so that the piston will have a two-point bearing in the vee. Inaccuracies are then determined by using the arbor in the crankshaft bearing of the rod in the same manner as when ascertaining the parallelism of the wrist-pin hole with the crankshaft bearing hole. For general garage use it is necessary to provide two arbors, one 1¼ inches in diameter for Ford cars, and another 1½ inches in diameter for other types of automobiles. A complete set of bushings ranges from 1¾ to 2½ inches in outside diameter, varying by increments of ⅛ inch. It is stated that inaccuracies of 0.001 inch can be detected. A pair of bench vise jaws are supplied as auxiliary equipment for use in straightening rods.

JONES, MAC NEAL & CAMP PORTABLE ELECTRIC DRILLS



One of a Line of Portable Electric Drills manufactured by Jones, MacNeal & Camp

The "Power King" portable electric drill shown in the accompanying illustration is made in eight sizes of various capacities for drilling up to 1 inch in diameter, by Jones, MacNeal & Camp, 522 S. Clinton St., Chicago, Ill. Each drill has a patented two-speed mechanism and is equipped with a universal ball-bearing motor. The two-speed mechanism enables the equipment to be used effectively for drilling in either metal or wood and with either carbon or high-speed steel tools. The drill consists of three distinct units; the unit on the drilling end contains all gears and the speed-shifting mechanism. The middle unit contains the motor, switch, and wiring, and the handle end is a protecting cap of sufficient strength to take pressures from a jack or to resist shocks produced by a fall. Combined radial and thrust ball bearings are placed at each end of the driving shaft, and ball bearings are also provided for the motor shaft. The brushes are easily accessible for inspection. A standard three-jaw chuck, interchangeable with a No. 2 Morse taper socket, is supplied as regular equipment. The switch is of the quick make-and-break type and is mounted for convenient operation.

ONSRUD GRINDING TURBINE ATTACHMENTS

A small pneumatic turbine equipped with a grinding arbor, which has been brought out by the Onsrud Machine Works, Inc., 3908-3932 Palmer St., Chicago, Ill., was referred to in October MACHINERY. The accompanying illustrations show two attachments for this turbine which may be supplied to increase its field of usefulness. The attachment shown in Fig. 1 converts the turbine into a bench machine, and thus provides a convenient equipment for the light grinding and sharpening of tools, cutters, dies, and taps. This unit may be used as a portable equipment or it may be mounted permanently in one place. The attachment illustrated in Fig. 2 makes the turbine suitable for the accurate grinding of 60-degree centers. A detachable plug is inserted in the spindle of the tailstock, and a bracket mounted on this plug holds the face of the grinding wheel at the proper angle so that when the tailstock is advanced on the center, the latter will be ground correctly. The tailstock plugs make the attachment applicable to both large and small machines.

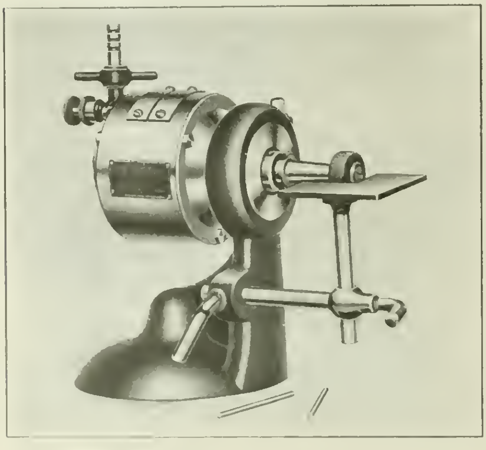


Fig. 1. Bench Stand for Pneumatic Grinding Turbine made by the Onsrud Machine Works, Inc.

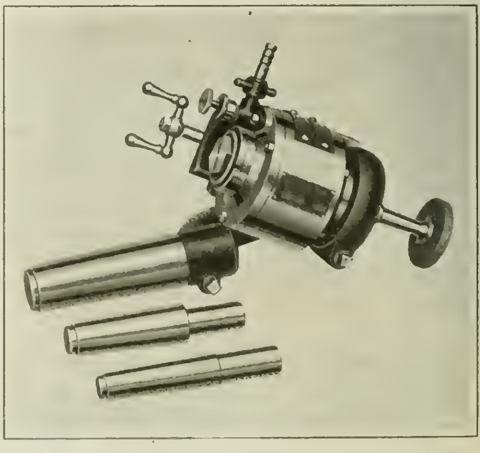

Fig. 2. Attachment which adapts the Pneumatic Turbine for grinding 60-degree Centers

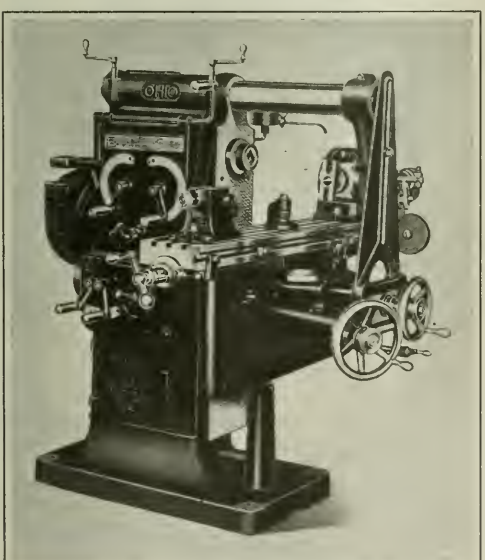
OHIO ALL-GEARED MILLING MACHINES

The Oesterlein Machine Co., Cincinnati, Ohio, has placed on the market a line of milling machines of the constant-speed or all-geared type consisting of six sizes, each of which is made in both plain and universal styles. The No. 2 universal machine is here illustrated. The speed mechanism furnishes sixteen geometric speeds through fifteen gears and 1 shaft, in addition to the spindle and pulley shaft. Speed changes are effected by means of "two-position" levers and a "four-position" knob, the latter controlling the selection of four adjacent spindle speeds. All speed changes may be made without stopping the machine.

Each gear is made from a low-carbon forging that is put through annealing, carburizing, and hardening processes and is sand-blasted to remove furnace scale. Automatic lubrication of the machine is effected by a system of three reservoirs; in the first of these, which is located in the top of the column, the fresh oil is poured. This oil seeps through felt and runs down tubing to cavities cast under the main spindle bearings, the intermediate shaft bearings, and the driving pulley. The oil is carried to the spindle bearings by means of wicks that dip into the cavities under the spindle. By this arrangement only fresh oil is admitted to the bearings that are heavily loaded. The oil passing through these bearings overflows into a second reservoir from which it is distributed to the speed gears and minor bearings by splash lubrication. The overflow from the second reservoir passes to the speed-box, which is the third reservoir, this being also oiled by splash lubrication. The capacity of the first reservoir is sufficient to supply the machine for about two months of ordinary service. Provision is made for raising the level of the oil in the last reservoir if the established level should decrease.

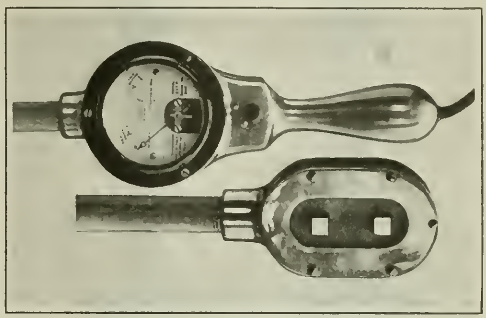
The driving pulley on each machine is 14 inches in diameter and runs at the rate of 400 revolutions per minute. A brake designed for stopping the spindle quickly is connected with the belt-shifter in such a way that as the belt is partially carried to the loose pulley, the brake is applied to the tight pulley by means of a spring-plunger releasing mechanism. The feed-box, knee, and table are similar to those supplied on the cone-type milling machines built by the same concern.



No. 2 All-geared Universal Milling Machine developed by the Oesterlein Machine Co.

"CRIT-POINT" HEAT-TREATING INSTRUMENT

Several years ago, the "Crit-Point," an instrument used in hardening steels, was placed on the market by the Gibb Instrument Co., Detroit, Mich. Patents and manufacturing rights for this instrument have now been taken over by the Illinois Testing Laboratories, Inc., 430 S. Green St., Chicago, Ill., and the instrument has been completely redesigned. The device is employed to indicate when the critical points are reached in heat-treating steels so as to enable the work to be hardened between these points. Steels lose their magnetic properties when heated to the decalescent point, and the principle upon which the device is based is to detect the absence of the magnetic properties.



Instrument made by the Illinois Testing Laboratories, Inc., for indicating Critical Points when heat-treating Steel

The instrument is used by making contact with the work in the furnace through the medium of special iron cores surrounded with two heat-proof electromagnets forming a small transformer, these coils being connected to the source of current and a suitable voltmeter. When the steel being heated becomes non-magnetic, a small amount of current is imparted to the voltmeter, causing the indicator on the instrument dial to move to the position marked "critical point." The dial end of the instrument is shown in the upper portion of the accompanying illustration while the end placed in contact with the work is shown in the lower portion, these two ends being connected by a long rod. This device is made in two types: Model 220 P is a portable unit, which is used by attaching it to a conveniently located electric light socket. Model 220 W is intended for use as a permanently installed instrument in connection with suitable switch and wire arrangements. Such an installation permits the use of one large instrument on several furnaces. Modifications of the fire-end are possible to permit its use with special shaped articles and under unusual conditions.

ST. LOUIS GRINDING AND POLISHING MACHINES

Among a complete line of grinding and polishing machines lately developed by the St. Louis Machine Tool Co., 932 Loughborough Ave., St. Louis, Mo., are the machines shown in the accompanying illustrations. The machine to the left in Fig. 1 is a grinding machine, while the machine to the right is equipped for polishing. A machine of the same general design but arranged for mounting a grinding wheel on one end of the spindle and a polishing wheel on the other end, is also built. Each machine is driven by belt from a fully enclosed motor of the repulsion start induction run type, either single- or three-phase squirrel-cage. The three phase motor will operate on only three-phase lines at one voltage, while the single-phase motor will operate on a one-, two- or three-phase current and at 110 or 220 volts. A

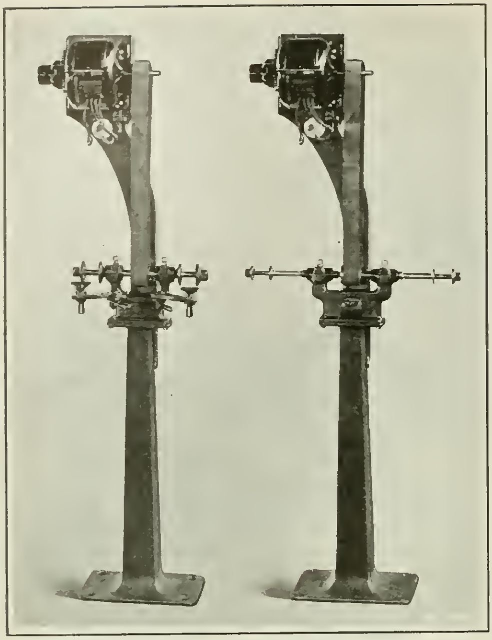


Fig. 1. Grinding and Polishing Machines of a Line brought out by the St. Louis Machine Tool Co.

direct-current motor may also be supplied. The wheels on the grinding machine are driven at a surface speed of 5000 feet per minute, and those on the polishing machine, at a surface speed of 7500 feet per minute. These machines are made in a large range of sizes and in stationary and portable types. The weight of the smallest size of portable machine is 170 pounds, and that of the largest, 290 pounds.

The heavy floor-type grinding machine illustrated in Fig. 2 is built in three sizes for which the dimensions of the grinding wheels recommended are 18 by 3 inches, 20 by 3 inches, and 24 by 4 inches, respectively. The arbors are made from 0.40 per cent carbon steel and have coarse-pitch square threads. The machine is driven through a pulley which may be either of a plain or cone type as desired. The bearings are provided with large oil chambers, which are filled and drained through a pipe connection at the back, so arranged as to prevent overflow of oil. The weight of the smallest size of this machine is 700 pounds, and that of the largest, 1000 pounds.

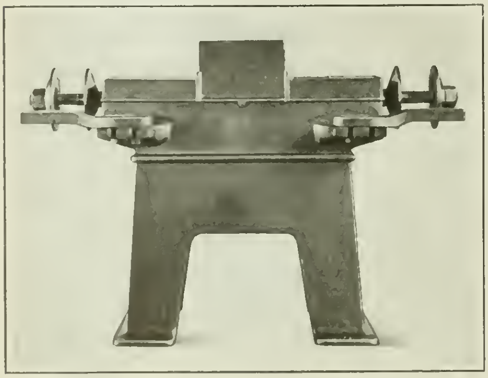

Fig. 2. St. Louis Heavy Floor Grinding Machine

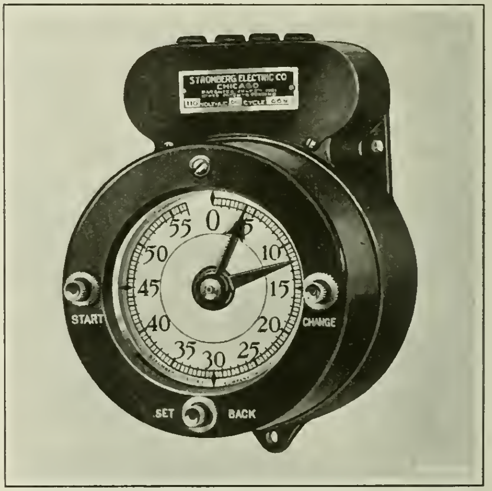
STROMBERG PROCESS TIMING AND SIGNALING INSTRUMENT

For use in manufacturing processes where the element of time is a factor, such as the heat-treatment of steel and rubber, the molding of insulating materials and enameling, plating, etching, and similar operations, the Stromberg Electric Co., 209 W. Jackson Blvd., Chicago, Ill., has developed a line of timing and signaling instruments, one of which is here illustrated. Each instrument is driven by a small synchronous motor connecting to any convenient alternating-current circuit. There are two indicating hands for the dial which are enameled red and black, respectively. The red pointer is set to indicate the length of the process, after which it remains stationary while the arrow indicator travels from this point to zero. When the latter point is reached, the duration of the process is at an end, and a signal (either a light or a bell) is operated until stopped by the attendant. At any position of the arrow pointer, the remaining time of the process can be ascertained by noting the graduation to which the pointer indicates.

Three buttons on the face of the housing control the indicating hands. By pushing in the one on the right and turning it, the setting hand may be placed to any graduation on the dial. By means of the button at the bottom of the case, the arrow hand, after having reached zero, may be quickly returned to the position of the setting hand for

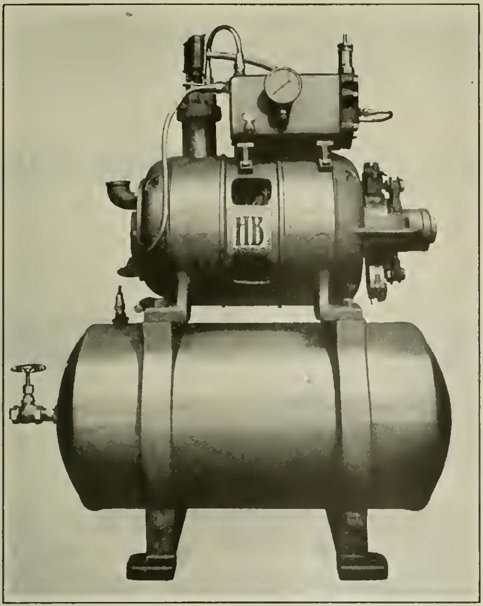


Process Timing and Signaling Instrument developed by the Stromberg Electric Co.

a second process of the same duration. The third button is used to start the arrow hand toward zero. The instruments are made with four standard dials which are graded in seconds, three-seconds, half-minutes, and minutes, respectively, and the maximum lengths of process which can be timed are 3 minutes 48 seconds, 11 minutes 24 seconds, 57 minutes, and 1 hour 54 minutes, respectively. The instrument illustrated is equipped with the 57-minute dial, so that the setting hand indicates twelve minutes while the arrow hand points to four minutes.

HOBART AUTOMATIC AIR COMPRESSOR

Automatic maintenance of air pressures between 125 and 140 pounds per square inch, or higher, in compressed air lines is the service for which the direct motor-driven compressor here illustrated has been designed by the Hobart Bros. Co., Troy, Ohio. An interesting feature of the outfit is a pressure release or magnetic pressure unloader, which

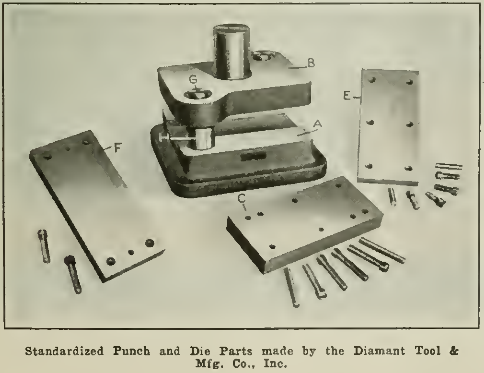


Gearless Automatic Air Compressor brought out by the Hobart Bros. Co.

automatically holds open the compressor valve until the motor develops full speed, and then releases when the outfit begins pumping. The pump is mounted directly on the motor shaft. The motor operates at a speed of 600 revolutions per minute, and is equipped with ball bearings to insure quiet running. The motor and pump housing is mounted directly on the tank, and on top of the motor and pump housing are located the air and oil filter, air gage, and automatic switch which starts up the motor without attention. This method of assembling the unit has resulted in a compact equipment. The current for the motor may be supplied from a light or power line.

DIAMANT STANDARD PUNCH AND DIE SETS

Certain detail parts of punch and die sets are invariably the same as regards shape, size, and the method of machining, and in order to reduce the cost of punches and dies and to enable sets to be provided for a new job with minimum delay, the Diamant Tool & Mfg. Co., Inc., 95 Runyon St., Newark, N. J., is manufacturing, on a quantity production basis, a line of standard parts that are complete in every respect except for the die openings and the holes for inserting punches in the punch-plate. Referring to the illustration, the standard parts consist of die-shoe *A*, punch-holder *B*, die blank *C*, stripper-plate *E*, punch-plate *F*, liner pins *G*, liner pin bushings *H*, and the necessary dowels and screws.



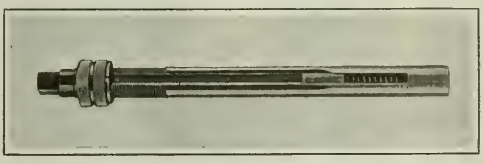
Standardized Punch and Die Parts made by the Diamant Tool & Mfg. Co., Inc.

When the designing stage of a die has been completed, a diemaker can take one of these sets and, by machining the openings in the die, stripper- and punch-plate and assembling the parts, have the die quickly ready for use. Although the dowel holes are shown on the parts in the illustration, these holes are not drilled when the parts are supplied to a customer, because different conditions control their location. The die blank is made of an oil-hardened tool steel, and is from 0.006 to 0.010 inch over size in width to allow for shrinkage in hardening and for final grinding of the sides.

In addition to the style of die-shoe illustrated, one is made with U-lugs at the ends for securing it to the machine, instead of having a flange running around the base. The slot in the die-shoe may run lengthwise or crosswise, or the shoe may be furnished without any slot. A set is also made with both liner pins at the rear rather than placed diagonally as shown. When a customer does not want all the parts mentioned, a four-component set, consisting of a punch-holder, die-shoe, liner pins, and liner pin bushings, can be furnished. All sets are made in a number of sizes.

LARSON ADJUSTABLE REAMER

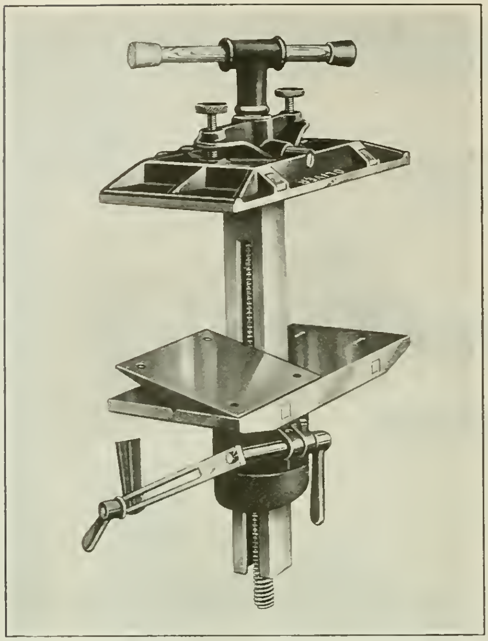
An adjustable reamer known as the "Larson," which is being manufactured by the Standard Tool & Supply Co., 651 S. Polk Ave., Mason City, Iowa, is designed especially for reaming the bushings of automobile pistons. In use, the reamer is inserted through both bushings, thus insuring proper alignment, and then expanded by turning the adjustable nut so as to permit the spring in the reamer at the opposite end to actuate the cutter-blade. One complete turn of the adjusting nut causes the reamer to be enlarged 0.001 inch. The cutter-blade is of a double-edge type, so that it can be rotated in either direction. It can be readily sharpened, replaced, or shimmed up.



Tool for reaming Bushings of Automobile Pistons which is made by the Standard Tool & Supply Co.

OLIVER NO. 1 UNIVERSAL VISE

A recent product added to the line of patternmakers' and woodworkers' equipment manufactured by the Oliver Machinery Co., Grand Rapids, Mich., is a No. 1 universal vise, which is shown in the illustration with the jaws in horizontal positions and an angle jaw in place. The usual mounting of this vise, of course, is with the jaws in vertical planes. The jaws are 7¼ inches wide, 18 inches long, and open up to a distance of 16 inches. The steel screw for the jaws has a double-buttress thread and a self-centering and detachable nut which can be readily removed for replacement. The jaws may be clamped in any position about a complete circle. The angle jaw is detachable and used with small irregular shaped pieces. The locking bar is flat and so prevents slipping of the vise, regardless of the position in which the jaws are set. The swiveling front jaw pivots at the center,

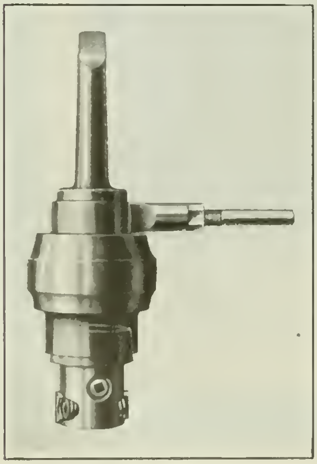


Vise for Woodworkers and Patternmakers, which is a Recent Product of the Oliver Machinery Co.

and therefore, can be set by means of thumb screws to take a wedge-shaped piece. Work can also be clamped on parallel sides without resetting the adjusting screws. The tilting feature of the jaws makes the vise convenient for working on frames and box forms. Dogs provided on the jaws facilitate the clamping of irregular and thin work.

JARVIS FRICTION TAPPING DEVICE

The feature of the Jarvis Style FD tapping device here illustrated, which is now being introduced to the trade by the Geometric Tool Co., New Haven, Conn., is a cone friction drive that is controlled by the pressure exerted on the machine spindle with which the device is employed. The dotted lines in the illustration indicate the relative size of the friction cone. Little pressure is necessary to drive this tool, and the starting and stopping of the tap while the spindle is rotating is under a free control. The device is equipped with a standard chuck. The tapping range is from 0 to 1/4 inch in diameter, the device being suitable for the tapping of light holes in tough metal.

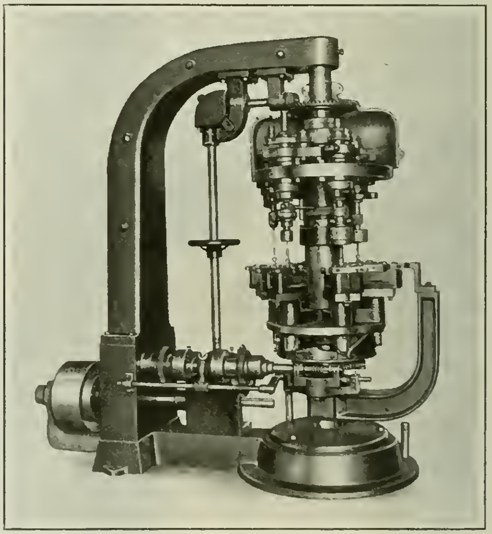


Jarvis Friction Tapping Device sold by the Geometric Tool Co.

JACKSON VERTICAL AUTOMATIC CHUCKING MACHINE

The Jackson vertical automatic chucking machine described in December, 1920, MACHINERY is now being brought out in several redesigned types by the Vertomatic Mfg. Co., Third and Buttonwood Sts., Reading, Pa., one of which is shown in the illustration. Type A is intended for work requiring a series of from three to five operations at one setting, such as spotting, sizing, facing, threading, and tapping. Type B is for work requiring two or three operations. These two machines are identical in construction, except that Type A has six chucks and five active spindles while Type B has four double chucks and three pairs of spindles. By providing one less spindle than the number of chucks, one chuck can be unloaded and loaded without interfering with the continuous operation of the machine.

The Type C machine is for work requiring but one operation or two operations performed by a combination tool, such as the facing and tapping of nuts or the pointing and threading of bolts. Types A and B are indexing machines on which the spindles remain stationary while the chucks are fed to the tools, independently of each other, at the desired speed and to the proper height, by the use of cams. When the chucks are dropped, the chuck turret is indexed to the next working position. On the Type C machine, each



Vertical Automatic Chucking Machine redesigned by the Vertomatic Mfg. Co.

spindle is mated with a certain chuck, and operates on the work placed in that particular chuck. The chuck and the spindle turrets are locked together and rotated in one direction. As the chucks leave the loading station they run up a continuous cam so that the work is raised to the tool in the spindle. The work is ejected when returned to the loading station. The machines are automatic throughout.

* * *

The College of the City of New York announces a course in cost reduction, largely in the interests of those already actively engaged in manufacture or commerce. The course is principally devoted to an analysis of the causes of expenses that may be either prevented or reduced, and to various financial, technical, organizational, or other remedies. Concrete examples from machine shops, foundries, etc., will be presented, and definite methods for reducing costs of material and labor and of overhead will be included.

NEW MACHINERY AND TOOLS NOTES

Gas Pressure Regulator: Alexander Milburn Co., 1420 W. Baltimore St., Baltimore, Md. A pressure regulator intended for the control and delivery of acetylene, oxygen, hydrogen, and other gases under high pressure, such as are used in welding. This device is said to maintain a constant predetermined pressure, regardless of fluctuations in the initial pressure line and variations in consumption at the torch.

Oil Reclaiming Outfit: S. F. Bowser & Co., Inc., Fort Wayne, Ind. An outfit adapted for reclaiming different kinds of lubricating oils, but especially intended for use on oils employed in internal combustion engines. The apparatus is said to restore the oil to its original viscosity, flash-point, and purity. The outfit is made in two sizes with capacities of 50 and 100 gallons, respectively, per twenty-four hours.

Adjustable Boring-bars: Power-Vosberg Co., Detroit, Mich. Adjustable boring-bars made in three styles (the angle adjustable, straight adjustable, and removable block types) for boring holes from 7/8 to 15 inches in diameter. These bars are intended for both rough- and finish-boring and reaming, and can be used on drilling machines, lathes, boring mills and other machine tools. The sales agent is the Firmhil Machine Supply Co., 602 Kerr Bldg., Detroit, Mich.

Combination Lathe and Grinding and Drilling Machine: Electric Motor Mfg. Co., Ludington, Mich. A combination machine sold under the trade name of "Utility," which is designed to handle a wide range of repair work requiring lathe, drilling, and grinding operations. The machine is driven by an electric motor, and is intended for bench use. The grinding wheel is mounted on the motor shaft, while the lathe spindle is driven from the motor shaft by gears.

Bench Drilling Machine: Model Specialty Co., 401 E. 19th St., New York City. A small portable bench drilling machine weighing only 34 pounds, which is intended for accurate work and all-around shop use. The column is high enough to permit objects up to 18 inches in height to be drilled. The table can be tilted to any angle and locked in position. The spindle is driven directly from a motor, and the head carrying the spindle and the motor can be positioned at any point on the column.

Brinell Hardness-testing Punch: Case Hardening Service Co., 2279 Scranton Road, Cleveland, Ohio. A punch for quick hardness testing by the Brinell method. A spring hammer in the barrel delivers to a 1/4-inch steel ball inside the cap at the bottom, a blow of sufficient force to make a depression of three millimeters diameter or less, according to the hardness of the test piece. The test is accomplished by gripping the knurled barrel of the punch and pressing downward quickly until the spring hammer is released.

NEW BOOK ON EMPLOYMENT METHODS

Employment Management, Wage Systems, and Rate Setting. 103 pages, 6 by 9 inches; 32 illustrations. Published by The Industrial Press, 140-148 Lafayette St., New York City. Price, $1.

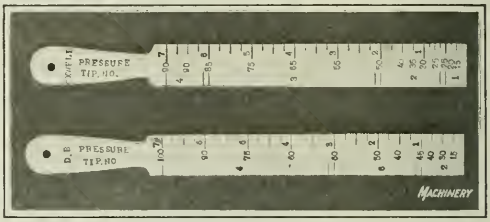
Haphazard methods of hiring men and of determining their compensation have probably caused more dissatisfaction on the part of labor and greater production losses to manufacturers than any other single factor. In addition to the manufacturers' losses the losses of employes due to being placed at work for which they are not adapted, are also very great. No doubt such losses are to some extent unavoidable, but more care on the part of those who hire would eliminate a large percentage of this waste. The problem expressed in simple language is to fit the "round pegs" in round holes and the "square pegs" in square holes.

This treatise deals with systems for use in employing men and placing them where they can do the most effective work; it also covers wage payment systems, explains the fundamental principles involved, and presents certain approved plans for determining compensation on the basis of individual merit. Articles on these different subjects previously published in Machinery aroused such interest among shop executives that it was decided to use them as the basis for this treatise, especially in view of the fact that the systems described have proved successful in well organized manufacturing plants. This material was contributed by several authorities, including W. D. Stearns, Secretary of the Occupations and Rates Committee of the Westinghouse Electric & Mfg. Co.; John C. Bower, Superintendent of the Employment Department, Westinghouse Electric & Mfg. Co.; R. K. Le Blond Machine Tool Co.; A. H. Dittmer, President of the Dittmer Gear & Mfg. Corporation; Russell Waldo; J. B. Conway; and John C. Spence, Superintendent of the Grinding Machine Division of the Norton Co.

RULE FOR OXY-ACETYLENE CUTTERS

A convenient rule for metal cutters who use the oxy-acetylene blowpipe was devised recently by K. McDermott, steam engineer and assistant mechanical engineer of the South Chicago Works of the Illinois Steel Co. It is in the form of a nickel-plated hand rule, about 12 inches long by 1 1/8 inches wide and 1/8 inch thick, so graduated as to indicate the tip sizes and oxygen pressures best suited for cutting steel sections of any thickness up to 7 inches. The rule shown in the accompanying illustration is graduated for use with "Oxweld" and Davis-Bournonville tips. As a common scale would not apply to both of these makes, one side of the rule is graduated for the "Oxweld" and the other for the Davis-Bournonville tips, as shown.

The device is simple and can be applied easily. Instead of reading thickness in inches and fractions, the tip size and pressure are read off directly, thus making it unnecessary to resort to memory or refer to a cutting table. The device saves time and eliminates waste by providing a simple means of determining the proper size of tip and the correct pressure to employ for each job. The idea is not patented, and anyone can easily make a rule of this type adapted for the equipment being used.



Metal-cutters' Rule for determining Correct Tip Size and Oxygen Pressure

CONVENTION OF INDUSTRIAL ENGINEERS

The fall convention of the Society of Industrial Engineers was held in Springfield, Mass., in the Municipal Auditorium, October 5 to 7. The principal subject of the meeting was industrial stability. In addition to the main gatherings, sectional meetings were held for the groups dealing with the departments of education, manufacture and selling, financing and accounting, and industrial relations. Tours of inspection were made to the principal manufacturing plants of Springfield and the vicinity. The officers elected for the year 1922 were as follows: President, Joseph W. Roe, head of the industrial engineering department of New York University; treasurer, F. C. Schwedtman, vice-president of the National City Bank, New York; secretary, W. G. Sheehan of Detroit, Mich.; and business manager, George C. Dent of Chicago, Ill.

* * *

The Board of Education of the City of New York offers during the coming winter evening courses in machine shop practice, machine shop theory and acetylene welding at a number of the evening trade schools in the city. The courses are open to those now employed in some branch of the industry, and the instruction given is to be supplementary to the day-time occupation, the aim being to fit the worker for greater earning capacity. Courses will also be given in shop mathematics, toolmaking and millwrighting.

* * *

The index to the twenty-seventh volume of Machinery, covering the year September, 1920, to August, 1921 inclusive, is ready for distribution, and copies will be sent upon request.

OBITUARIES

Allan Ransom, who was closely connected with the machine tool industry for many years, died in San Francisco, September 21, at the age of sixty-one. Mr. Ransom was associated at one time with the Lodge & Davis Machine Tool Co., in Cincinnati, and later was in the Chicago store of the Prentiss Tool & Supply Co. For a number of years he was one of the partners of the Marshall & Huschart Machinery Co. of Chicago.

* * *

PERSONALS

Lyle W. Orr has resigned as general manager of the Modern Tool Co., Erie, Pa., with whom he had been connected for ten years. His plans for the future have not yet been announced.

Alan A. Wood, for a number of years connected in an engineering and sales capacity with the Providence plant of the Builders Iron Foundry and the Diamond Machine Co., associated companies, is now sales manager of the Philadelphia district, and is located at 419 Widener Bldg., Philadelphia, Pa.

M. A. Green, who for ten years was superintendent of branches and agencies of the Crucible Steel Co. of America, has become associated with the Newman-Andrew Co., 26 Cortlandt St., New York City, as manager of its tool steel department. Mr. Green's experience in the tool steel field extends over a period of more than twenty years.

George L. Sawyer, formerly sales manager of material handling machinery for the Barber-Greene Co., Aurora, Ill., has been appointed New York representative of the Universal Crane Co., Cleveland, Ohio, for the sale of universal cranes. His headquarters will be at the Allied Machinery Center, 141 Center St., New York City.

Fritz R. Lindh, formerly chief engineer of the Graton & Knight Mfg. Co., Worcester, Mass., has joined the sales organization of the Chicago Belting Co., Chicago, Ill. Mr. Lindh will be in charge of the Pittsburg factory branch, and will also make personal engineering surveys for many of the larger users of belting throughout the United States. His headquarters will be at 336 Third Ave., Pittsburg.

Mortimer Elwyn Cooley, dean of the College of Engineering and Architecture of the University of Michigan, has been elected president of the American Engineering Council of the Federated American Engineering Societies. Mr. Cooley is a past president of the American Society of Mechanical Engineers, and has a long record of distinguished service in education under the government and in private capacities.

William H. Severns has been appointed assistant professor of mechanical engineering at the College of Engineering, University of Illinois, Urbana, Ill. Professor Severns was graduated from the University of Kansas in 1914, and since then has served as instructor at the University of Kansas, Purdue University, New Hampshire College, University of Wisconsin, and University of Illinois. He has also been employed as assistant field engineer by the New Jersey Zinc Co., Palmerton, Pa.

R. A. Lundquist of Minneapolis, Minn., will head the newly created electrical machinery division of the Bureau of Foreign and Domestic Commerce. This is one of the new industrial divisions made possible by Congress through the Export Industries Act. It is expected to secure the services of experts to specialize on the more important export commodities. Mr. Lundquist is a graduate of the University of Minnesota, and an electrical engineer of wide experience. He has also made extensive studies of the sale of electrical machinery in Australia, New Zealand, China, Japan, and South Africa, the results of which have been published by the Bureau of Foreign and Domestic Commerce.

* * *

NEW PRESIDENT OF THE A. S. M. E.

Dexter S. Kimball, dean of the College of Engineering of Cornell University, has been elected president of the American Society of Mechanical Engineers, and will take office at the next annual meeting to be held in New York City early in December. Dean Kimball was born in New River, New Brunswick, Canada, in 1865, and graduated from the Leland Stanford Jr. University in 1896. He served his apprenticeship with Pope & Talbot, Port Gamble, Wash., and in the shops and the engineering department of the Union Iron Works, San Francisco. In 1898 he became designing engineer for the Anaconda Mining Co. For three years he served as assistant professor of machine design at Sibley College, Cornell University, and later became works manager for the Stanley Electric Mfg. Co., Pittsfield, Mass. In 1904 he returned to Cornell University as professor of machine design and construction, and since 1915 he has occupied the chair of industrial engineering. He became Dean of the College of Engineering in 1920.

Dexter S. Kimball, Newly Elected President of the American Society of Mechanical Engineers

Since 1911, Dean Kimball has been a member of the Council on Industrial Engineering, New York State Department of Education. He is also a member of the Society for the Promotion of Engineering Education, and of the Society of Industrial Engineers. He is vice-president of The Federated American Engineering Societies. He is co-author with John H. Barr of "Elements of Machine Design," and author of "Industrial Education," "Principles of Industrial Organization," "Elements of Cost Finding," and "Plant Management," as well as of many contributions to the technical press.

Dean Kimball became a member of the American Society of Mechanical Engineers in 1900. He has served as chairman of the Committee on Meetings and Program of the society, having charge of the professional features of the annual and spring meetings. He has also served on the Committee on Aims and Organization and as chairman of the sub-committee on Relation of the Engineer to his Work. He was elected a manager of the society in 1919.

COMING EVENTS

November 1-4—Annual convention of the Industrial Relations Association of America in New York City; headquarters, Waldorf-Astoria Hotel. Acting executive secretary, E. A. Shay, 671 Broad St., Newark, N. J.

November 2-4—Fall conference of Industrial Cost Association in Pittsburg, Pa. Headquarters of the association, 2828 Smallman St., Pittsburg.

November 4-5—Regional meeting of the American Society of Mechanical Engineers in Kansas City, Mo.

December 1-3—Fall meeting of the Taylor Society in New York City. Secretary, Harlow S. Pearson, 29 W. 39th St., New York City.

December 6-9—Annual convention of the American Society of Mechanical Engineers in the Engineering Societies' Building, 29 W. 39th St., New York City.

May 8-11, 1922—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga. Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

The sectional meetings of the American Society of Mechanical Engineers for the month of November are as follows: November 1—Cleveland Section at Hotel Winton, Cleveland, Ohio, and Virginia Section at Richmond, Va.; November 2—Buffalo Section at the Lafayette Hotel, Buffalo, N. Y.; November 3—Hartford Section at the Bond Hotel, Hartford, Conn.; November 8—Waterbury Section at the Chamber of Commerce Hall, Waterbury, Conn.; November 9—Baltimore Section at the Engineers' Club, Baltimore, Md.; November 14—New Haven Section at Mason Laboratory, Yale University, New Haven, Conn.; November 17—Bridgeport Section at the Chamber of Commerce, Bridgeport, Conn., Toledo Section at the Toledo Commerce Club, Toledo, Ohio, and Worcester Section at Worcester, Mass.; November 21—Chicago Section—joint meeting with the Western Engineering Society at the headquarters of that society; November 22—Atlanta Section at Atlanta, Ga., and Philadelphia Section at the Roof Garden of the Adelphia Hotel, Philadelphia, Pa.; November 25—Colorado Section at the Metropole Hotel, Denver, Col.; November 28-29—Kansas City Section at Kansas City, Mo.

NEW BOOKS AND PAMPHLETS

The Working of Steel. By Fred H. Colvin and K. A. Juthe. 245 pages, 6 by 9 inches. Published by the McGraw-Hill Book Co., Inc., New York City. Price, $3.

This book contains a discussion of the annealing, heat-treating, and hardening of carbon and alloy steel. It describes approved methods of working the various kinds of steel now in commercial use. As is well known, the automotive field has done much to develop new alloys and methods of working them, and this field has been drawn on liberally by the authors to show the best practice. The practice in government arsenals on steels used in firearms is also described. The book contains twelve chapters having the following headings: Steel Making; Composition and Properties of Steels; Alloys and their Effect upon Steel; Application of "Liberty" Engine Materials to the Automotive Industry; the Forging of Steel; Annealing; Casehardening or Surface-carburizing; Heat-treatment of Steel; Hardening Carbon Steel for Tools; High-speed Steel; Furnaces; and Pyrometry and Pyrometers.

AJAX

(Trade Mark Registered)

Draws Taper on 1400 Fender Irons in 8 Hour Day

Ajax Forging Rolls draw these tapered round shanks 20-in. long on fender irons at an average rate of 1400 per 8 hour day.

The stock used is ⅞-in. square cut in blanks 11¾-in. long. The shank 20-in. long, tapering from ⅝-in. round to ½-in. round, is drawn in the rolls leaving a block of square stock from which the foot is drop forged.

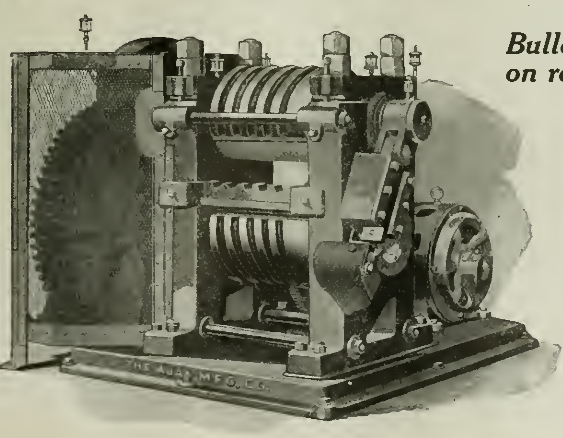
The output from the rolls is considerably higher than was obtained from other methods. The uniform taper and smooth surface make the quality highly satisfactory.

A great variety of straight drawn and tapered pieces is made most efficiently and economically on Ajax Forging Rolls. From blue prints of your forgings Ajax engineers can determine their adaptability for production by the Forging Roll Method.

The Ajax Manufacturing Co.

621 Marquette Bldg. Chicago, Ill. | Cleveland, Ohio | 1369 Hudson Terminal New York City

Bulletin on request



Centrifugal Pumps. By J. W. Cameron. 142 pages, 5½ by 8½ inches. Published by the D. Van Nostrand Co., 8 Warren St., New York City, and Scott, Greenwood & Son, 8 Broadway, Ludgate, E. C. 4, London, England. Price, $3.75.

The development of the electric motor and the steam turbine has led to a tendency in present-day practice to substitute rotary for reciprocating machinery, and the author of this work believes that the time is not far distant when the centrifugal or turbine pump will displace the reciprocating type of pump. The book deals with the theory, action, and design of centrifugal pumps, and contains considerable formula matter for making the necessary calculations in design. It is intended to be used by engineers, draftsmen, and students who have a knowledge of the elementary principles of hydraulics. The examples on the design of centrifugal pumps illustrate the method used by the author in fixing upon the principal dimensions of this type of pump, and may serve as a guide to the young designer. The book contains twelve chapters headed as follows: Action and Advantages of Centrifugal or Turbine Pumps; The Theory of the Centrifugal Pump; Hydraulic Losses during the Passage of Fluid through Pump; Manometric Head, Change of Pressure, and Hydraulic Efficiency of Centrifugal Pumps; Bearings, Disk Friction; Effect of Angle at Discharge on the Efficiency of a Centrifugal Pump; Details of Centrifugal Pump; Axial Thrust and Its Balancing; Calculation and Design of a Single-stage Pump; Calculation and Design of Multi-stage Pumps; Types of Pumps; and Testing.

NEW CATALOGUES AND CIRCULARS

Electrical Alloy Co., Morristown, N. J. Circular advertising "Magno" ignition metal, especially suitable for spark plug electrodes.

New Departure Mfg. Co., Bristol, Conn. Loose-leaf data sheets, 137 and 138 FE, showing the application of ball bearings to motor-driven grinders, and "Sirocco" blowers.

Cutler-Hammer Mfg. Co., Milwaukee, Wis. Circular 2038, illustrating and describing the Type 9604 automatic starter for small alternating-current motors, which is equipped with mercury type overload relays, enclosed in a safety case.

Armington Engineering Co., Wickliffe, Ohio. Catalogue containing illustrations, specifications, and price lists for Armington hand-power hoisting equipment, including I-beam trolleys, flat-rail trolleys, hand-power hoists, and jib and traveling cranes.

Northern Engineering Works, Detroit, Mich. Bulletin 517, containing illustrations showing the application of Northern electric traveling cranes in foundry service, where the enclosed features and strong design of the trolley are particularly valuable features.

Cleveland Punch & Shear Works Co., Cleveland, Ohio. Circular illustrating Cleveland punches and shears and some of their products. The illustration of an aisle in the emergency stock-room of the company gives an idea of the large quantity of small tools carried in stock.

Union Switch & Signal Co., Swissvale, Pa. Booklet entitled "What is a Drop-forging?" containing general information relating to the drop-forging process and methods, as well as characteristics of drop-forgings. The booklet contains several pages of illustrations, picturing typical drop-forgings made by this company.

Geometric Tool Co., New Haven, Conn. Circular descriptive of the Jarvis friction tapping device, which is equipped with a cone friction drive, designed to prevent the breakage of taps when tapping holes in tough metal. Circular describing the features of the Geometric solid adjustable tap for machine and hand tapping.

Cincinnati Lathe & Tool Co., Oakley, Cincinnati, Ohio. Circular entitled "Guaranteed Service at a Fair Price with Cincinnati Lathes," containing illustrations and descriptions of the different types of lathes made by this company which include cone type and geared-head lathes in 16-, 18-, 20-, 22-, 24-, 26-, and 28-inch sizes.

Smalley-General Co., Inc., Bay City, Mich. Circular containing a number of time studies showing the time required for producing six different parts on the Smalley-General No. 23 thread milling machine. A time study is also given of the threading of a rotary tool joint by the use of the adjustable taper attachment supplied with the No. 23 machine.

Kinite Co., 1338 St. Paul Ave., Milwaukee, Wis. Booklet illustrating and describing the use of "Kinite" for shear blades, redrawing tools, blanking dies, drawing dies, embossing and forming dies, broaches, etc. Examples of increases in the number of pieces that may be produced per each dressing of the tool when this alloy steel is employed are given.

Pawling & Harnischfeger Co., 38th and National Aves., Milwaukee, Wis. Bulletin 56X, illustrating and describing P & H excavating equipment. Records are given of the actual performance of P & H excavators under a wide diversity of service in different sections of the country. Copies will be sent to anyone interested in this class of machinery.

National Safety Council, 168 N. Michigan Ave., Chicago, Ill. Safety calendar for 1922, containing on each sheet the calendar for the current month and a cartoon showing common dangers in the industrial world, and the results of ignoring the necessary precautions. The calendar is available to manufacturers in quantities at a nominal cost, by application to the National Safety Council.

Ingersoll Milling Machine Co., Rockford, Ill. Bulletin 41, containing a brief description and illustrations of Ingersoll drum type continuous milling machines. The possibilities of this type of machine are clearly indicated by the illustrations showing some of the different classes of work for which these machines are adapted, and the production figures which are given for each job.

W. S. Rockwell Co., 50 Church St., New York City. Bulletin 234, discussing the continuous heat-treatment of metals with automatic and semi-automatic furnaces. This pamphlet is the fourth of a series dealing with fundamentals influencing the quality and cost of heated products. The illustrations show various types of Rockwell furnaces for heat-treating, hardening, tempering, and annealing.

Cleveland Automatic Machine Co., Cleveland, Ohio. Loose-leaf catalogue, 9 by 12 inches, entitled "Production by Users of 'Clevelands'" containing reprints of articles descriptive of Cleveland automatics, previously published in MACHINERY, as well as reprints of advertisements showing the high rates of production which have actually been attained with these machines on various classes of work.

Sharon Pressed Steel Co., Sharon, Pa. Circular containing illustrations, general specifications, and description of the Sharon "Bluenose" all-steel truck, which is made in two sizes with lengths of 54 and 64½ inches. Circular containing specifications for the Sharon "Brute" all-steel trailer, which is also made in two sizes—46 by 60 inches and 42 by 60 inches—with capacity for carrying 6000 pounds.

Timken Roller Bearing Co., Canton, Ohio, is issuing a publication known as "The Timken Engineering Journal," which contains general information on the selection, fitting practices, adjustments, tolerances, enclosures, and use of Timken roller bearings on machinery and industrial appliances. It is the intention to issue different editions covering specific fields of application, which will be furnished upon request.

W. S. Rockwell Co., 50 Church St., New York City. Bulletin 239, descriptive of the "Economizer" shield type of forge furnace, designed to meet the demand for equipment which will lower production costs. The features to which especial attention is called are the means for better application of heat, protection of the operator, utilization of waste gases to preheat air and fuel for combustion, and the close grouping of furnaces made possible by the comparatively cool working end.

Smith & Serrell, Central Ave. at Halsey St., Newark, N. J. Bulletin 32, containing data on Francke flexible couplings for direct-connected machines. In addition to a general description of these couplings, directions are given for selecting the correct size of coupling for different classes of machines, as well as information on the installation of direct-connected machinery. Particular attention is called to the new light-duty type of flexible coupling for use with small light-duty motors up to from 50 to 75 horsepower.

Supreme Machine & Tool Co., Cleveland, Ohio. Bulletin AC-3, containing a detailed description of the "Supreme" universal boring, milling and drilling attachment, which is designed to meet the need for a jig boring machine that will eliminate the slow and costly process of figuring angles and sines. Instructions are given for the use of the chart, with which the attachment is equipped, by means of which the exact movement of the dividing gears may be determined for setting the boring head at the required angle.

Oakley Chemical Co., 26 Thames St., New York City. Booklet 1042, entitled "Modern Cutting and Grinding," containing information on cutting and grinding compounds and their relation to production. The application of "Oakite" compounds is described, and formulas for Oakite cutting and grinding compounds are given. Suggestions relating to the best practice in metal cutting and grinding are included, as well as tables of cutting and grinding speeds, tap drill sizes, and other useful data. Copies will be sent free upon request.

Metals Coating Co. of America, 495 N. Third St., Philadelphia, Pa. Booklet entitled "The Schoop Metal Spraying Process," containing a detailed description of this process of metal spraying, by means of which metallic coatings of any kind may be sprayed on all kinds of surfaces. The equipment used in connection with the process is also illustrated and described. The process may be applied for five different purposes as follows: Protective coatings, bonding or junction coatings, electrical coatings, decorative coatings, and detachable coatings.

Williams Tool Corporation, Erie, Pa. Booklet entitled "Don't Let It Happen to You," written for the purpose of instructing operators of power pipe machines in producing better threads and securing greater production. Considerable general information is given which is applicable not only to the machines made by this concern but also to other types of pipe machines. The principles of correct pipe threading are discussed, such points being considered as proper alignment of pipe and dies, proper lip, chip space, clearance, number of chasers, etc., and instructions are given relative to the care and use of dies. At the end of the book illustrations are shown of two styles of Williams pipe threading machines, which are built in eight sizes with capacities ranging from ¼ inch to 16 inches. Copies of this booklet will be sent upon request.

TRADE NOTES

Lovejoy Tool Co., Inc., Springfield, Vt., manufacturer of metal-cutting tools, announces that on October 10 a 25 per cent reduction was made on the list price of high-speed steel inserted cutters for Lovejoy holders.

Kearney & Trecker Corporation, Milwaukee, Wis., announces that the New York branch office of the company is now located at Room 371, Hudson Terminal Bldg., 50 Church St., having been moved on October 1 to this location from 1801 Singer Bldg.

Austin Machinery Corporation, Chicago, Ill., announces that Canadian Austin Machinery, Ltd., of Woodstock, Ontario, Canada, will henceforth act as sole manufacturer and distributor in Canada of the complete Austin line of earth-moving and concrete-mixing equipment.

Wilmarth & Morman Co., 1180 Monroe Ave., N. W., Grand Rapids, Mich., manufacturer of grinding machinery, announces that it has issued revised price lists of its products, effective October 1, which represent pronounced reductions in the prices of the different styles of grinding machines.

Metals Coating Co. of America, 495 N. Third St., Philadelphia, Pa., manufacturer and distributor of the Schoop metal spraying process, announces that it is now in full operation at its new plant in Philadelphia, to which it has recently removed from its former locations in Boston and Woonsocket.

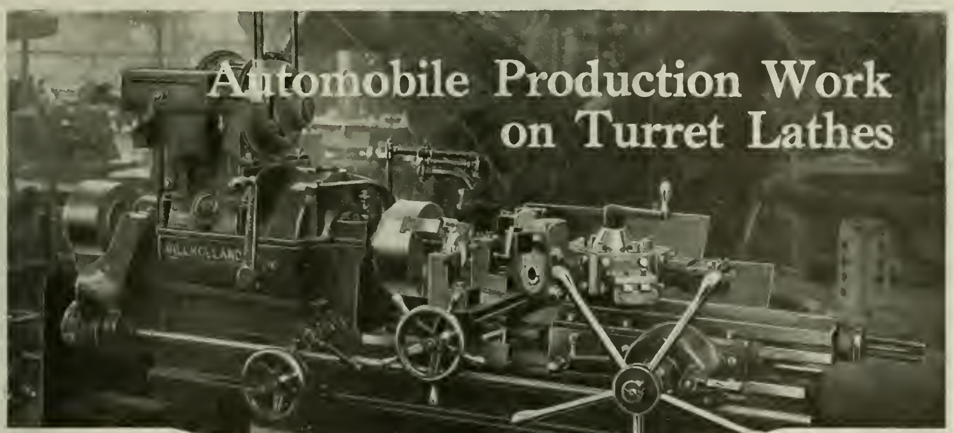
Heppenstall Forge Co., Bridgeport, Conn., announces that it is changing all the heating furnaces in its forge department from the coal to the oil-fired type, because of the satisfactory experience it has had with furnaces of the latter type. The machine shop of the company is working single time, and preparations are being made for putting the forge shop on a schedule of two or three days a week.

Fay & Scott, Dexter, Me., manufacturers of lathes, announce that their plant started operation on full time on October 3, with a fifty-two-hour weekly schedule, this being the first time for nine months that the plant has been operated on full time. With the present slight upward trend in business the company hopes to maintain this schedule with its present force of approximately 100 men, which represents one-fourth the normal force.

Chain Belt Co., Milwaukee, Wis., has opened offices at 735 Ellicott Square, Buffalo, N. Y., and has announced the appointment of T. E. Cocker as district manager of that territory. Mr. Cocker will handle the "Rex" line, including chain, sprocket wheels, traveling water screens, elevators and conveyors. For the last five years Mr. Cocker has been handling elevating and conveying equipment. He is a civil engineer, having graduated from the Rensselaer Polytechnic Institute in 1907. From 1907 to 1917 he was connected with the New York Central Railroad at Buffalo, and at the time he left this company was assistant engineer.

L. C. Biglow & Co., Inc., 232 W. 55th St., New York City, have been appointed New York district agents for the Hartford Tap & Gauge Co., the Hanson-Whitney Machine Co., Inc., the Taylor & Fenn Co., and the Whitney Mfg. Co., all of Hartford, Conn. L. C. Biglow & Co., as agents for these companies, will handle taps of all kinds, finished after hardening to correct lead, pitch, and outside diameter; plug thread gages; bore grinding machines; two-spindle automatic spline-milling machines; sensitive drilling machines; vertical die-shaping machines; centering machines; automatic thread-milling machines; roller, block and silent types of chain; and Woodruff keys.

Central Steel Co., Massillon, Ohio, announces the consolidation and merger of that company with the Massillon Rolling Mill Co. and the National Pressed Steel Co., also of Massillon. The new corporation will take the name of the Central Steel Co., and the other two companies will be operated, respectively, as the Massillon Rolling Mill Division, and the National Pressed Steel Division, of the Central Steel Co. The officers of the company are as follows: President and chairman of the board of directors, R. E. Bebb; first vice-president, F. J. Griffiths; second vice-president, C. C. Chase; third vice-president, H. M. Naugle; and secretary and treasurer, C. E. Stuart. The combined companies will have facilities for making all kinds of commercial alloy steels, hot- and cold-rolled sheets, hot-rolled strip steel, and light structural steel sections, with a capacity for producing 450,000 to 475,000 tons of finished material annually.



Automobile Production Work on Turret Lathes

Time-saving and Cost-reducing Methods Developed for Use in the Engine Department of a Motor Car Plant

By EDWARD K. HAMMOND

IN the engine plant of the Olds Motor Works in Lansing, Mich., a number of turret lathes built by the W. K. Millholland Machine Co., of Indianapolis, Ind., are used for machining operations on parts produced in large lots. When these machines were ordered, the turret lathe builder was also required to design and supply the work-holding fixtures and all the tools used for taking successive cuts. As all these turret lathes were to be used on repetition manufacturing work, care was taken to develop the designs in such a way that a minimum of time would be required for loading and unloading the fixtures. Wherever possible, the order of successive cuts was worked out in such a way that two or more tools could operate simultaneously. It is only through the application of such methods that repetition turret lathe work can be handled with maximum efficiency.

How To Reduce Production Costs ?

This article describes a number of tools and methods that could be used to advantage in the turret lathe department of manufacturing plants handling widely diversified lines of work. Particular attention is called to the design of work-holding fixtures for locating a piece for boring eccentric holes or for turning eccentric bosses. Other valuable features of the tool equipments shown are the provision made for operating two or more cutting tools simultaneously, and the use of air chucks for increasing the speed with which castings can be set up and removed.

Machining Operations on Water Pump Bodies

Fig. 1 shows a No. 4 Millholland turret lathe equipped for the machining of Olds water pump bodies, which are made of aluminum. On this job there is a small hole (not shown) which is concentric with hole *A*. The first turret face carries a combination tool *B* for rough-boring the large hole *A* and the small hole. On the second face there is a boring-bar *C* for taking an intermediate cut in the small hole; and a reamer *D* on the third face finishes this diameter to the required degree of accuracy. The fourth turret face carries a combination tool *E* for facing three surfaces at the top and bottom of hole *A*, and at the top of a boss surrounding the small hole in the work.

A combination tool *F*, on the fifth face of the turret, breaks the corners of the work at the tops of the large and small holes; and on the sixth turret face, there is a Murchey collapsible tap *G*, which is employed for threading the small hole. The machine is equipped with a Hannifin air chuck, which greatly facilitates the rapidity with which the castings can be set up in and removed from the lathe. The rate of production attained in handling this job is twelve finished pump bodies per hour.

Machining Rear Crankcase Covers

Fig. 2 shows another No. 4 Millholland turret lathe equipped for the rapid machining of duplicate aluminum castings. The piece shown in this illustration is a rear crankcase cover and, being made of aluminum, it is of light weight and can be handled rapidly; this material can also be worked at an unusually high cutting speed, which is an important factor in expediting production. On the first face of the turret there is a plug *A* which is moved forward into contact with the work to force it firmly back against the chuck jaws prior to tightening them. In this way, a uniform location of the successive pieces of work is assured.

After the casting has been set up in the manner described,

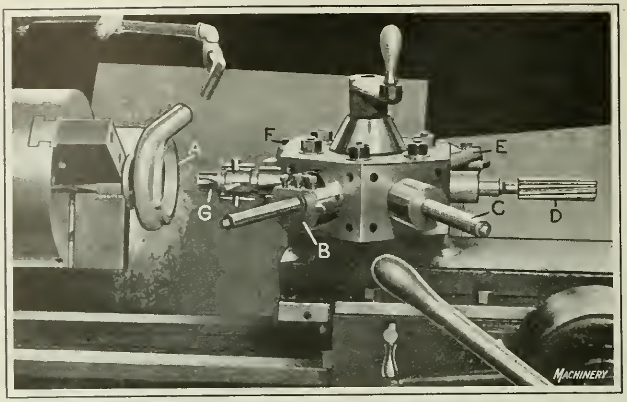


Fig. 1. Tool Equipment of a Turret Lathe used for facing, boring, reaming, and tapping Water Pump Bodies

the following sequence of operations is performed: On the second turret face, there is a tool *B* that is used for rough-boring; and the third turret face is equipped with a tool *C* for finishing the rough-bored hole. The final cut in this hole is then taken by a reamer *D* carried on the fourth turret face. The surface of a boss at the opposite side of the work from that on which the tools have been operating must now be back-faced.

For back-facing this surface, use is made of a tool-slide *E* carried by the fifth turret face, which is furnished with stops to locate the cutting tool in the proper positions for starting and concluding its cut. The tool is inserted through the opening in the work, after which the starting stop is brought into contact with it, and the point of the tool is then brought up against the work. The cross-slide on the tool-holder *E* is then brought into operation, so that the point of the tool is fed across the surface of the boss at the back of the work, thus facing it down to a uniform surface. The depth of cut is determined by means of a stop on the carriage slide. Finally, a surface *F*, adjacent to the periphery at the front of the work, is faced off with a cross-slide tool *G*.

These rear crankcase covers are cast in two pieces. As they come to the machine shown in Fig. 2, the flanges between the two halves of the casting have been milled, so that the two members may be bolted together. On this job the production is twelve rear crankcase covers per hour.

Indexing Fixture for Machining Distributor Brackets

In Fig. 3 is shown an aluminum part of the Olds engine known as a "distributor bracket," in which it is required to finish two eccentric holes and to turn and face the body. In handling this job on a lathe, it can be done only by successively locating the work in line with the center of rotation of the spindle for performing operations at different points on the casting. To obtain the three centers of rotation necessary, an indexing type of work-holding fixture is used. This fixture allows the casting to be centered in such a way that the body can be turned and faced; then it is indexed to locate the casting in position for machining one hole; and after that has been done, the fixture must be indexed a third time to locate the work for finishing the other hole.

On the first turret face, there is a tool *A* that rough-turns the outside diameter *B*, and faces the flange and lugs *C* at each side of the work. The second turret face carries a tool *D* for finishing the same surfaces. The cutter bit in each of these tools is formed in such a way that it turns the outside diameter *B* and faces the flange and lugs *C*. Feeding of the tool to the work is checked by a carriage stop. Next in the order of operations comes the facing of the area surrounding the two holes at the front *E* of the work, by a tool *F* mounted at the rear of the cross-slide. After the work has progressed to this point, it is necessary to index the fixture in order to center the work on the axis of the large hole *G;* and with the piece located in this way, a boring cut is taken with a tool *H* on the third turret face. After the boring operation, this hole is reamed with a chucking reamer *I* on the fourth face of the turret.

After the reaming operation, the fixture is once more indexed to center the casting in a position corresponding to the axis of the small hole *J;* a boring tool *K* on the fifth turret face then takes a roughing cut. Next the turret is indexed to bring a reamer on the sixth face into the operating position, for taking the finishing cut in the small hole. The work-holding fixture is mounted on a cross-slide *L*, and has an index-pin *M* which enters one of three holes to give the different work settings necessary to complete the job. It is required to hold all dimensions on this piece within limits of 0.0005 inch. Handling this job on a No. 4 Millholland turret lathe, the rate of production is eleven pieces per hour.

Machining Operations on Water Pump Impellers

In machining aluminum impellers for pumps used on Olds automobile engines, the sequence of turret lathe operations is different from that employed in the cases previously described. For the manufacture of these parts, it is necessary to remove the work from the chuck and turn it over during the process of machining, as operations are required on both sides. The method of procedure is first to face a hub at the center of the impeller with a tool *A*, Fig. 4, carried at the rear of the cross-slide. After this has been done, the work is removed from the chuck and turned over, and a small flange at the outside diameter is faced with a tool *B* mounted at the front of the cross-slide. The casting is held by means of a Hannifin air chuck, so that little time is required to set up and remove the work; hence, the necessity of resetting is not a serious hindrance.

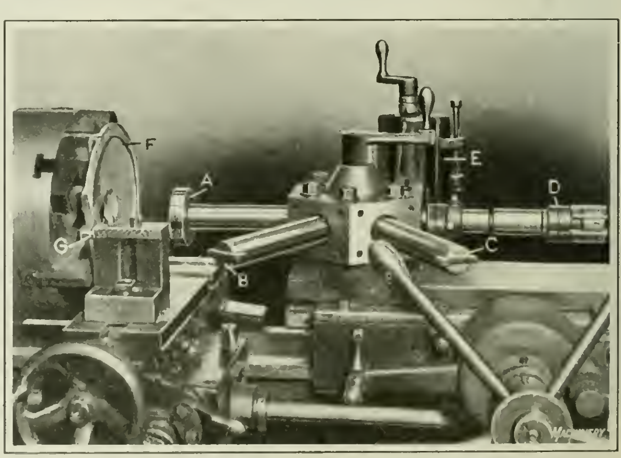

Fig. 2. Tool Equipment of a Turret Lathe used for boring, reaming, and facing Rear Crankcase Covers

After the work has been reset in the chuck, the next step is to drill the center hole and rough-turn the outside diameter of the casting. This work is done by a combination tool-holder on the first turret face, which carries a twist drill *C* and a turning tool *D*. Next the drilled hole is bored and the outside diameter finish-turned. This is done by a similar tool-holder on the second turret face, which carries a boring tool *E* and a turning tool *F*. Then a tool *G* carried on the fourth face of the turret is indexed into the operating position, for counterboring the rim and facing the area immediately surrounding the center hole in the work. When this step has been taken, the hole is reamed by a tool *H* on the fifth face of the turret. Finally, the corners at the top of the hole and at the periphery of the work are broken by a tool on the sixth turret face, thus completing the required sequence of operations. This job is handled on a No. 3 Millholland turret lathe, and the production is twenty-four pump impellers per hour.

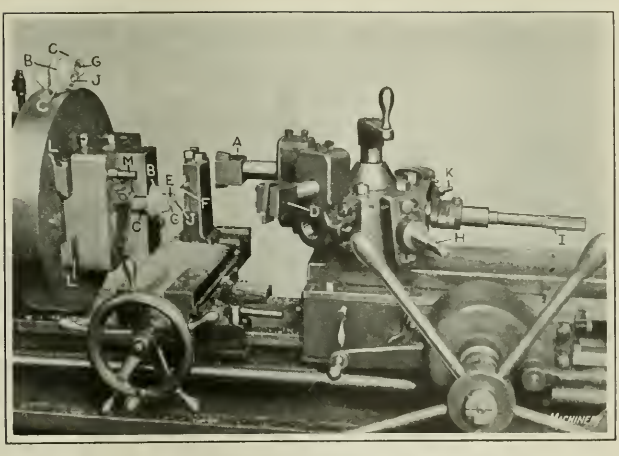

Fig. 3. Three-station Indexing Fixture for locating Distributor Brackets for turning the Body and boring Two Eccentric Holes

Machining Bronze Camshaft Bearing Bushings

When a plant is engaged in the quantity production of duplicate parts, but when the number of a given part to be machined is not great enough to occupy all the time of a machine tool, it may be possible to equip a machine in such a way that two or more production jobs can be handled, without a serious loss of time in changing tools, thus substantially reducing the amount of overhead to be charged against each of the jobs.

An example of this kind is illustrated in Fig. 5, which shows a close-up view of the tools and Hannifin air chuck used on a No. 4 Millholland turret lathe, for machining bronze bushings for the front and rear camshaft bearings of the Olds engine. The rear bearing *A* is shown in position in the chuck, while one of the front bearings will be seen lying on the bed of the lathe at *B*. The procedure in machining the rear bearings is as follows: On the first turret face there is a combination tool *C* that faces the end and takes a preliminary cut on the inside of the bushing. The combination tool *D* carried on the second turret face takes an intermediate boring cut, and also breaks the corner of the hole. Reamer *E* on the third face of the turret finishes the inside diameter of the bushing.

When the machine is working on the front bearing bushings *B*, the order of operations is as follows: Rough-bore, finish-bore, face, and ream. From the description of the machining of the rear bushings, it will be apparent that there are three turret faces available for carrying tools for machining the front bearing brasses. The rough-boring tool *F*, the finish-boring tool *G* and the facing tool *H* are permanently carried on these three turret faces, so that in order to switch over from one job to the other, it is merely a case of removing the rough-boring and facing tool *C* used on the rear bearing brass *A* and substituting the holder which carries a reamer *I* for finishing the inside of the front bearing brass. The same Hannifin air chuck can be used for holding both the front and rear brasses. On each of these jobs the rate of production is twenty brasses per hour.

Machining Oil-pump Covers

In machining cast-iron covers for oil-pumps used on Olds engines, there are two holes to be finished. This is another case where an indexing type of turret lathe fixture is used for centering the work in two positions. From Fig. 6 it will be seen that the method of setting up this job is quite different from those previously described. As the castings come to the machine they have been turned and faced, and these finished surfaces are utilized as locating points. There is a space behind the top plate *A* of the work-holding fixture, and the turned diameter of the oil-pump cover enters a counterbored pocket in the back of this plate. Two hooked bolts *B* are then tightened to pull the work firmly up against the back of the fixture.

In finishing these parts, the actual machining operations are quite simple, consisting of drilling, rough-reaming, and finish-reaming one hole, after which the fixture is indexed to center the work for the same sequence of operations in the other hole. The twist drill *C* and the roughing reamer *D* are carried on the first and second turret faces; and the finishing reamer is carried by a floating holder *E* which is shown on the third turret face. It will be seen that a slip bushing *F* is provided, which enters either of two openings in the work-holding fixture to bring it into line with the positions where the holes are to be drilled in the work. The drill is guided by the bushing, while the reamer is guided by the

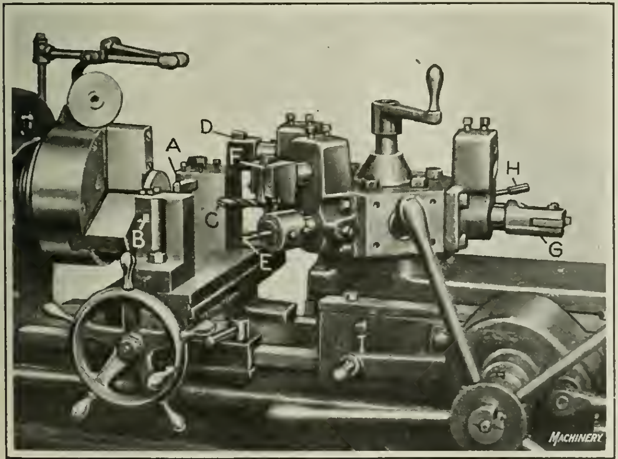

Fig. 4. Turret Lathe Equipment used for boring, counterboring, and facing Water Pump Impellers

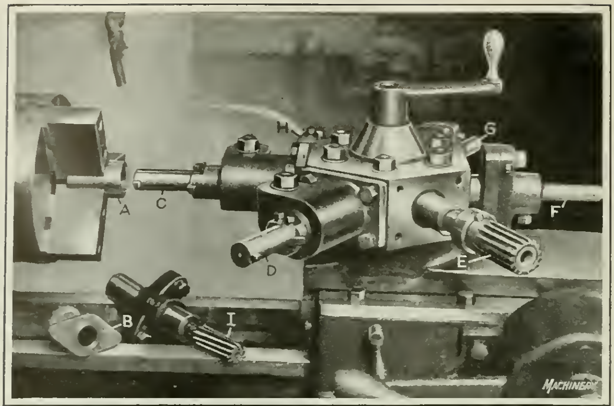

Fig. 5. Equipment for machining Bronze Bushings for Front and Rear Camshaft Bearings

finished cylindrical part of the shank directly behind the reamer blades. There is a cross-slide *G* and an index-pin *H* for locating the fixture properly for machining the two holes. In this way a good accurate job is secured. This job is done on a No. 4 Millholland turret lathe. The rate of production is twelve castings per hour.

Machining Operations on Fan Driving Pulley Hub

Fan driving pulley hubs for Olds engines are made of cast iron, and in Fig. 7 is shown a close-up view of a No. 4 Millholland turret lathe tooled up for the required machining operations on these pieces. One of the castings *A* is shown lying on the cross-slide. On the first turret face there is a twist drill *B* which takes a preliminary cut through the hub, and carried by the same toolholder, there is a tool *C* for rough-turning the hub. Tools *D* and *E*, arranged similarly on the second turret face, bore and finish-turn the hub.

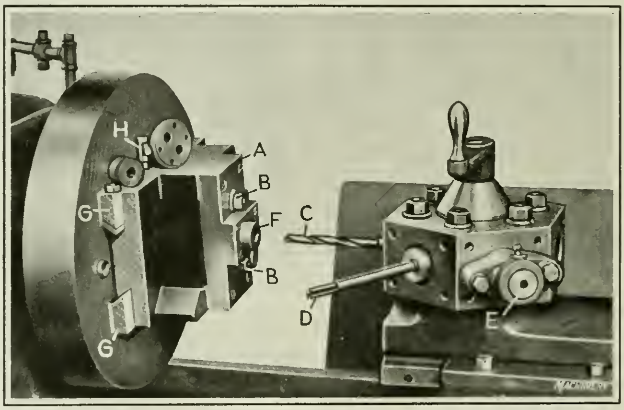

Fig. 6. Indexing Turret Lathe Fixture used for drilling and reaming Two Eccentric Holes in Oil-pump Covers

Next, it is required to break the corners of the hub and of the hole, and for this purpose a combination tool *F* is provided on the third turret face. This tool has a cutter bit slotted in such a way that the notched portion straddles the face of the hub and simultaneously breaks the corners of the hole and of the outside diameter. A reamer *G* on the fourth turret face then finishes the hole.

The next operation in the series is the facing of the front of the hub, and for this purpose there is a tool *H* mounted at the front of the cross-slide. The final operation consists of facing the back of the hub with a tool *I* carried on a rod extending through the lathe spindle and connected to the bar feed in such a way that it may be moved up into contact with the rear side of the work as it rotates. The rate of production attained in performing this series of operations is twelve castings per hour.

Turret Lathe Operations on Water Pump Covers

In the heading illustration is shown one of the No. 4 Millholland turret lathes equipped with a Hannifin air chuck and tooled up for machining covers for water pumps used on Olds engines. These pieces are made of aluminum, and it is required to perform roughing and finishing operations on the front faces of the flange and hub. Two tools are provided at the rear of the cross-slide, which simultaneously rough these two faces of the work, and after the preliminary cut has been taken, two similar tools mounted at the front of the cross-slide, perform the finishing operations on the same surfaces of the work.

On the first face of the turret, there is a drill for taking a preliminary cut through the center hole, and another tool with which a rough-turning operation is performed on the outside of the hub. On the second turret face, a similar tool provides for finish-turning the hub. Carried on the third face of the turret, there is a tool for facing the area adjacent to the center hole in the work. Finally, on the fourth face of the turret, there is a combination tool that breaks the corners of the inside of the hole and the outside of the hub. It consists of a holder with two bits, one of which extends farther than the other, so that it is able to reach the hole which is some distance inside the level of the front face of the hub. The rate of production in performing the machining operations on these water pump covers is eighteen pieces per hour.

Some Aspects of the Present Situation

By A. W. HENN, President, National Acme Co., Cleveland, Ohio

THE question that doubtless causes the greatest amount of anxiety in the machine tool field today is prompted by the great expansion in the industry during the last five years. Many believe that it will be several years before there will be sufficient demand for machine tools to absorb the entire machine-building capacity of the country as we know it today. This belief seems reasonable, and in view of all conditions to which we can point today, it would seem entirely too optimistic to hold a contrary view. The foreign trade, which in past depressions has been an important source of business, is at the present time reduced to very small proportions; and in the domestic field there is no great and important outlet for machine tools in view. Hence, it would seem that a much smaller machine tool building capacity than that at present available would be sufficient to meet the needs of both the domestic and the foreign trade for several years to come.

What has been our Past Experience?

As I look back upon my experience in the machine tool field for the last thirty years, however, I find that we have passed through several periods that in many respects were similar to the present one, although the details differ, and in view of those experiences it is difficult to look toward the future without considerable faith in the prospects of the machine tool industry. In the early nineties, previous to the depression which then held the country in its grip for several years, there was a great expansion in the machine tool industry. Many new concerns were started, and as compared with the ten years previous, the expansion in the machine tool building capacity of the country assumed great proportions; so much so that when the depression struck us, many of the older machine tool builders pointed to what they called an over-expansion, and predicted that it would be a great many years before the demands for machine tools would be equal to the capacity then existing. Yet a few years later—owing in a large measure to the activity in the bicycle industry—not only did the domestic and foreign trade absorb the entire capacity at that time, but the demand was so great that in the late nineties a number of new concerns started which have since grown into important factors in our machine tool industry, and which have found ever since sufficient employment for their activities to warrant their existence.

In the fall of 1903 we had another depression, and there did not seem to be a reasonable prospect for an early revival. Yet a couple of years later the machine tool builders found themselves engaged to capacity in building machine tools for many industries, but largely for the automobile industry which then entered upon its first stage of real development. A few years later we entered upon another depression, again followed by a boom and an expansion in the machine tool industry due to the second expansion in the automobile industry. In 1914 business was again almost at a standstill, and many manufacturers were working almost exclusively for stock. Then came the war with the effect on the industry well known to everybody; and finally, after the armistice, when everyone in the machine tool business predicted several years of stagnation because the world had all the machine tools that it could absorb for five years to come, at least, we found ourselves after a few months again fully occupied in building machine tools for various industrial purposes, but mainly for what might be called the third stage of development in the automobile industry.

Now we have again reached the bottom of a depression, and we can see nothing definitely ahead for years to come. Yet, in the light of past experiences, it is almost certain that the new developments that are constantly taking place in the entire industrial field will make demands on the machine tool builders, so that the industry that now appears to be over-expanded will again find itself occupied to such an extent that it will regain a healthy condition. It seems quite certain that we have already passed the lowest point in the depression. In many cases in the machine tool industry this occurred in July and August, with a slow but steady improvement since that time.

Possible Outlets for Machine Tools

As soon as business conditions in the general industrial field become normal, or nearly so, the machine tool builder will find an outlet for his products in two directions: He will enter new fields where machine tools will be required for the manufacture of new articles constantly being invented for the comfort and convenience of modern life, and he will be busy replacing machines that have become obsolete, with new and improved types. In the foreign trade the greatest opportunities now seem to offer themselves in the Far East, there being little hope for any great demand from Europe for some time to come. We all know that the railroad field would offer a great opportunity for machine tool equipment, if the railways were financially in a position to buy. This problem is a difficult one, and at present it is the most pressing of any now confronting us as an industrial nation. Freight rates must be reduced, but in order to reduce freight rates there must also come reductions in wages and an increase in the working efficiency of railroad employes.

The most important thing in regard to wages at the present time is not so much what might be termed a *reduction* in wages, as an *equalization* in wages. There are certain classes of labor that have not received, during the last five years, any more than a fair compensation for their work. There have been other classes of labor, again, who have received a great deal more, proportionately, than their fellow workers. Compare, for example, the wages in the railroad field and in the building industries with those in the general machine building field, and it becomes evident that in justice to the highly skilled men in the field last mentioned, the wages of overpaid workers should be proportionately reduced. In that manner industry can get under way again, and the prosperity of all can be insured.

Importance of Education of Workers

The last years have been an era of extravagance—there has been waste not only of money and the things bought with money, but also of time. The young men who years ago entered the trade devoted their spare time to study in order to qualify themselves by knowledge and skill in that trade. During recent years of high wages and short hours, the spare time has not generally been thus employed. Motion pictures and other pleasures and entertainments have taken a position in our community life that has temporarily overshadowed the value of educational development along specialized lines.

The motion picture, however, lends itself exceptionally well to the furthering of an educational campaign, and it is to be expected that after the present era of abnormal conditions, we will see this effective means of transmitting information used more and more for serious purposes.

Reducing Costs by Gang Drilling

How To Reduce Production Costs?

THE practice of grouping machines to facilitate the performance of a number of operations in rapid succession on a part, or the mounting of several machines in a gang on one base for the same purpose, makes possible high production rates at low costs. The accompanying illustrations are representative of typical jobs on which standard machines built by the Barnes Drill Co., Rockford, Ill., have been successfully applied to effect reductions in manufacturing costs. The photograph reproduced in Fig. 1 was taken in the shops of the Benjamin Electric Mfg. Co., Chicago, Ill., and shows three drilling machines and one tapping machine placed in a line for the manufacture of small flanged parts.

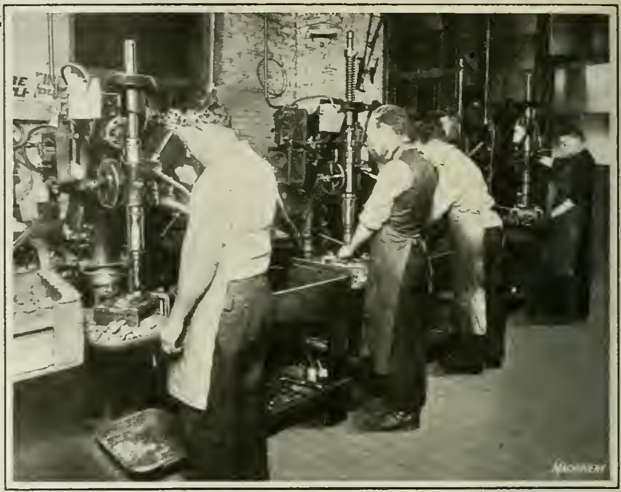

Fig. 1. Three Drilling Machines and a Tapping Machine grouped to obtain High Production Rates on a Small Flanged Part

Each machine is supplied with an individual motor drive and a controller. The machine at the left is used for drilling a hole through the center of the part, and the next machine is employed for tapping this hole. The third machine turns and faces the hub, while the tapping machine at the extreme right threads the hub, a Wells self-opening die-head being utilized for this operation. The outside diameter of the hub is 1 inch, and the length of the threaded portion 3/8 inch. The production obtained with these machines averages 334 completed parts per hour.

Drilling Automobile Axles

An all-geared gang drilling machine equipped with four 24-inch adjustable spindle heads is used in the plant of the Adams Axle Co., Findlay, Ohio, for drilling the king-pin hole at each end of an automobile axle and the spring-pad holes. This operation is illustrated in Fig. 2. The center distance between the spindles at each end is about 12 inches. The outside spindles and their guide bushings have a quick adjustment to compensate for small variations in the lengths of axles. This adjustment is obtained by revolving the handwheel at the right to rotate a shaft having threads engaging with nuts, which shift the spindle heads and jig members to the desired locations. Special equipment is supplied for supporting and locating the axle forgings, which are made from S. A. E. specification No. 1035 steel. The inner spindles used for drilling the spring-pad holes are each provided with a five-spindle auxiliary head.

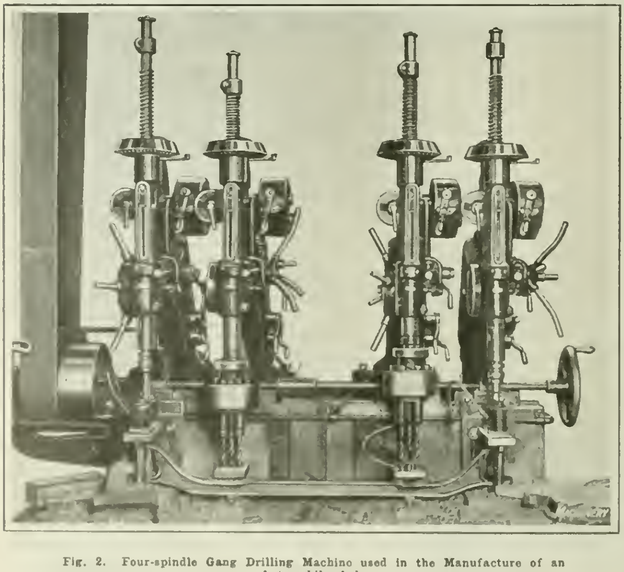

Fig. 2. Four-spindle Gang Drilling Machine used in the Manufacture of an Automobile Axle

At the top of each main spindle there is a coil spring and adjustable return stops. When an operation is completed the automatic feed is tripped, and the spindle and tool are lifted. through the action of the coil spring, sufficiently to clear the work. The raised position is governed by a shock absorber, located in a sliding member at the front of each head, with which the upper end of the spindle sleeve comes in contact. The king-pin holes are drilled 31/32 inch in diameter and reamed to 1 inch in diameter, while the spring-pad holes are drilled 17/32 and 1/2 inch in diameter. The production obtained with this machine is from ten to twelve axles per hour, with the drills driven and fed at their maximum speeds and feeds, respectively.

Machining Forged Clutch Levers on Gang Drilling Machine

Another four-spindle gang drilling machine having independent columns and tables is employed by the Hart-Parr Co., Charles City, Iowa, for drilling, reaming, and hollow-milling operations on forged clutch levers. This machine is illustrated in Fig. 3. The spindles are equipped with an automatic raising mechanism similar to that described

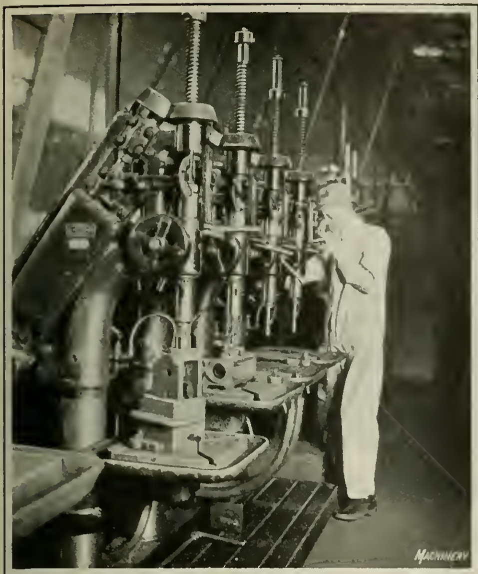

Fig. 3. Four-spindle Gang Drilling Machine used for machining Forged Clutch Levers

in connection with the machine shown in Fig. 2. In feeding a spindle, the operator simply lifts a throw-in lever and begins to feed. One operator attends to the four spindles, dividing his time about evenly between them. The production rate attained with this machine is one lever per minute or sixty per hour.

* * *

NATIONAL INDUSTRIAL COST CONFERENCE

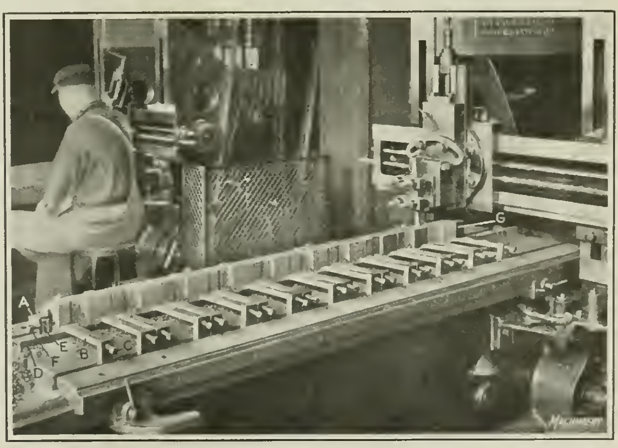
The Industrial Cost Association held its second national conference in Pittsburg, Pa., November 2 to 4. The objects of the association are to stimulate the interest of all manufacturers in correctly determined costs; to standardize cost and accounting terminology and establish governing principles in order to simplify cost accounting; to educate the members in the use and advantages of graphic charts and other methods of cost analysis and control; to assist members who are identified with cost committees of trade organizations in formulating uniform cost methods and to recommend the adoption of such methods; to provide a forum for the discussion of cost problems and practices through general and local meetings, and to gather and disseminate such information; to establish a cost library and maintain a bureau of information through which members may be assisted in solving their individual cost problems; and to coordinate the efforts of members so that cost of production may be considered in its proper relation to the problems of industrial management. Among the papers presented were: "What the Sales Manager Should Have from the Accounting Department"; "Inventories—Methods of Taking"; "Responsibility of the Comptroller or Accountant in Times of Business Depression"; "Terminology"; "Budgeting the Plant and Office"; "Sanitation and Safety"; "Cost and Profits of Welfare, Sanitation, and Safety"; "Looking into the Future"; and "How Can a Cost System, Although Efficient, Demoralize an Organization?".

MULTIPLE SET-UPS FOR PLANING

Attention has previously been called in these columns to the advantages of setting up a number of pieces of work at one time for planing. In this way the non-productive time of the machine is decreased, and the setting-up time per piece is usually less.

The economies resulting from this method of setting up work for planing are not always in direct proportion to the number of pieces that are set up at one time. For example, in one case where milling machine table castings were to be planed, two set-ups were tried, and it was found more economical to do the work with four castings set up at a time, rather than with eight, although ample power was provided to pull the work under the planer tools in each case. This is probably due to the fact that when too many pieces are set up at one time the non-productive time of the machine while the operator is engaged in setting up the work, and the idle time of the operator while the machine is at work, more than counterbalance the savings effected by the multiple set-up. The number of pieces that can best be planed at a time can only be determined by experience in handling many different classes of work, or by experimenting for each new job.

An example of the way in which a string of castings can be advantageously set up on a planer is shown in the accompanying illustration. The method of mounting is the important point in this case, because the job itself is very simple, consisting merely of planing a flat top face on each of ten castings. The planer is a 24- by 28-inch machine built by the G. A. Gray Co., of Cincinnati, Ohio, and it is shown in use in the plant of the National Acme Co., Cleveland, Ohio. Secured to the planer table there is a finished parallel bar *A*, the sides of which are in accurate alignment with the line of travel of the planer table. This bar is used as the locating point against which the castings are clamped by fingers or so-called "butters" *B*, which are tightened against the work by bolts *C* carried by stops placed in one of the table T-slots. A bar *D* is placed on the planer table to support the forward end of the clamping fingers *B*, so that their pressure is applied at a point about midway up the side of locating bar *A*. Means for supporting the end thrust of the cutting tools are furnished by a plug *E* placed in one of the clamping bolt holes in the table; this plug carries a bolt *F* which is screwed up against the end of the first casting. As all of the pieces of work are in contact with each other, end to end, it will be evident that pressure is transmitted from one piece to another. At the opposite end of the string of castings there is a plug *G* against which the work is tightened by bolt *F*.



Application of the Multiple Set-up Principle on Planer Work

Planning in Large Contract Plants

Organization of a Department for Planning the Progress of Work through the Shop

By GEORGE H. SHEPARD, Professor of Industrial Engineering and Management, Purdue University

ADEQUATE planning in a large contract or jobbing plant requires a well-organized planning department. This department should be a part of the shop organization with each departmental chief planner directly under the authority of the general foreman of the particular department, as shown in the organization diagrams presented in connection with the article entitled "Organization of Large Contract Plants," which was published in August MACHINERY.

The accompanying diagram shows the organization of a planning department in a contract or jobbing machine shop employing about one thousand workmen. It will be noted that the departmental chief planner is again directly responsible to the general foreman, and that the technical experts who are in an advisory relation to the method man are responsible only to the chief of staff. The following detailed description of a departmental planning office is based on an actual functioning organization, plans for which were originally prepared by W. H. Smith, first assistant to the author at the time when he was engaged in this line of work.

Purpose of a Planning Department

The general foreman of a large plant requires a special organization to assist him in handling the vast amount of detail involved in properly planning and preparing the work of the various shops, and, this is the particular function of a planning department. In the organization illustrated, the planning department provides a central point to which persons outside of the machine shop send all information and instructions which pertain to the work to be done by the shop. The planning department converts such information and instructions into shape for use in the shop. In so doing, the actual functions of the planning department consist of: (1) Issuing instructions as to what, how, where, and when work will be done; (2) providing all material, special tools, etc., necessary to complete the work on a given job; (3) keeping record of the actual progress and production of work to know how the scheduled plans are being carried out.

Many a shop has a staff of executives highly experienced in machine shop work and capable in devising and introducing labor-saving methods. Such shops may be excellently equipped with modern machine tools, and have every facility for producing at low cost, and yet find it difficult to compete with other plants less ably manned and equipped. The difficulty can sometimes be traced back to the lack of proper planning of the work, which sometimes is overlooked even by the best mechanical executives. Careful planning is especially necessary in shops where a variety of work is handled; for lack of planning may, in cases of that kind, greatly increase costs. A study of the possibilities for reducing costs by adequate planning of the work in the shop is well worth the careful attention of the best executive.

Function of Each Man or Unit in the Organization

According to the organization diagram the departmental chief planner has general charge of the department. The method man is the first assistant to the chief planner, and when the latter is absent, he automatically becomes the head of the department. The progress man is directly responsible to the chief planner, but in the absence of this supervisor he reports to the method man. The material man, planners, and the blueprint man are directly responsible to the method man; men in the material section, to the material man; men in the progress section, to the progress man; and jacket file clerks and messengers, to the departmental chief planner. The duties of each man are given in the following:

Departmental Chief Planner. The departmental chief planner has general supervision of the planning department and is responsible for its efficiency and results obtained. His main duty is to see that the various sections of the office are performing their work properly. He should handle personally only the most important questions, turning over all detail work possible to his subordinates, and to that end should train them to handle whatever work he gives them.

Method Man — The method man has general supervision of the method section and should maintain the same relation to that section as does the departmental chief planner to the entire department. He is responsible for the clerical work involved in writing up instruction cards, progress cards, etc., and should see that the planners analyze the jobs correctly. He should answer all questions from shop supervisors pertaining to the work of the planners and should consult fully regarding the various details with the technical experts of the plant staff.

Progress Man—The progress man has general supervision of the progress section and should maintain the same relation to that section as does the departmental chief planner to the whole department. The progress man is responsible for the accuracy of progress records, the soundness of schedule dates, and the constant surveillance of work in the shop to see that it is not delayed. He should reply to important inquiries from outside of the shop and from supervisors relative to the work in his section.

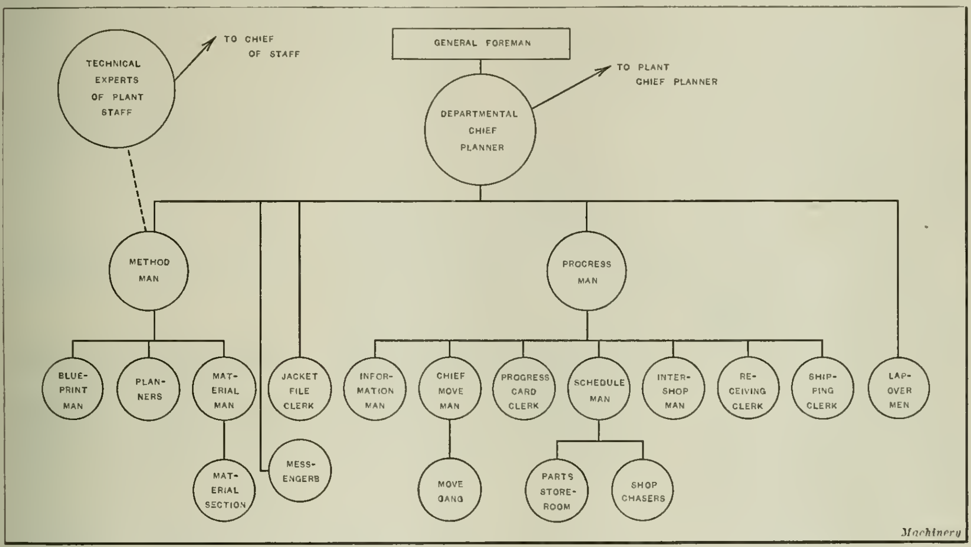
Planners—The work of the planners is to decide what work must be done; what operations are to be performed on each job; what classes of machines are to be used and the routing of the work from section to section of the shop; what kind and size of material is to be used; and as far as possible, what special tools will be needed.

In making these decisions the planners should consult job orders, drawings, and other instructions, and inspect samples and equipment to be repaired, etc. The aim of planners should be: (1) To specify the most economical method of performing operations from the standpoint of time and equipment; (2) to assign the jobs to machines best adapted to the work; (3) to make the best possible use of material, that is, a piece of material should be no larger than necessary to do the job. If the kind of material is not specified, the least expensive material suitable for the job should be used; tobin bronze should not be used in cases where brass would do, and solid material should not be used when a casting or forging would be more economical.

Planners write the necessary instructions and route tags to cover the jobs, and advise the blueprint man as to what sections of the shop should receive prints. In handling repair work, planners are responsible for issuing sufficient instructions to do the work properly. Planners should endeavor to foresee what will be required to complete a job and should either make necessary provision for it, or else refer the case to the method man.

Blueprint Man—The blueprint man obtains the necessary number of blueprints for a job from the drawing-room as directed by a planner, and files them. He issues them to the shop as directed by the planner, or when called for by the shop. He keeps an index of the blueprint file showing the supply of prints on hand, and to whom prints have been issued.

Material Man—The material man keeps a perpetual inventory of material in shop stores, and looks after the replenishment of the material; issues all necessary requisitions for material from stores, and has the material delivered to the shop. He is also assistant to the method man relative to materials, and in such matters, his decisions are accepted by the planners. In this capacity the material man must keep in close touch with the condition of materials in store, must carefully censor all lists of material for jobs made out by the planners, and take up doubtful points with them. In short, his main duty is to secure the most economical specifications from the planning office, so planners should consult him freely as to the availability of material.



Organization of a Planning Department for a Machine Shop employing about One Thousand Workmen

General Function of Progress Section

Repair jobs coming to a plant, as a rule, must be completed by a certain date, and, in the same way, job orders on new work may have to be finished at stated times. It is the work of the progress section not only to determine when each job shall be done, but also to secure information, material from other shops, etc., and to guide the work through the shop so that each job order will be finished by the specified date.

Inter-shop Man—The inter-shop man deals with other shops in the plant for the planning office and determines when the machine shop should deliver work on a job order to the next shop, so the latter will be able to complete work in time; secures from other shops any information needed by the machine shop in completing its work; consults the progress man or the schedule man, and then advises shops which feed work into the machine shop when the work should be delivered to it; and follows up these other shops when they fail to deliver material on the date specified.

Schedule Man—The work of the schedule man is: (1) To make a daily schedule of important jobs, showing the required dates of completion, and to issue this list to the foremen. This schedule is the means whereby the planning department guides work through the shops, and sets completion dates for the shops to attain and for the general foreman to hold the shops to. (2) To make a daily schedule of important jobs to be worked on at night by the night shift. (3) To watch the progress of every item on all classes of orders, particularly important work, by using the progress section records and shop chasers, to see that nothing falls behind. He should start action on delayed items through the inter-shop man where other shops are involved, and through the shop chasers or the progress man where the machine shop is at fault. (4) To notify the method man when any job orders ahead of the shop should be planned by the planners, the information being obtained by reference to the progress section records. (5) To keep in touch with the store-room man by means of shop chasers as to the condition of the assemblies in the store-room, and take action to get assemblies ready for the assembly section, reference also being made to the progress section records.

Parts Store-room—It is essential to economical production that, when a job is sent to the assembly section, all the necessary parts are together, so that the job can be worked on steadily until completed, and then shipped out of the section. In this way only live jobs will be on the assembly floor, and there will be no delay because parts are lacking. This is true for sub-assemblies as well as for final assemblies. To attain this end it is necessary to collect the parts after they have been machined until all parts for one job are ready for assembly. The store-room provides a reservoir in which these parts can be collected and turned over to the assembly section as a complete group. The planners, therefore, route all such parts to the store-room preparatory to assembly.

In order to expedite work it is equally essential that the planning department have some means of knowing definitely at all times what parts are ready for an assembly and what parts are lacking. It is apparent that different parts take different routes through the shops and require varying amounts of machine work. The store-room provides a means whereby the planning department can know just how assemblies stand; hence, parts which are lacking can be pushed. For this purpose, a card-index inventory is kept of parts in the store-room. The store-room also serves to collect partial deliveries of castings from the foundry until all the castings for a part have been received, at which time they are sent through the shops. By this means the planning office can avoid the machining of castings in partial lots with the consequent extra expense.

Shop Chasers—The shop chasers secure any information on work in the machine shop asked for by the schedule man. Each chaser has certain jobs assigned to him to watch particularly, and any noteworthy facts observed are reported to the schedule man.

Information Man—The information man answers all questions relating to the status of work in which the machine shop is involved, and acts as a censor on the condition of the progress section records, calling any defects to the attention of the progress man.

Chief Move Man and Move Gang—The move men who are not definitely assigned to a section of the shop and work directly under its foreman for movement within the section only, are organized in a general gang under the chief move man. The duties of the latter in directing this gang are, in the main, to carry out inter-sectional movement, as directed by the route tags on work deposited at the outgoing space by the section move men. The chief move man is in all matters under the orders of the progress man, and will perform such other duties as the latter may direct.

Progress Card Clerk—The duties of the progress card clerk are to keep the records of the progress section; the various forms used will be discussed in a subsequent article.

Receiving Clerk—The duties of the receiving clerk are to check incoming material and turn in all papers, shipping tags, etc., to the progress card clerk, after ascertaining whether all essential information is on the papers and tags. He sends partial deliveries of castings to the parts store-room.

Shipping Clerk—The shipping clerk sees that every sample piece of work delivered from the shop is provided with a delivery tag. He also insures proper identification of work sent to another shop for repairs.

Jacket File Clerk—The file of jackets (large manila envelopes) provides a receptacle for each job order for copies of all written matter pertaining to an order, job order, instructions, tags, etc. This is a reference file only, and the majority of questions as to the status of work should be answered from the progress section records as previously mentioned.

Messengers—The messengers maintain a mail service within the planning department between the office and the shop, and between sections of the shop. They also perform miscellaneous messenger work.

Lap-over Men—The duties of the lap-over men are to consult day foremen and assistant foremen and arrange the work for the night force of workmen.

The superintendent or general foreman of a large contract plant requires a special organization to assist him in handling the immense amount of detail involved in properly planning and preparing the work of the various departments, and this is the particular function of a planning room. The planning department provides a central point to which is sent all the required information and instructions from the customers' plants which pertain to the work to be done by the shop. The planning department converts this information and all instructions given into proper shape for use in the shop.

SIMPLIFICATION OF AUTOMOBILE DESIGN

With reduced prices for automobiles comes, by necessity, renewed efforts to reduce manufacturing costs. These reductions will come about partly through lower labor costs and improved means of production, but also through renewed activity among automobile manufacturers and their engineering staffs toward greater simplicity in automobile design. It is apparent that the fewer the parts, the less the cost, and it is also more generally recognized than ever before that the fewer the parts, the less the liability of trouble to the user. The Willys-Overland Co. is especially emphasizing this point in a recent circular, pointing to the fact that if fewer parts reduce motor troubles they will tend to increase the reputation of the car, increase the sales, make possible greater production, and, through greater production, reduce manufacturing costs. There is much food for thought in this reasoning, and there is no doubt that there is still great room for improvement in the simplification of automobile design and in so arranging the parts that may need adjustment that they are easily accessible.

* * *

DUTCH EAST INDIAN MACHINE TOOL MARKET

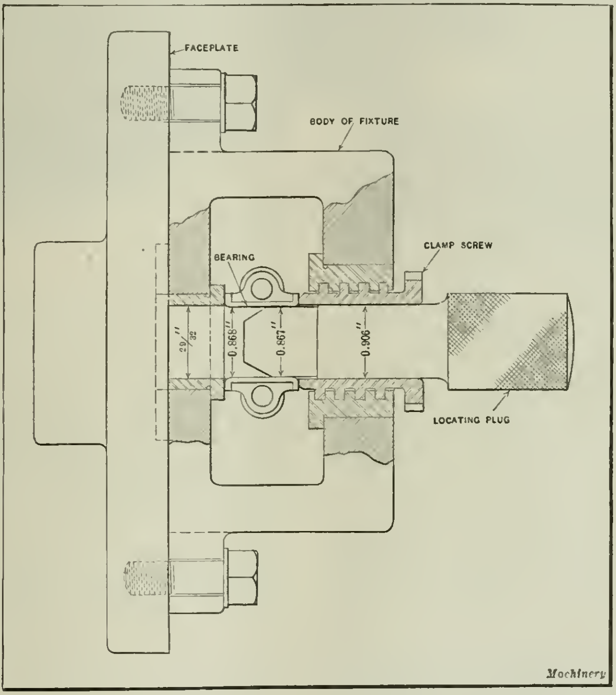
The Dutch East Indies are a colony with which Americans as a whole are not very well acquainted. The Island of Java is practically as long as the distance from Chicago to New York and has a population of 39,000,000 people. In addition to the sugar industry, there is the rubber industry, and the mining industry. The Dutch East Indies are the greatest tin producers in the world. The exports of metal-working machinery ran from $4000 in 1910 to $326,000 in 1920, while in 1919 the machine tool exports alone amounted to $614,000.

REDUCING COST OF FITTING CONNECTING-ROD BEARINGS

By A. K. SCHWARZ
Superintendent, American Motorcycle Mfg. Co., Louisville, Ky.

The writer was recently confronted with the problem of cutting down the cost of fitting and assembling the split bearings at the large ends of connecting-rods used on small motorcycle engines of the two-cylinder opposed type. Owing to the scarcity of skilled mechanics in the locality in which the plant was situated, this problem proved anything but an easy one to solve. The halves of the bearing referred to are made of the best grade of bronze obtainable, and run on carburized, hardened, and ground crankpins, 7/8 inch in diameter by 15/16 inch in length. The piston displacement of the engine is 21 cubic inches, and the maximum speed of the engine under load is 4100 revolutions per minute. These facts are mentioned to show the necessity of obtaining as nearly a perfectly fitted bearing as possible.

Broaches and several types of reamers were given a trial, but owing to the light sections of the connecting-rod, they did not produce a hole having the required roundness and straightness. As a last resort grinding was tried. This method proved a complete success, and in fact, resulted in the production of a better bearing than the writer has ever seen produced by other methods. A set of bearings finished in this manner, which were carefully examined after a run of 500 miles, were found to be in such good condition that less than 0.001 inch removed from the shims between the halves of the bearing would cause the shaft to bind or "freeze." The speed of the motorcycle during this run was thirty miles per hour. The speed ratio between the motor crankshaft and the motorcycle wheel equipped with tires 26 inches in diameter was 6½ to 1.



Fixture used in grinding Connecting-rod Bearing

The following description of the method and grinding fixture developed for grinding the connecting-rod bearing may be of interest to those having similar work to do. The connecting-rod caps with the bearing shells in place were faced off on a disk grinder to allow from 0.005 to 0.007 inch for finish-grinding the bearing to the required diameter. While the fixture illustrated was being built, a grinding wheel manufacturer was asked to recommend a grinding wheel for this job. Using the wheel recommended, the actual time required to grind the bearing was about 3½ minutes, while the time necessary for loading and unloading the fixture was about forty seconds. The limits on the 0.875 diameter were plus 0.0005 and minus 0. Before adopting the grinding method, it required two hours to produce a hand-finished bearing which would be passable, and even then it was not nearly as perfect as one finished by grinding.

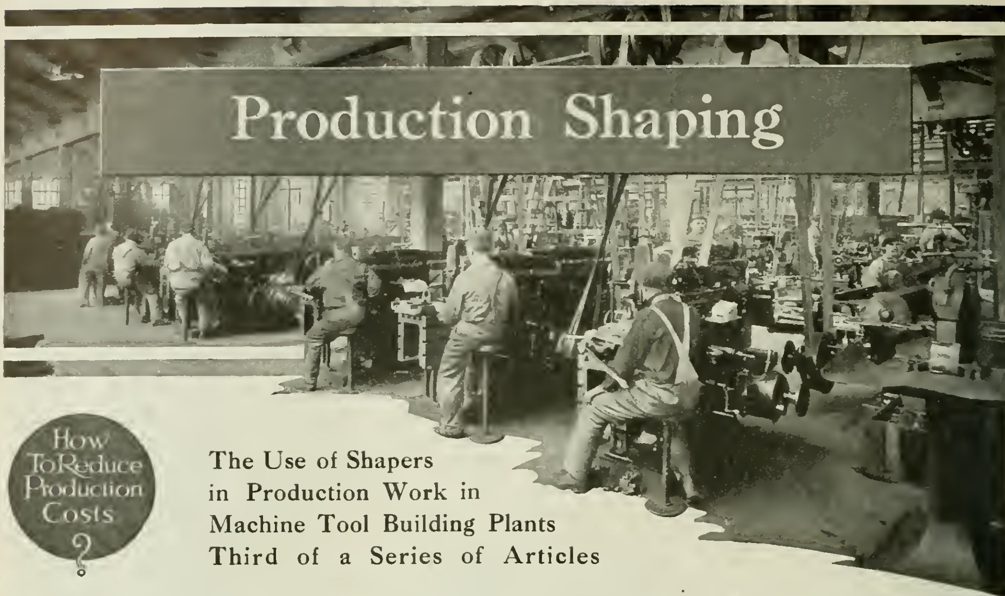
UNDERPAID POSTAGE ON FOREIGN MAILS

The American Chamber of Commerce in France calls attention to the constant lack of full foreign postage on mail received from the United States. It is pointed out that much adverse criticism results from sending letters, circulars, and advertising matter with underpaid postage to foreign countries. The penalty paid by the receiver is double the amount of postage lacking, so that on a letter that should have five cents postage, mailed with a two-cent stamp, the penalty payment would be six cents. Now six cents, it is pointed out, is not much, but if 100 letters are received with underpaid postage, the extra expense amounts to $6 or, at present exchange, nearly 100 francs.

It is also pointed out that the United States appears to be the only country in the world where business houses do not put sufficient postage on their foreign mail, and that, therefore, the feeling of resentment toward this country is all the greater. Attention is called to cases where an agency abroad had gone to the trouble of writing to the firms who had sent letters with underpaid postage, and in several cases very nice letters were received in reply with two-cent stamps on them, so that it was necessary to pay the penalty again.

One correspondent refers to a case of a firm doing business with him, that always sent him letters with short-paid postage. He collected all the envelopes with the penalty stamps due, and returned them to this firm. In reply, he received a very apologetic letter, and was allowed full credit for the amount of underpaid postage, but the reply was placed in an envelope with a two-cent stamp, so that he paid extra postage to receive the apology, and to cap the climax, he received a Christmas card on which he was obliged to pay extra postage.

This neglect on the part of American business houses finally resulted in a complaint being made to the Postmaster General at Washington, about the amount of mail that is allowed to leave the United States with underpaid postage. The Department took up the question at considerable length; the correspondent who made the complaint received a copy of the departmental circular being sent out relating to the matter, together with copies of the entire correspondence. When this letter from the Post Office Department of the United States was received it had on it a postage-due stamp, so that the correspondent was obliged to pay the equivalent of twenty cents in order to find out what the Postmaster General had to say about the matter. Recently, however, a ruling has been made by the Post Office that all foreign mail on which the postage is underpaid will be returned to the sender, provided a return address is on the envelope.



Production Shaping

How To Reduce Production Costs ?

The Use of Shapers in Production Work in Machine Tool Building Plants Third of a Series of Articles

THE shaper is a machine having sufficient flexibility to adapt it for handling a wide range of production work, provided care is taken in the planning of operations and in the designing of tools and fixtures. The following article illustrates the application of shapers for the performance of miscellaneous manufacturing operations in machine tool building plants. All the methods referred to involve the use of principles of general application, so that although these methods are applied to the manufacture of parts of machine tools, they could be utilized with equal success in plants handling various other classes of work.

Planing the Legs of Springfield Lathes on the Shaper

Engine lathes and shapers are built by the Springfield Machine Tool Co., of Springfield, Ohio, and in this firm's plant it is the regular practice to use shapers of their manufacture for planing lathe bed legs. In Fig. 1 a Springfield shaper is shown equipped for this operation, and it will be seen that the table has been removed so that a fixture *A* may be bolted to the saddle, this fixture being of much the same shape as the lathe bed legs. There are two projecting feet *B* on which the casting rests until it has been secured in place.

The cast-iron member *C* of the clamping mechanism carries three hardened plugs (two of which are shown at *D*); these plugs are held in contact with the lathe bed leg casting by three bolts *E*, thus clamping the casting in place on the fixture. The simplicity of the arrangement makes it possible to employ apprentices to do work for which high-priced mechanics might otherwise be required. These lathe bed leg castings are generally rather hard, and for that reason the cutting speed is kept within conservative limits, so that the figures given in the following do not represent maximum production. The cutting tool is carried by a holder and located behind the point of support, as it has been found that a tool of this type gives better results than are obtained with a straight one.

In machine tool building plants, as in many other shops engaged in the manufacture of metal products, there are numerous operations for which the shaper is well adapted. The following article describes methods that are employed in tooling up and operating shapers for such work in plants building lathes, milling machines, grinders, planers, and other types of machine tools. The examples selected are sufficiently general in their scope to suggest applications of similar principles and methods in plants that are engaged in the manufacture of a variety of products.

In planing these lathe legs, the work consists of taking roughing and finishing cuts. There are two surfaces to be planed at the top of the work; on a 16-inch lathe, these surfaces measure 12 inches long by 3 inches wide. A round-nosed, high-speed steel tool is used for taking the roughing cut at a speed of 50 feet per minute, with a feed of 0.011 inch per stroke, and a depth of cut of about 1/8 inch. The finishing cut is taken with a round-nosed, stellite tool of a greater radius of curvature than the one employed for roughing. This tool is operated at the same cutting speed, but with a feed of 0.008 inch per stroke and a depth of cut of about 1/16 inch. Approximately one-half hour is required to set up and plane a casting by the method described.

Facing Bosses on American Lathe Lead-screw Supports

A rather simple surfacing operation is shown in Fig. 2, which illustrates the use of a 16-inch shaper made by the American Tool Works Co., Cincinnati, Ohio. The operation consists of rough- and finish-planing a circular boss *A* on the lead-screw support for American engine lathes. A roughing cut is taken with a round-nosed tool at a speed of 45 feet per minute, using a feed of 0.032 inch, and leaving 0.006 inch of metal for removal by the finishing cut, which is taken at a speed of 45 feet per minute, with a feed of 1/2 inch. The production time on two pieces of work which are set up for simultaneous machining is ten minutes.

The method of setting up the work is the point of particular interest in this job. As the castings come to the machine, they have been planed on their under side, forming a finished right-angled shoulder that is located against the corner of the shaper table. The two pieces of work are held against the side of the table by means of a bar *B*, which passes through cored openings in the castings and is drawn toward the table by means of clamping bolts (not shown in the illustration). The work is held down on top of the table by straps *C*. The thrust of the cutting tools is taken by an end-stop *D*.

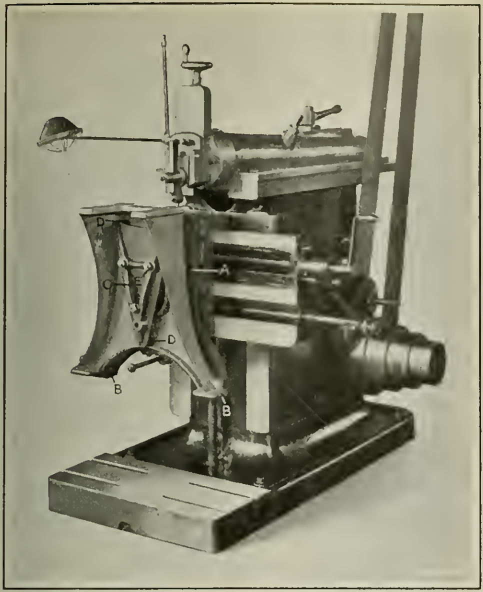


Fig. 1. Shaper equipped for a Short Planing Operation on the Legs of an Engine Lathe

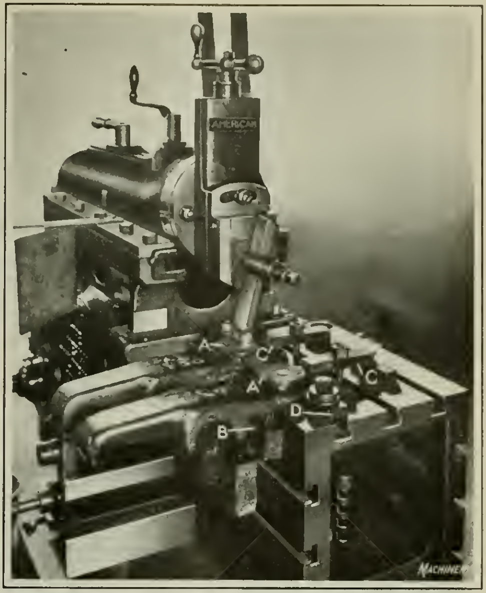

Fig. 2. Shaper equipped for planing the Faces of Bosses on Screw Supports for Engine Lathes

Planing Steptoe Milling Machine Knees on the Shaper

In machining knees for hand milling machines built by the John Steptoe Co., of Cincinnati, a practice is made of planing the dovetailed bearing for the saddle, with the work set up on one of the shapers of this company's manufacture. As the castings come to this machine, the back of the knee has been planed so that it may be used as the locating surface. The table is removed from the shaper and the milling machine knee to be planed is clamped directly to T-slots in the apron. This operation, as shown in Fig. 3, consists of planing the dovetailed bearing for the saddle on the knee, roughing and finishing cuts being taken, as in the preceding cases, with the standard forms of tools employed for this purpose. This is a regular production job in the Steptoe plant.

Shaping Queen City Grinder Driving Shaft Brackets

On grinding machines built by the Queen City Machine Tool Co., of Cincinnati, the main driving shaft located at the back of the machine is supported by brackets of the form shown set up on a shaper table in Fig. 4. While held in this way it is required to plane surface *A* on the casting. An interesting feature of this job is the provision made for holding pieces of work that are of rather an unusual form. The work is held in an offset jaw vise mounted on top of the shaper table, and an auxiliary bracket *B* is bolted to the finished side of the table to support the bearing boss, which would otherwise overhang and cause severe vibration while the cutting tool is at work. The upper part of the casting is further supported by a jack-screw *C* that is furnished with lock-nuts, so that it may be raised under the

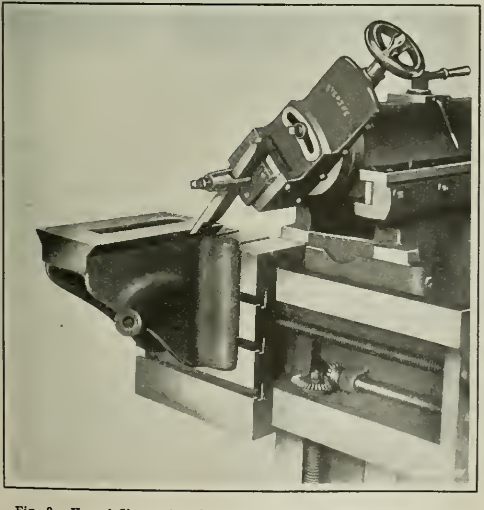

Fig. 3. Use of Shaper for planing the Dovetailed Saddle Bearing of a Hand Milling Machine Knee

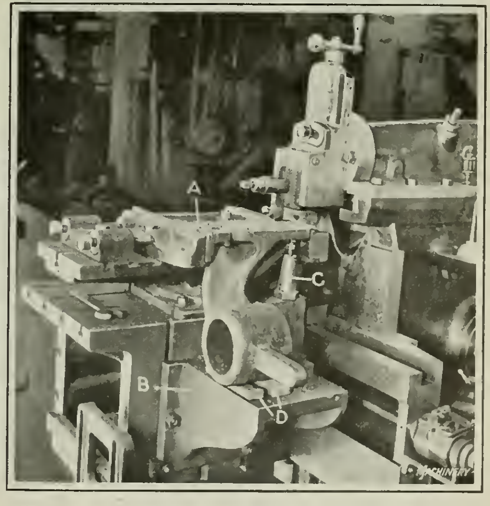

Fig. 4. Planing and tonguing the Face of a Grinding Machine Driving Shaft Supporting Bracket

corner of the casting and clamped in position to support a section of the work that is too thin and flexible to withstand the pressure of the tool without this additional support.

After the casting has been set in the vise and lined up ready for planing, hard wood wedges *D* are driven in between the surface of bracket *B* and the under side of the bearing boss, in order to afford a secure foundation. In the illustration the roughing cut is being taken on the face of the bracket with a round-nosed tool. The sequence of operations is quite simple, consisting of the planing of this face of the casting and the forming of a tongue that fits into a corresponding groove planed in the bed of the grinding machine. After the roughing cut has been completed, a finishing cut is taken with a square-nosed tool. The tongue is finished to the required width with a duplex tool which straddles the tongue and simultaneously finishes its two sides. The operation is performed on a 28-inch Queen City shaper and takes twenty-one minutes.

Shaping Front Plates for American Planer Frictions

In Fig. 5 is shown the work of planing a piece known as the "front plate" for an American planer friction. As the work comes to this shaper, it has been faced on the under side, and a fixture of the form shown is employed, because there is a boss on the bottom of the work, for which a clearance space must be provided in the fixture; otherwise, it would be practicable to strap this piece directly to the shaper table. The job consists of rough- and finish-planing the horizontal surface which surrounds the dovetail bearing, and also rough- and finish-planing the bearing. As the shoulder at the end of the dovetail makes it impracticable to handle more than one piece of work at a time, it is not possible to apply the principle of setting the work up in a string for planing, and consequently this may be regarded as a production job for which the shaper is particularly adapted.

At best, the planer could operate only on one piece at a time, for the reasons mentioned, and the positive stroke control of a shaper is a desirable feature when the tool traverses almost into contact with a shoulder on the work, as in the present case. This job is done on an American 24-inch shaper. At the back of the fixture on this machine is a tool-setting gage *A* used in setting the tools for operation on both the horizontal top face of the work and on the inclined surfaces of the dovetail. The method of procedure is first to rough the top face with a round-nosed tool, and then take a finishing cut with a broad square-nosed gooseneck tool.

Next, a dovetail roughing tool is used for taking the first cut on the inclined faces of the bearing, after which a finishing tool is substituted for the final operation. The dovetail bearing is required to be accurate within 0.001 inch. For testing the work after the finish-planing operation, a gage *B* is used, which is coated with a thin film of red lead and inserted in the bearing in order to test the accuracy of the form and the straightness of the inclined sides. All operations are performed at a cutting speed of 55 feet per minute. On the horizontal surface, the feed for roughing is 1/8 inch, and for finishing 3/4 inch; on the inclined faces of the dovetail, the feed for the roughing cut is 0.020 inch, and for the finishing cut 0.250 inch. There is an allowance of 0.006 inch of metal for the finishing cut. On this job an operator can finish five pieces in eight and three-quarter hours.

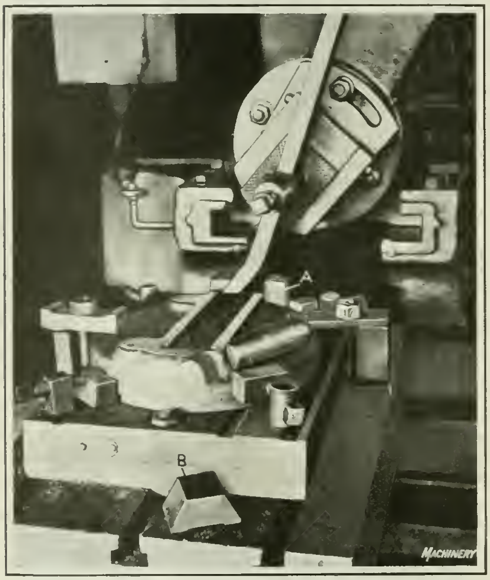

Fig. 5. A 24-inch Shaper equipped for planing the Dovetail Bearing and the Horizontal Face of Front Plates for Planer Frictions

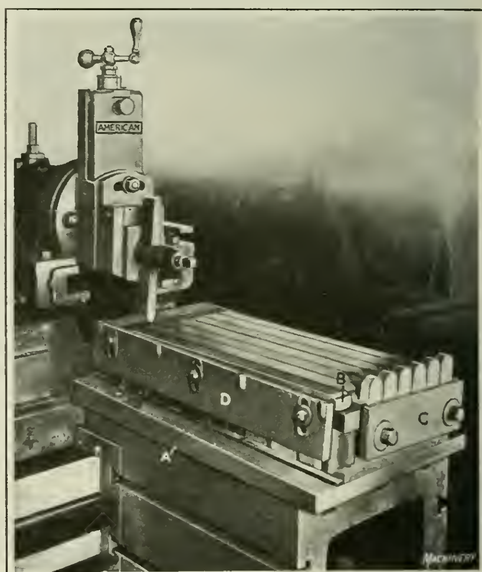

Fig. 6. A 24-inch Shaper equipped for planing the Tapered Face of Gibs held on a Magnetic Chuck

Planing Tapered Gibs on a Shaper

In the plant of the American Tool Works Co., 24-inch shapers of this company's manufacture, which are equipped with magnetic chucks as shown in Fig. 6, are used for taper planing operations on various types and sizes of gibs employed in the construction of American machine tools. The sides and straight under side of the gib are machined before the work is set up for planing the tapered side. It will be seen that six gibs are set up on the magnetic chuck at one time. In order to obtain the required location for the taper planing operation, a master plate *A* is placed between the shaper table and the chuck; this tilts the chuck to the proper angle, so that horizontal strokes of the shaper tool will result in planing the top face of each gib at the required taper to the previously finished lower side.

These gibs are required to be accurate, after finish-planing, within 0.001 inch from end to end. Hence it is important to set up the magnetic chuck on the tapered foundation plate *A* in such a way that the angle of the work will be brought within the required limits. For checking the set-up

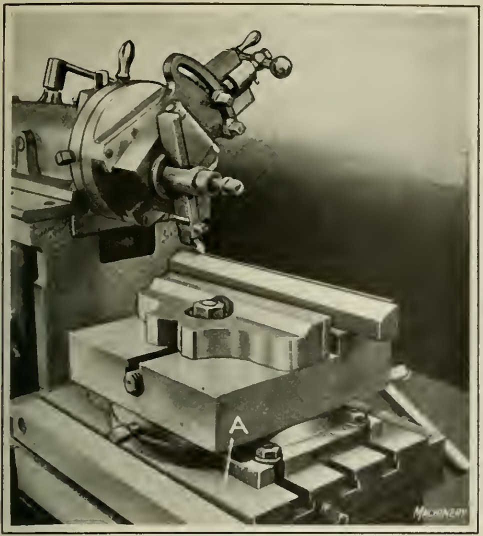

Fig. 7. Method of planing Double-angled Gibs

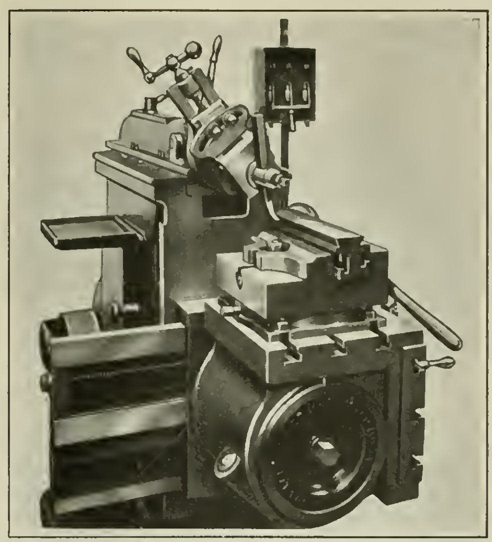

Fig. 8. Planing Inclined Side Faces of Dovetailed Slide Bearing

before planing, a master gib *B* is used, which is placed on the face of the magnetic chuck, a dial indicator being mounted in the shaper toolpost. This master gib is accurately planed, so that if the chuck has been properly set up, the indicator will give a uniform reading from end to end of the gib *B*. Any error which is discovered in making this test is corrected by placing one or more sheets of packing paper between the shaper table and the plate *A* at the low end. Then the operator can set up six of the gibs ready to be planed.

Provision for Supporting End Thrust

The magnetic chuck is furnished with an end plate *C* and a side plate *D* for the double purpose of assisting in locating the work against its previously planed side faces, and of supporting the end thrust of the tool that could not be carried by the holding power of the chuck. A roughing cut is taken over the work with a round-nosed tool, using a cutting speed of 55 feet per minute with a feed of 0.035 inch. For finishing, a round-nosed tool is used, the end of which has been slightly flattened by rubbing it down on an oilstone. This tool is also operated at a cutting speed of 55 feet per minute with a feed of 0.030 inch.

With an equipment of this kind, the setting fixtures may be depended upon to hold the work within accurate limits, after the original set-up has been made by an experienced mechanic. Consequently, it is found economical to employ a semi-skilled operator on this job, and it is for that reason that the finishing cut is taken with a tool of the type described. Otherwise, it would be regarded as better practice to employ a broad square-nosed finishing tool of the goose-neck type, with a feed of from ½ to ¾ inch per stroke. The production time for the rough- and finish-planing operations on the tapered side of six gibs is thirty minutes.

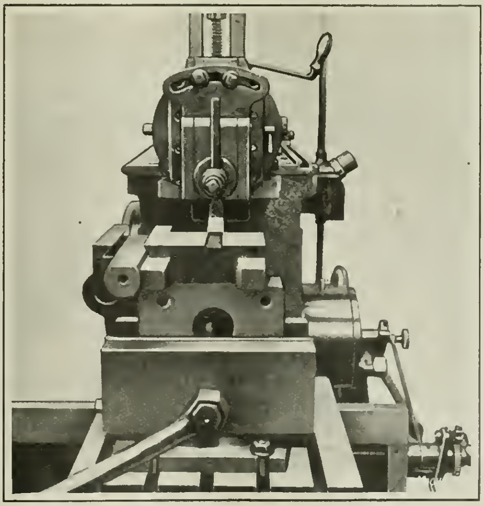

Fig. 9. Use of a Broad Square-nosed Tool for planing a Shallow Slot in the Work

Shaping a Gib Having a Double Taper

Fig. 7 shows how a shaper of the type made by the Potter & Johnston Machine Co., Pawtucket, R. I., can be utilized for machining a piece of work on which there is a double angle. The piece shown in process of manufacture is a tapered gib on which a 45-degree angle is required to fit the dovetailed bearing of the slide, while the usual lengthwise taper is also provided. On shapers of this company's manufacture there is a tilting flap (shown at *A*) at the top of the table, which can be raised to any required angle in order that the surface of the work being machined can be planed at any desired angle with the lower surface of the work that is clamped to the table. It is this application of the tilting flap that provides for obtaining the lengthwise taper on the work; and by setting the tool-head at an angle of 45 degrees, the single-point tool may be fed down the inclined side of the work, thus obtaining the desired form.

Shaping the Angular Sides of a Dovetailed Slide

Fig. 8 shows the method used in shaping the angular sides of a dovetailed slide bearing on a Potter & Johnston shaper. This job is similar to the one illustrated in Fig. 7 in so far as the planing of the 45-degree angular sides is concerned. It will be noticed that the tool-head is set at an angle to give the desired form to the work, but there is one noteworthy difference in this case, which is that the tool is required to cut on the under side of the inclined face instead of at the top. Consequently, the tool had to be forged with an offset on which the cutting point is ground, so that there will not be any interference between the side of the tool and the work. In Figs. 7 and 8 it will be seen that the pieces to be machined are secured in an ordinary shaper vise.

Cutting a Tongue-slot with a Shaper Tool

Fig. 9 shows a Potter & Johnston shaper on which the dovetailed bearing for a slide has just been machined at the setting illustrated. After completing this part of the work, the table is moved over to provide for cutting a tongue-slot; the tool is shown engaged in the performance of this operation in the illustration. For this job, the tool is made of the proper width to take the cut with only a vertical feed movement.

* * *

LENGTH OF ROPE FOR DRUMS

By G. W. TREWHELLA

The formulas given on page 768 in MACHINERY, April, 1921, for finding the length of rope that can be wound on a drum, appear to give results that are too high. One important point not taken into consideration in the previous discussion is that when a rope is wound on a drum the direction of the helix changes with every added layer so that the rope in the second layer will not lie in the groove between the coils of the first layer but must lie across these coils at an angle. This will make the distance between layers nearly equal to the diameter of the rope, so that for practical purposes it is allowable to use the diameter of the rope as the radial pitch of the coils.

The number of coils in a layer will be one less than the width of the drum divided by the diameter of the rope, which will be evident when considering the winding of a rope 1 inch in diameter on a drum 2 inches wide. There is room for but one coil in a layer if the rope forms a true helix. The coils in successive layers will be seen to cross every time at a point opposite the starting point. This will make the increase in radius per layer less than the diameter of the rope at the starting point of a coil, and equal to it at a point opposite the starting point, making each added coil eccentric relative to the first. For such a condition the diameter of the rope must be taken as the radial pitch of the coils, or the most eccentric side will project beyond the flanges. It will also be seen that if the drum is increased from 2 inches to 2½ inches in width, there will be room for 1½ coils under the same conditions, so that it is not "impossible to have a fraction of a coil," as stated in the former article.

In the case of the 1½-coil condition, the coils will cross at opposite sides in alternate layers, so that a dimension slightly less than the diameter of the rope should be used as the radial pitch of the layers. On a drum having a small number of coils per layer, there will be an error in the true helix, but on a longer drum any variation from the true helix will be very slight. In practice, it is not likely that eccentric windings will cause trouble.

The following formulas contain certain theoretical errors which are believed to be immaterial for most practical purposes. No account is taken of the extra length due to the helix of each coil; of the extra fraction of a coil in each layer due to the wedging action against the flanges; or of the rope lying in the groove of the under layer during a part of each coil. The last error works both ways, as it will in some cases allow an extra layer, but will slightly shorten each coil owing to its shorter radius when in the groove. It is only under very favorable conditions that a large number of layers is wound close enough to crowd more rope on the drum than the following formulas indicate; furthermore, for a few layers the errors are so minute that it is believed these formulas will answer the purpose in all ordinary cases.

In the following formulas,

d = diameter of rope, in inches;
D = diameter of drum, in inches;
F = diameter of flange, in inches;
W = width of drum, in inches;
N = number of layers;
O = total length, in feet, of rope in one coil taken from each layer;
Q = number of coils per layer;
L = length of rope, in feet, that can be wound on the drum = OQ

Then

$$N = \frac{F - D}{2d}$$

This formula gives the number of layers to the nearest whole number, unless it is not allowable for any part of the rope to project beyond the flanges of the drum. If such is the case, the fractional remainder should be dropped and the whole number used. If the diameters of the drum and of the flange are considered as the inner and outer circles, respectively, of a ring, the area of this ring may be used to obtain the value of O; thus,

$$O = \frac{0.7854\ (D + 2Nd + D)\ (D + 2Nd - D)}{12d}$$
$$= 0.2618N(D + Nd)$$
$$Q = \frac{W}{d} - 1$$
$$L = OQ = 0.2618N(D + Nd) \times \left(\frac{W}{d} - 1\right)$$

Applying the formulas to the conditions stated in the previous article in which the diameter of the drum equals 12 inches, the width 6 inches, the diameter of the flange 18½ inches, and the diameter of the rope ⅜ inch, we have:

$$N = \frac{18.5 - 12}{2 \times 0.375} = 8\ 2/3 \text{ or, say, } 9 \qquad Q = \frac{6}{0.375} - 1 = 15$$

Then,

$$L = 15 \times 0.2618 \times 9\ (12 + 9 \times 3/8) = 543.4 \text{ feet}$$

as compared with 620.5 feet, obtained from the previously published formula.

In the second case the drum is widened ¼ inch, and the other dimensions remain as before, so that $N = 9$ and $Q = (6.25 \div 3/8) - 1 = 15\ 2/3$.

Then

$$L = 15\ 2/3 \times 0.2618 \times 9\ (12 + 9 \times 3/8) = 567.5 \text{ feet}$$

as compared with 640.6 feet, obtained from the previously published formula.

When the flange is reduced to 18⅛ inches, and all the other dimensions are the same as in the first example,

$$N = \frac{18.125 - 12}{2 \times 0.375} = 8\ 1/6 \text{ or, say, } 8 \qquad Q = 15$$

Then,

$$L = 15 \times 0.2618 \times 8\ (12 + 8 \times 3/8) = 471.2 \text{ feet}$$

as compared with 548.4 feet, obtained from the previously published formula.

The only piece of rope available for checking these formulas was a reel containing 5000 feet of wire rope, 2¼ inches in circumference. The values used in checking the formulas were D = 14 inches; W = 29 inches; F = from 40 to 41 inches; and d = 0.75 inch. It was not practicable to test the concentricity of the windings, owing to the small hole in the end of the reel, but the larger value of F was used as representing the required diameter of a flange to support the rope. This was new rope, wound evenly on the reel, closer than would be the case in average usage. The formulas here presented give the length as 4881 feet, while the formulas published in April MACHINERY give the length as 5388 feet.

Selling Machine Tools

By a Machine Tool Sales Manager

As nearly as the writer has been able to determine, there were in the spring of this year approximately 1400 salesmen in the great manufacturing section of the United States east of the Mississippi and north of the Ohio and Potomac Rivers devoting their entire time to the selling of machine tools. This figure includes the members of firms dealing in machine tools who devote their time to selling, their outside salesmen, their store salesmen, and the direct selling representatives of machine tool manufacturers, as well as sales correspondents. It excludes service men, demonstrators, and those officials of machine tool firms and their assistants whose work is business routine rather than direct sales work.

On the Pacific Coast and in the southern states there are a great many machine tool salesmen, but in those sections there are probably not more than fifty who devote their entire time to the closing of sales agreements relative to machine tools. In those parts of the country the relative scarcity of machine shops requires the salesmen to handle more lines than machine tools only, thereby dividing their sales efforts. These salesmen usually sell supplies and equipment for woodworking and mining, and also handle contractors' machinery, in addition to machine tools. Were these "part-time" salesmen included, as well as those members of machine tool firms who are not directly active in the selling organization, the total number of men engaged in the distribution of machine tools in the United States would be in the neighborhood of 8000.

Tendencies in the Selling of Machine Tools

There is a rapidly growing tendency in industry in general for the manufacturer to get closer to the point of sale. In the machine tool industry this tendency is indicated by the rapid increase in the number of manufacturers who have their own selling organizations and salesmen and who deal directly with the consumer. It is also indicated by the number of sales engineers, district representatives, and special representatives traveling through the country for concerns who continue to distribute their machines through dealers.

In the distribution of some commodities, such as food products for example, a direct distribution system eliminates time and waste and results in a lower price to the consumer. This, however, does not apply to the machine tool industry. In the majority of cases manufacturers of machinery are not so much impressed by the economy of direct distribution; they are mainly interested in cutting down the distance between themselves and their customers in order that they may keep in closer touch with the trade. They desire to observe tendencies, combat harmful influences, and watch the effect of their sales and advertising work. The machine tool salesman enjoys the unique distinction of knowing the mechanical phases of the business almost as well as the manufacturer whom he represents. He is therefore able to pass on information that the manufacturer otherwise would find difficulty in obtaining.

Apart from this close contact with the trade, there is perhaps less to be gained in the machine tool industry from direct dealing with the customer than in other industries, and the question as to whether machinery house salesmen or manufacturers' direct salesmen are to be preferred is a question that must be settled individually. It depends to a considerable extent upon the product, the locality, and the machinery dealers in the territory under consideration.

Characteristics of Machine Tool Salesmen

Whether employed by a machinery dealer or by the machine tool manufacturer, the machine tool salesmen generally possess unique characteristics. They occupy a class by themselves in the selling profession. In knowledge and training in the business which they represent, machine tool salesmen can confidently challenge those of other industries. The majority of machine tool salesmen obtain their early training in machine tool plants and later branch out into the selling department, either as representatives of their own company or of machinery dealers. Many have developed into salesmen from minor positions within the organizations of machine tool dealers, and only a few have come into the field from industries not connected with the machine tool business.

Another characteristic of the machine tool salesman is that he seldom has sold any other product. The fact that he so largely originates from within the industry accounts for some of his distinguishing methods. The machine tool salesman depends almost exclusively upon his mechanical knowledge in his sales work. He knows the goods more thoroughly and gives to his customers and prospects a greater amount of definite and valuable information than the salesman in practically any other line of industry. The machine tool salesman also, in the course of his work, absorbs and is able to later distribute a great fund of mechanical information. On the other hand, he does not seek and is somewhat slow to absorb and practice many points of salesmanship that could be advantageously used.

The Salesman's Position Today

There are times when the business relations between the manufacturer and the customer in all industries need to be carefully handled. This is true of the machine tool industry as well as of any other industrial field. The late inflated period was to no man's liking. There are instances in it that are stamped upon our memory. The object of our late wrath may have been the landlord, or the butcher, or we may have a mental waiting list of those that were paid a higher price than we considered reasonable. In the excitement of boom times we paid what we were asked, reserving only the determination to even matters up in some way when the opportunity presented itself.

As a matter of fact we are justified in harboring a feeling of resentment in but few instances. The seller of articles or products at what we termed exorbitant prices was himself caught in the same whirlwind of economic conditions. Few understood or understand now these economic conditions. The average buyer of machine tools does not dig deeply into the study of economics—it is apart from his regular line of duty, and it is a very dry pastime. However, the position and the policy of the machine tool builders during the period of inflation was, as a rule, exceptional, and it is the machine tool salesmen's opportunity to capitalize that position. He need not be an economist in order to be able to represent fairly the machine tool manufacturer's position, and he can employ his opportunities as a salesman to gain advantage in giving accurate information as to the relation of costs and selling prices during the entire period of inflation. In this way he can safeguard his industry as well as gain greater results from his sales efforts. In articles to follow the writer will dwell in greater detail upon some of these points.

HOW PRODUCTION COSTS ARE REDUCED

October and November MACHINERY presented numerous practical examples of cost-reducing methods, particular attention being directed to the necessity for a careful study of present shop practice in order to determine the possibilities for substantial cost reductions through the use of more efficient methods and equipment.

In this number the educational campaign is continued. Specific examples are mentioned here only to emphasize to mechanical executives the importance, in these rapidly changing times, of keeping abreast of the new machines, tools, methods and processes which automatically bring down manufacturing costs. These new tools and new ways of doing things cover a wide range of shop practice and are applicable in all branches of the metal-working industry.

The article in this number on reducing costs in the assembling department is typical in giving ideas and suggestions that may be profitably studied. The cost-reducing tooling equipments for automobile work described in two different articles show principles that may be applied with equally satisfactory results to any line of manufacture where the quantity is great enough to permit the use of such methods. Other articles refer to efficiency and lower costs obtained through careful study of drilling problems and of combination die design. The value of the die-casting process for reducing costs is more and more being recognized, and an article on this subject gives comparative costs on making certain parts by former methods and by die-casting.

The great need is for more radical thought in regard to equipment and methods. Because a method used for years proved satisfactory in days when cost was relatively unimportant, when more orders could be had than the factory could fill, it is far from certain that the same methods will serve today when price is almost the chief consideration.

* * *

THE NEW BASES FOR ADVANCEMENT

Jobs are not so plentiful as they were, and they will not be back to the heyday of 1917, 1918 and 1919 for many moons to come. The fevered period of war production ended long ago, and the day when any good-for-nothing could get a job has passed. The amazing labor replacement, which was as high as 70 per cent in many industries, no living man may see again. A job, almost any kind of job, has taken on greatly increased value. The better jobs are scarcer than at any time in twenty years, and hereafter it will take more knowledge and ability to get those jobs and hold them than ever before. Manufacturers are endeavoring to reduce their production costs to meet the keen competition for orders that is here now; machinists, toolmakers, draftsmen, machine designers, foremen, works managers, are also facing a period of keen competition—for jobs.

Prices have been reduced; costs must follow. Greater production for the dollar expended in the plant will force the elimination of every factor below the most efficient, and the human factor cannot hope to escape this inevitable readjustment. A great many designers, foremen and men higher up in the mechanical world have lost their places for good, but many of them do not know it yet; nor do they realize that there is a new deal in industry, that credentials which were satisfactory years ago will not do now. The world is demanding new men as well as new methods, men who are energetic, alert, better equipped, eager to win their way to the top, keen to note the new bases in industry.

Useful knowledge will be more important than ever before. Successful men are always great students. It is knowledge and character that advance a man, and now the tests are more severe. Success is won, not at the movies or in any of the other primrose paths of dalliance, but in the faithful hours of study and preparation for the bigger job ahead. Merchants and manufacturers are keenly watching for the men who are to carry on—to take up their burdens, as they took up the burdens of those who preceded them. Upon these men depends America's place in a world battling for industrial and commercial supremacy—which means everything else. It is a direct and ringing challenge to the men, especially the younger men, in the mechanical industries of America. Industry demands the best they have.

Every field has developed and more or less systematized a body of literature, a fund of craft data, available for the earnest worker determined to make his way up the ladder of success. It is a great treasure house in which is stored the priceless data worked out by generations of men in the exacting school of practical experience. Unless he masters this educational material and makes it his own, the worker in the engineering field is not equipped for advancement and responsibility and he will fail when the tests come. The data are there, the educational facilities are available for any man who can read and think. It is up to him. Unless he is willing to make the effort he must be content with a humble place in the ranks.

* * *

INTEREST IN STANDARDIZATION GROWS

In his address before the National Machine Tool Builders' Convention, the president, A. H. Tuechter, strongly emphasized the importance of machine tool builders taking more active interest in the work of standardization, and pointed out that if the machine tool builders did not voluntarily standardize such of their products as lend themselves to uniform design, engineering bodies representing the users of machine tools would be likely to take up this work, to the disadvantage of both manufacturer and user.

The American Gear Manufacturers' Association has done some excellent work in connection with the standardization of gearing. A comprehensive plan, covering all classes of gearing, has been laid out; and, step by step, each of the details making up this plan is studied by committees composed of men having the training needed for handling each particular detail. The standards accepted by the society are in many cases agreed upon by cooperation with the American Society of Mechanical Engineers and the Engineering Standards Committee, which acts as a clearing house for all standardization work in the United States.

It is evident to every manufacturer that standardization is one of the most important factors in cost reduction, and without question it will be applied more generally to manufactured products in the near future. Builders and users of machinery will be the first to benefit, but the general public will also profit in greater measure through the decrease of manufacturing costs. In Germany the engineering profession is now engaged in important standardization work, and our competitive strength in the world's markets will largely depend on our ability to keep abreast of the advances made there and in other manufacturing countries.

Reduced Prices of Machine Tools

THERE has been a decided reduction in the prices of machine tools during the past year, and those who are thoroughly familiar with the machine tool industry believe that further reductions can be expected only in exceptional instances. The reductions that have been made have not been uniform for all classes of machine tools, because the conditions governing the manufacture of different lines and types vary. Furthermore, the increases in prices in the last seven years have varied considerably for different types. There are some purchasing agents who seem to believe that machine tool prices should return to the 1914 level, but those who expect this are not familiar with the conditions in the machine tool industry and the reasons why it would be impossible to conceive of any return to the 1914 price level.

In February, 1921 MACHINERY, a thorough analysis was published of comparative machine tool prices in 1914 and 1921. Since that time conditions have changed somewhat. In many respects they have become more stabilized, and it is possible to show definitely why a return to pre-war prices in machine tools is impossible. In fact, even a near approach to the pre-war price is not to be expected. As machine tool builders appear to have some difficulty in obtaining orders even where the machines are needed at the present time, because some purchasers insist upon prices more nearly like those of 1914, it might be well to point out a few of the conditions prevailing in the manufacture and selling of machine tools, for the information of buyers who have not taken these conditions into consideration.

The 1914 Price Level

As pointed out in the article in MACHINERY previously referred to, the prices in 1914 were so low, because of extremely keen and ruinous competition, that they returned no profit. The prices at that time were too low to support the industry permanently. The competition due to the industrial depression at that time had forced manufacturers to accept prices that did not cover all their costs, and it was not until two years later—in 1916—that prices had risen to a level where a profit sufficient to sustain the industry permanently was obtained. The figures of a well-known manufacturer show that if the 1914 prices had been based upon costs with a fair profit, they should have been about 40 per cent higher than they were at that time. To expect prices to return to a level that even previous to the war did not produce sufficient profit to sustain the industry is evidently impossible.

Wages and Taxes in 1914 and 1921

It should not be necessary to point out to anyone familiar with industrial conditions that wages are permanently on a higher level than they were in 1914. Even in the industries, like the iron and steel industry, where wages have been most drastically cut, the rate for unskilled labor is now 50 per cent above the pre-war rate, and for skilled labor it is still higher. In addition to this, working hours are shorter now than before the war, and are likely to remain so, which means that there are added costs on that account.

It has been pointed out by many who have studied the history of wages that the wage rate never goes back to the same low point from which it has once started to rise, and therefore there is no reason to believe that machine tool builders will ever again be able to hire skilled machinists for 25 or 28 cents an hour, which was the rate commonly paid in many machine tool centers previous to the war.

The national taxation program due to the war, and the increased state and municipal taxes made necessary by the conditions created by the war, comprise a very important part of the cost of all products, and cannot be eliminated in determining upon the selling price. The influence of taxes upon price will continue to be an important factor of costs for many years to come, because we have an enormous national debt to pay, the interest of which alone is twice our largest national budget previous to the war. Any business man who thinks that business can be carried on without passing the taxes on to the consumer ignores one of the fundamental facts in economics, because a manufacturer must, out of his production, obtain a return over all expenditures, including taxes, or he will not be able to stay in business.

The Effect of Increased Freight Rates

Another element that enters into cost calculation all along the line is that of freight rates. Generally speaking, freight rates have been increased from 100 to 120 per cent on the materials and the finished products of the machine tool industry. Reductions in freight rates are desirable, but by necessity it must be quite a while before they can be materially reduced. If they are suddenly reduced to the detriment of the railroads, this will, in turn, react unfavorably upon the metal-working industries, because the railroads are big purchasers of the products of these industries; so that no matter how desirable it is that freight rates be reduced, it is even more important that the efficiency of railroad labor be increased and an equitable adjustment made in railroad wages, and this cannot be done suddenly. The transportation element, therefore, will continue to increase the cost of manufacturing for a long time to come.

Improvements Made in Machine Tools

In addition to all the factors mentioned, there is the fundamental one to be considered that all machine tool builders have greatly improved their product during the last seven years, so that even if there had been no abnormal price advance due to conditions created by the war, there would by necessity have been an advance in price due to the improvements in the product. This was specifically pointed out in the article in February MACHINERY, where reference was made to a machine that weighed 15,200 pounds in 1914, and which now, redesigned, weighs 19,000 pounds. Not only was the weight of this machine increased so as to afford increased strength and capacity for greater production, but the speed was also increased nearly 100 per cent, and the power from 8 to 20 horsepower. These changes necessitated gears made from higher grade material, properly heat-treated, and the material in some parts had to be made from steel costing three times as much as the material formerly used. The machine is known by the same designation as to size and other characteristics as it was seven years ago; yet no reasonable buyer would expect to purchase it for the same price even if there had been no other factors increasing costs and prices in the last seven years.

In comparing 1914 and 1921 prices, the factor of improved design should be particularly emphasized. The machines sold today are heavier, their capacities greater, they have more power and speed, they are made from better material, and they will therefore last longer and produce more. There are also many attachments provided that were not provided in the past. No such comparisons can be made in regard to clothing, shoes, sugar, or numerous other commodities which should be more likely to return to the pre-war price level than machine tools; these are an entirely different class of manufactured products.

Making One-piece Corrugated Elbows

Machines Employed for the Performance of Corrugating, Forming, Compressing, and Bending Operations

By separating the manufacture of one-piece corrugated stove-pipe elbows into a series of logical steps and designing a machine for performing each of these, the Niagara Machine & Tool Works, Buffalo, N. Y., have succeeded in building an equipment which produces elbows that are uniform in diameter, accurately bent to a right angle, and have tight throat seams and evenly spaced corrugations. Only four machines are required for producing the bent and corrugated elbows from blank sheets of metal, and by grouping these machines as shown in the heading illustration, the transportation of parts between the machines is eliminated, and a minimum amount of labor is required for maximum production. The process is such that the metal is not stretched along the outer curve of the bend, and hence its strength is not decreased nor the surface broken, the latter being a condition that mars the appearance and hastens corrosion.

Corrugating the Sheets and Rolling into Pipe Form

The blank sheets from which the elbows are formed may be purchased trimmed to the correct size, or they may be cut and squared by means of a squaring shear, a 30-inch machine of this type being satisfactory for the purpose. In the first operation, these blanks are fed between the two corrugating rolls of the machine illustrated in Fig. 1, which revolve at the rate of 20 revolutions per minute. Each sheet is placed on the table and properly positioned relative to the rolls by means of front and side gaging strips. When the foot-treadle is depressed, the sheet is automatically fed through the rolls. The number of corrugations produced can be varied to suit the different sizes of elbows. Offsets are formed in the corrugations along one edge of the sheet, which insures a close lap joint in the finished product. A piece of work, after having been operated on by this machine, is shown in the lower right-hand corner of the illustration.

In the next operation the sheets received from the corrugating machine are run through the machine shown in Fig. 2, the sheets again being aligned on the table by means of gaging strips while the upper roll is raised. This roll is then lowered, and an initial bend put in the front end of each blank by means of a vertically moving slide. Next by operating a friction clutch, the rolls are caused to revolve, with the result that the sheet is formed into a corrugated pipe, which can easily be removed after the upper roll has been raised. This machine can readily be adjusted to produce pipes of various diameters. The rolls make seventy-five revolutions per minute.

Compressing the Corrugations and Bending

In the third operation the corrugations of the pipe are compressed by means of the machine illustrated in Fig. 4, so that the pipe length is considerably shortened. A ring is inserted in each end of the work prior to placing it in the mold of the machine, the upper half of this mold being shown in a lifted position in the illustration. After the work has been inserted, the upper section of the mold is lowered and locked to the lower section. The pipe is compressed at one stroke of a ram which is controlled by a pin clutch, actuated by a foot-treadle. The rings placed in the ends of the pipe prior to the operation can be readily removed after the work is taken from the mold. This member may be adjusted to suit various sizes of elbows, by means of steel rings, inserts, and liners, and the amount of compression can also be varied. When the machine is operating continuously the ram makes fifty-one strokes per minute.

The fourth operation in the manufacture of the corrugated elbows consists of bending the pipe so that its ends form a right angle. The machine illustrated in Fig. 3 is employed for performing this operation, the work being firmly clamped on each end by means of a chuck. The relative positions of the chucks after the work has been placed in the machine is shown in the upper portion of Fig. 5. The operation of the machine

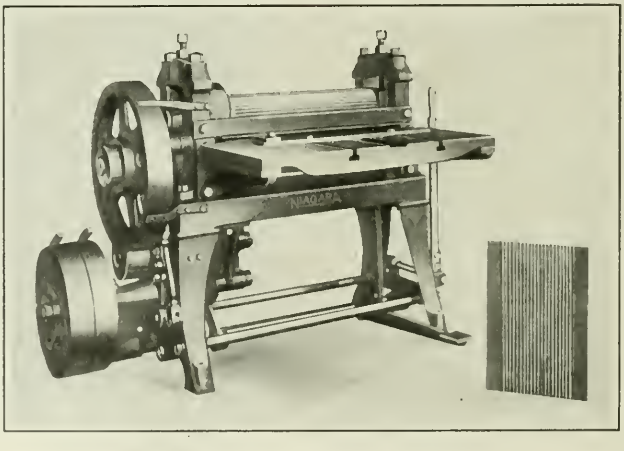

Fig. 1. Corrugating Machine on which the First Operation on the Blank is performed

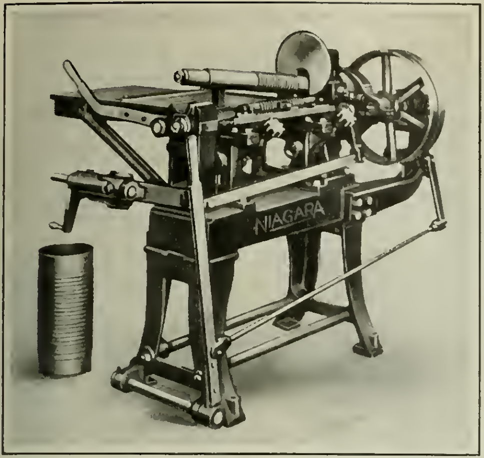

Fig. 2. Machine used to roll the Corrugated Sheet into the Form of a Pipe

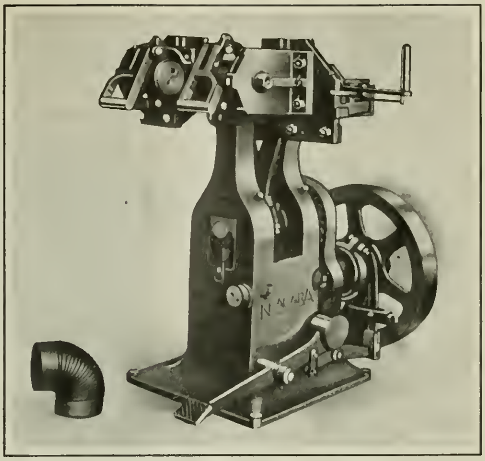

Fig. 3. Bending Machine with Chucks in Positions occupied prior to an Operation

causes these members to swivel to the position shown in the lower view, Fig. 5, in which they form a right angle to each other. The movement of the chucks separates the corrugations on the outer curve of the elbow and compresses them on the throat, thereby pressing the seams more firmly together, as the pipe is always so placed in the machine that the seam will come at the throat. In order that this machine may accommodate various sizes of elbows, it is provided with the essential adjustments and extra chucks and clamps. This operation completes the forming of the elbows. They are later spot-welded at each end, and then one end is crimped by means of a belt-driven machine having two crimping rollers between which the elbow end is passed. The bending machine may be operated at sixty-seven strokes per minute.

It is a known fact that the metal sheets supplied by the mills are not always uniform in gage, and so to compensate for any variations, the equipment described is designed to accommodate, without readjustment, sheets of more than ordinary variation. Metal sheets of No. 26 gage and lighter can be handled. The sheets also are not always uniform in quality, but it is said that sheets that could not be formed into elbows by other processes have been satisfactorily handled by means of the Niagara equipment. Usually a special quality of sheets is required for elbow manufacture, but with the machines described ordinary blue annealed sheets of good quality are suitable. The entire equipment may be driven by a 5-horsepower motor, and will produce elbows ranging from 4 to 8 inches in diameter.

SECTIONAL MEETINGS OF THE AMERICAN SOCIETY FOR STEEL TREATING

At a recent meeting of the board of directors of the American Society for Steel Treating it was decided to hold two sectional meetings of the society during the coming year, in addition to the regular annual convention. One meeting will be held in New York during January or February and the other in Pittsburg in May. The meetings will continue for one or two days and a few papers will be presented but no exhibits will be shown. The next annual convention and exposition will be held in Detroit on September 25 to 30.

The Pratt & Whitney Automatic Lathe

VARIOUS types of hand-operated and automatic turret lathes and screw machines have been developed for rapidly turning short work from the bar or while holding it at one end only; however, the engine lathe is still used in innumerable cases of quantity production, when the work must be supported on centers during turning. These cases include work which, because of its length or peculiar requirements as to accuracy or finish, can only be satisfactorily turned on centers; work which is turned in preparation for a later grinding or machining operation, the engine lathe permitting the turning to be done on the same centers that are afterward used for other operations; forgings and other irregular pieces which, on account of their shape, cannot be readily held in chucking machines; and work in comparatively small quantities which does not warrant the cost involved in setting up a turret lathe or automatic screw machine.

With a view to eliminating a large part of the cost of turning work such as has been described, and at the same time retaining the advantages of the hand-operated engine lathe, the Pratt & Whitney Co., Hartford, Conn., has produced the automatic lathe shown in Fig. 1 equipped with a geared head. The rear view of a smaller machine driven by a four-step cone pulley is illustrated in Fig. 2. These lathes have a headstock, tailstock, magazine for holding the work, and an automatic work-handling and control mechanism. The automatic mechanism places the work on the centers, adjusts and clamps the tailstock spindle, grips the work by means of the rotating chuck, which serves only as a driver, starts the feed of the tool carriage, releases the tailstock and chuck at the end of the cut, and, finally, returns the carriage to the starting position. These steps are repeated automatically for each piece of work so long as the magazine is supplied with blanks. After setting up, the only attention required is that of refilling the magazine, taking away the finished parts, and grinding and setting the lathe tools. Because of this fact it is possible for a battery of machines to be handled by one man.

Although these lathes are only now being introduced to the trade they have been used in the Pratt & Whitney shops for years in turning high-grade tap and reamer blanks and other similar work, and have proved their ability to rapidly and cheaply turn cut-off bar stock, forgings and other parts with the accuracy and finish generally obtained in good engine lathe practice. The smaller machine takes work from 1/4 to 5/8 inch in diameter and up to 12 inches in length, and has a carriage travel of 8 inches. The larger lathe takes work from 1/2 to 1 1/8 inches in diameter and up to 15 inches in length, and has a carriage travel of 12 inches. Many forgings of irregular shape and with a swing larger than the diameters given can be handled to advantage.

As previously mentioned, the lathe has been developed with either a cone-head or a geared-head drive. On the cone-head machine a belt from a countershaft drives the headstock spindle and feed mechanism, while a separate belt from the countershaft drives the automatic mechanisms at a constant speed. On the geared-head machine, one belt from a lineshaft drives the entire machine, all speeds and feeds being obtained within the machine. The number and range of spindle speeds is greater with the geared-head machine, and the drive is more powerful. Speed changes are made by shifting the ball-handle lever *A*, Fig. 1, on the headstock, in an H-slot to any one of four positions, and also shifting the adjacent back-gear lever. This gives a total of eight speeds. On the larger machine four feeds are available for each spindle speed, and on the smaller machine, three feeds may be obtained for each spindle speed.

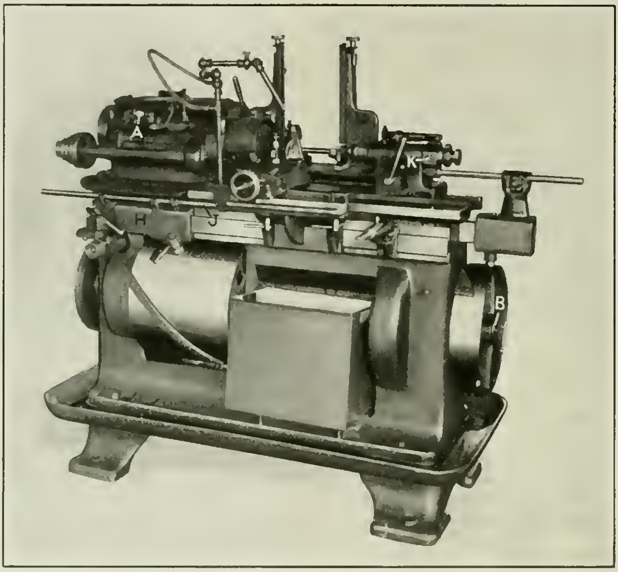

Fig. 1. Geared-head Automatic Lathe developed by the Pratt & Whitney Co.

The Camshaft Drive

The cams which operate the automatic mechanisms of the machine are mounted on shaft *B* running the entire length of the machine. This shaft is rotated at two different speeds. The slow rotation is adjustable and gives the advancing feed for the carriage, while during the rapid rotation, which is constant, the chuck is opened, the footstock spindle withdrawn, the carriage returned, the stock from the magazine advanced, the footstock spindle advanced and clamped, and the chuck closed. Power for the slow rotation is obtained through the small cone pulleys seen on the end of the machine in Fig. 2. The center distance between these cones is adjustable so that the proper belt tension may be maintained. The lower cone shaft transmits power through worms and worm-wheels, clutch *E*, and shaft *D* to camshaft *B*, as shown in the sectional view in Fig. 3.

Power for the rapid rotation of the camshaft is delivered to the small plain pulley *C*, Fig. 2, on the gear-box, a swinging idler being provided to maintain a sufficient belt tension to operate the mechanism. Power is transmitted from pulley *C* through spiral gears *F* to clutch *E*, Fig. 3, the drive from this point to the camshaft being through shaft *D* and a worm and worm-wheel used in the slow rotation. The toothed clutch serves to throw in alternately the feed and high-speed mechanism, at predetermined intervals, being actuated through the medium of levers by adjustable trip-dogs *G*, Fig. 2, mounted on a disk at the left-hand end of the camshaft. The piping for the cutting coolant and the circulating pump, which is chain-driven at a constant speed, are also shown in the same illustration.

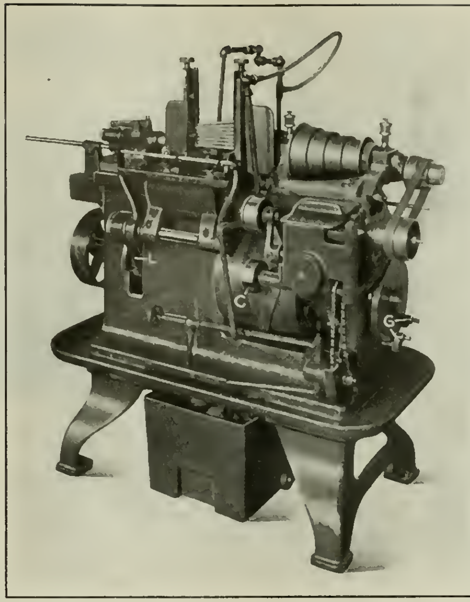

Fig. 2. Rear View of Cone-driven Automatic Lathe

The hand-lever seen at the left-hand end of the machine in Fig. 4 gives a complete control of all machine movements except the rotation of the headstock spindle. Depressing this lever stops the rotation of the camshaft, and when it is raised and drawn forward, the camshaft rotates at high speed. When the lever is pressed toward the machine, the feed is thrown into engagement, and when elevated above the horizontal position, the feed will stop at the end of the cut to permit calipering or inspection of the work. The squared end of the shaft which is located below this control lever enables the machine to be operated by a hand-crank for trial when it is being set up.

The Carriage and Footstock

The carriage slides on the front of the bed and allows finished work to drop through an opening in the bed to the box below. The carriage has a cross-slide with adjustments on which may be mounted a toolpost and a follow-rest when needed. A jointed taper bar carried on a heavy bracket clamped to the front of the bed provides for turning taper work, and both straight and taper surfaces can be turned in one continuous cut. Various former bars may be substituted for the adjustable taper bar. The carriage is traversed the desired length of cut by the rotation of the large drum which carries cam straps, that, through a roller on slide *H*, Fig. 1, move the carriage-actuating rod *J*. Slide *H* is dovetailed to the bed. Provision is made for hand adjustment of the carriage by a rack and pinion which may be seen near the right-hand end of the machine in Fig. 1.

The spindle of the footstock is drawn back to release finished work and advanced to take new work by the operation of cams mounted on the pulley which may be seen at the extreme right-hand end of the camshaft. These cams, through a roller, move the slide mounted directly above it, and this slide, in turn, is coupled to a friction ring *K* on the footstock spindle. The rod connecting the slide and friction ring allows the footstock to be placed as far forward on the ways of the bed as the shortest work will require.

A slight slip of the friction ring takes place each time the spindle is drawn back, this being caused by the stop-collar on the front end of the spindle coming into contact with the front of the footstock casting. Therefore, when the spindle is advanced into contact with the work, the friction will again slip, insuring the proper contact with work in

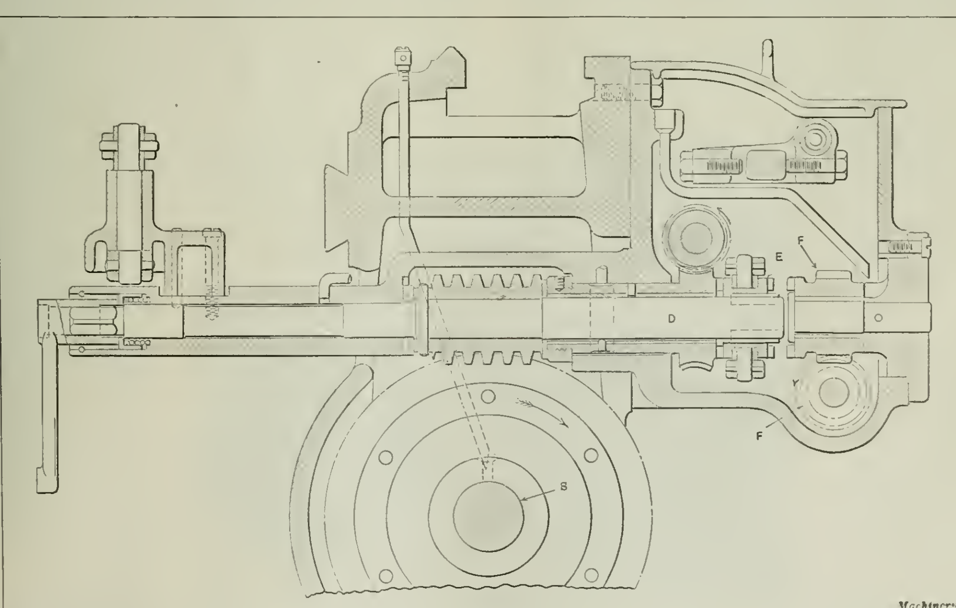

Fig. 3. Sectional View of Mechanism by Means of which Fast and Slow Rotation is imparted to the Camshaft

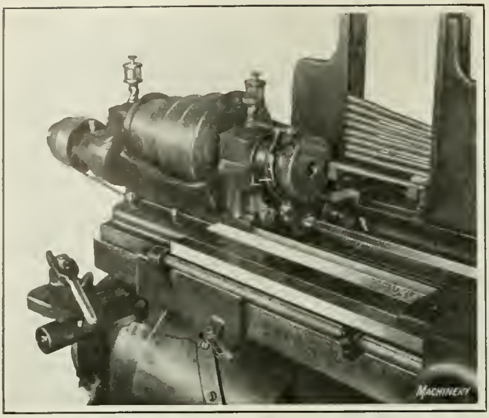

Fig. 4. Close-up View of Head End of Machine, showing Chuck and Work-feeding Mechanism

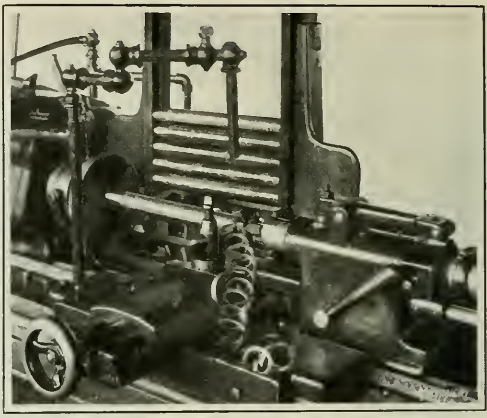

Fig. 5. Automatic Lathe engaged in taking a Heavy Cut on Work mounted on the Centers

spite of variations in length due to inaccuracies in cutting off and variations in depth of centering. The pressure with which the center is brought in contact with the work may be adjusted by the square-head screw on the friction ring. The footstock spindle is firmly clamped in place, after the center has made proper contact, by a further movement of the friction ring, which operates the horizontal lever over the footstock, thus forcing a plug on the spindle.

Construction of the Chuck

The chuck is mounted on the headstock spindle in such a manner that it floats laterally when necessary to compensate for inaccuracies in centering. Thus it can exert no lateral pressure on the work which is carried on the headstock center. Detail views of the chuck with the cover removed are shown in Fig. 6. At *A* the chuck is shown with the jaws drawn back ready to receive the work, which is inserted by the movement of the footstock spindle, as previously explained. The chuck jaws are moved into this position, while the lathe is running, by friction exerted on a drum carried by the chuck body. The friction is applied by the levers *L*, Fig. 4, and momentarily retards the rotation of the outer member of the chuck. This action not only draws the jaws back but also stretches the three springs shown in Fig. 6. Upon the release of the external friction, the springs move the outer member of the chuck in the forward direction, and thus swing the three jaws into contact with the work as shown at *B*.

An effective drive is obtained by the cam action of the jaws themselves without depending on the springs, and although the contact surface of the jaws is smooth so as not to mar the work, they will drive work under any cut which the lathe is capable of taking. The knurled surface on the outside of the chuck is used for setting it to the desired work diameter. Diameters between and including those indicated on the face of the chuck are taken care of by the rise of the cam surfaces on the jaws. Thus any size of stock within the capacity of the chuck may be driven if the knurled ring is revolved to the nearest indicated diameter on the chuck face. The alternate opening and closing of the chuck in proper sequence is controlled by a cam located on the camshaft directly beneath the headstock.

Operation of the Work Magazine

The position of the magazine, which is located on a bracket at the rear of the machine, is clearly shown in Fig. 4. The magazine consists of two uprights, adjustable to take both short and long work, and two guides on each upright adjustable to suit work of different diameters. Horizontal slides are provided for moving the pieces forward, one at a time, from the magazine to the machine centers. These slides are adjustable for all diameters within the capacity of the machine. As soon as a piece is brought into line with the centers, it is engaged at one end by the footstock center which pushes it endwise so that the other end enters the chuck and engages the headstock center. The tailstock is then clamped and the chuck closed on the work.

Yielding fingers are provided at the front of the transfer slides, so that when the work is securely mounted on the centers the slides withdraw before the lathe tool advances. In Fig. 4 the transfer slides are shown partially advanced with the work in place, the footstock and the carriage being removed so as not to obstruct the view. The transfer slides are operated simultaneously by levers shown at the rear of the machine in Fig. 2, which fulcrum on a horizontal shaft below the magazine. These levers, in turn, are actuated by the lever *L* which carries a roll engaging lugs on a cam. Leather friction washers are inserted between the cam lever and the adjacent vertical lever to allow slip in case work gets caught by being improperly inserted in the magazine.

Care was taken in designing the machine to make it fool-proof, yielding elements being inserted in the mechanism where trouble from irregularities in the work may occur. The geared-head machine can be driven by a constant-speed motor mounted on the rear of the bed. Fig. 5 shows a close-up view of an operation in which a heavy cut is being taken.

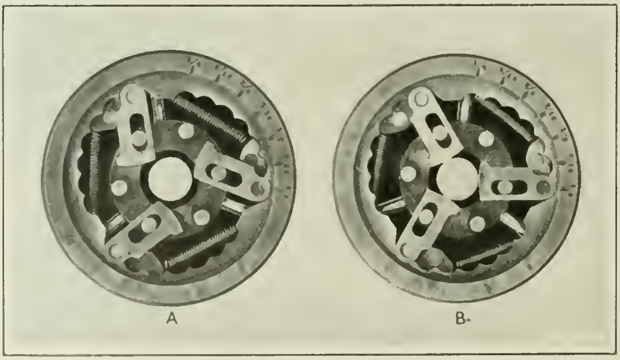

Fig. 6. Views of Chuck with Cover removed, showing Jaws in Open and Closed Positions

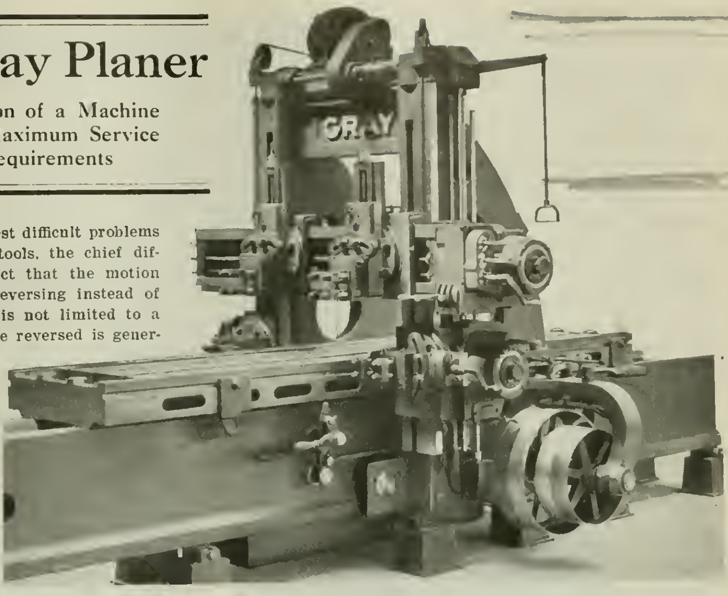
The New Gray Planer

Features of Construction of a Machine Designed to Render Maximum Service Under Modern Requirements



PLANERS offer some of the most difficult problems to the designer of machine tools, the chief difficulties arising from the fact that the motion of a planer is intermittent and reversing instead of continuous; the length of stroke is not limited to a short distance; and the work to be reversed is generally heavy, so that the whole mechanism must be strong and durable. Another difficulty is due to the fact that a planer is a general-purpose machine, and while it must be rugged and powerful for the rapid removal of large quantities of metal, it must also be accurate for the generation of flat surfaces, and must produce a finish free from chatter marks.

The new line of planers built by the G. A. Gray Co., Cincinnati, Ohio, and termed by the builder "Maximum-service" planers, presents a good example of recent developments in planer design. Power, rigidity, durability, automatic lubrication, finish of the work, and convenience and safety of operation have all received due attention in the design of this line. A general view of the 36-inch machine is shown in the heading illustration.

Helical-geared Table Drive

The table is driven by a system of helical gearing which produces a smooth and powerful drive. A properly designed pair of helical gears is stronger than a pair of spur gears of the same pitch and width of face for the following reasons: In the case of a spur gear, the load at a certain point of a tooth engagement is concentrated along a line at the tip of the tooth, and the leverage is practically equal to the depth of the tooth. In the case of a helical tooth, the load comes on a line passing obliquely across the tooth face, and the leverage of the force amounts to only one-half the depth of tooth. Further, the helical gear tooth enters engagement gradually, eliminating shock. In addition to their greater strength, helical gears give a continuous pitch-line rolling action, since there is always some point on the pitch circle where mating teeth of the gears are in actual contact.

The helical gearing in the Gray planer table drive has a tooth form which is thicker at the root than teeth of the conventional form. This modification is said to increase the strength 40 per cent, eliminate interference, and reduce the angle of approach. It is while moving through part of the arc of approach that the so-called "stuttering" action takes place in gearing of the ordinary type. The angle of recess is purposely lengthened, however, because while a tooth is passing through the arc of recess the tooth friction tends to reduce instead of increase vibration. In the design of this gearing, use has not been made of stub teeth and large pressure angles, because while these features are of great advantage in certain kinds of work, the requirements of general planer service prohibit their successful use except for roughing and other service where gear chatter is not objectionable. The full-length tooth and low pressure angle of the special tooth form adopted in this gearing distribute the load among a greater number of teeth than would be the case with a larger pressure angle.

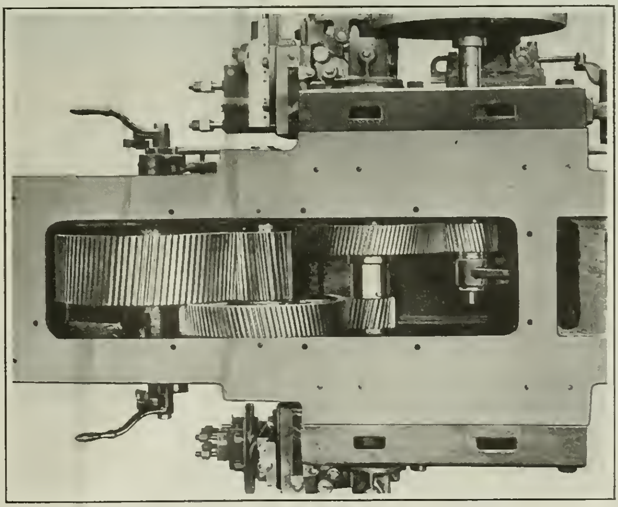


Fig. 1. Helical-geared Drive provided for the Planer Table

The gears dip into a reservoir of filtered oil so that the teeth are always covered with lubricant. This results in smooth action and long life of the gearing, because the oil film interposed between the teeth tends to cushion any shock that might be transmitted from one tooth to the other.

An objection to helical gearing sometimes raised is the fact that gears of this kind produce end thrusts. While such end thrusts may be eliminated by the use of herringbone gears, the Gray Co.

contends that a better system of gearing with wider faces, greater strength, smoother action, and longer life may be obtained if helical gears are used and advantage is taken of the end thrusts to counteract the tool pressure. A planer normally operates with the tools feeding from right to left, the operating side of a planer always being the right-hand side, and the side thrust of these tools tends to push the work and the table toward the left. The teeth of the bull gear in the planer design under discussion are so cut that the end thrust which the gear produces on the table is about one-tenth of the driving force, thus practically balancing the side thrust of ordinary cutting tools; because of this design the planer table bears equally on all four faces of the guiding ways.

The bull gear does not tend to move endwise since the end thrust of the bull pinion balances that of the table rack. The remaining gears of the train are so disposed that each one partially balances the end thrust of another, leaving only a small end thrust which is taken care of by bronze washers supplied with oil by forced lubrication. Most planer work does not occupy the entire width of the planer, and for convenience is placed close to the operating side of the machine. It is, of course, desirable that the line of action of the force which drives the table rack should coincide as nearly as possible with the line of action of the cutting tools. The rack of this planer is, therefore, widened toward the operating side of the machine which brings the line of action of the forces in an advantageous position.

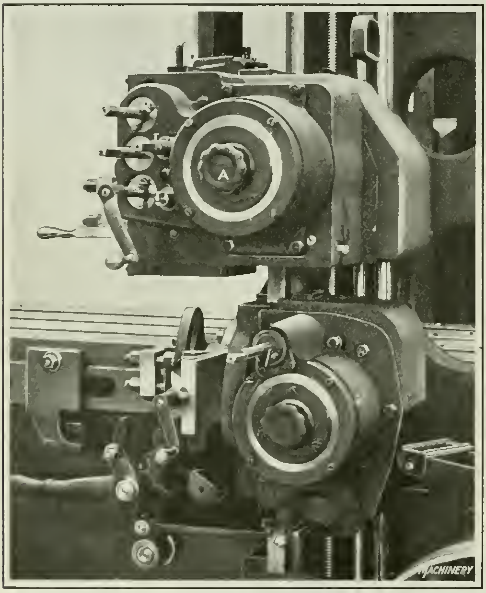

Fig. 2. Feeding Mechanisms for the Rail- and Side-heads

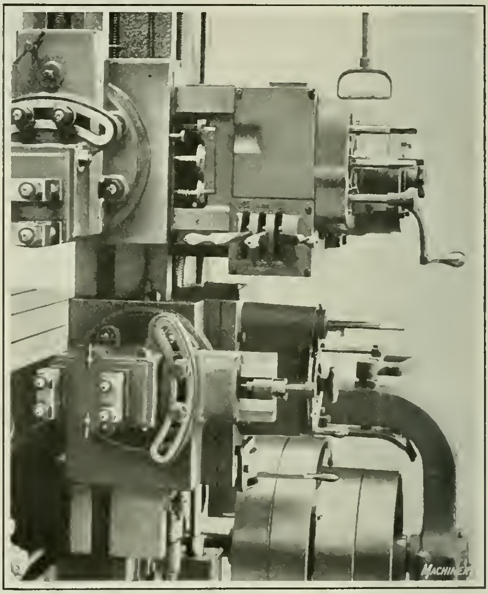

Fig. 3. Feeding and Power-traverse Mechanisms

The "Cantslip" Feeding Mechanism

One of the greatest advances in lathe design was the development of the quick-change-gear system, and it is not too much to say that quick-change gearing has increased the production of the lathe from 20 to 30 per cent by making instantly available the feed best adapted for the work in hand. While the conventional friction-and-rack feed of the planer has undergone a great deal of refinement that has made it much more satisfactory and efficient than originally, many engineers consider the positive feeding and quick-changing devices employed in the lathe, boring mill, and milling machine to be still better. In designing the feeding mechanism, the Gray Co. had in mind the following points:

1. The mechanism must be positive and not subject to slip or wear.
2. The mechanism must be enclosed so that chips and dirt cannot affect it.
3. The side-head feeds must be independent of the rail feeds.
4. The amount of feed must be instantly adjustable while the planer is operating.
5. The adjusting mechanism must indicate exactly the amount of feed for which it is set.
6. The direction of feed of the rail-heads must be instantly changeable.
7. The adjusting mechanism must be in a convenient and accessible position.

The design developed to meet these requirements is illustrated in Fig. 2. One of the intermediate shafts in the main drive is extended through the housing, and by means of a flexible coupling, drives a pair of bevel gears running in oil. From these gears there rises a vertical splined shaft which rotates alternately in either direction as the planer operates. This motion is transmitted to a ratchet mechanism on the cross-rail, so designed that pawl lifters projecting from the aluminum case which completely encloses the mechanism, strike upon stop-pins, one of which is fixed, while the other is adjustable. When one of the lifters strikes the corresponding stop-pin, the ratchet mechanism is automatically disengaged and the aluminum case brought to rest, remaining so until the vertical shaft which drives the mechanism reverses its direction with the reversal of the planer. The ratchet mechanism operates noiselessly, and all parts are lubricated by oil contained in the case and supplied through oil passages in the driving shaft. On the periphery of the case is pressed a large ring gear which transmits its motion to the gears on the feed-screws and feed-rod.

The ratchet box is enclosed in a cylindrical case which forms a gear guard and serves to support the feed-adjusting device, consisting of a circular plate in which a hole is broached for a sliding bolt. The bolt engages teeth cut in a nickel steel ring and is withdrawn from engagement by slightly turning knob *A*. Any further turning of the knob revolves the plate and its attached stop-pin to the desired position. When the knob is released, the bolt re-engages the teeth in the ring, and the plate and pin are locked firmly in place. Graduations on the disk indicate the amount of feed in thousandths of an inch. It will be seen from this description that only an instant is required to obtain any desired feed, which may be varied by multiples of 0.010 inch. The smallest feed obtainable is 0.010 inch and the largest 1.250 inches.

The side-head feed is independent of the rail-head feed, but is operated and adjusted in an identical manner. With this arrangement the side-head feed may be large while the rail-head feed is small, whereas with the conventional friction-and-rack feed, the side-head feed is necessarily equal to or less than the rail-head feed. The feed mechanism is provided with a safety device in the form of a small pin at the lower end of the vertical feed-shaft, which will shear without damaging the mechanism if the heads are fed together or any other accident results from carelessness or inattention on the part of the operator. The vertical shaft is hardened to receive the pin, and it is but the work of a moment to replace the latter.

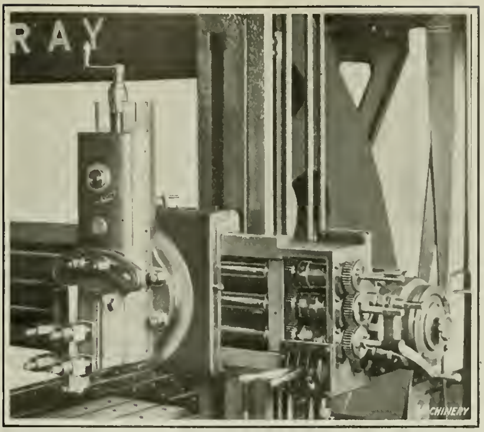

Fig. 4. Close-up View of Rapid Power-traverse Mechanism with Cover removed

Developing the Rapid-power Traverse

With the increased speed of cut permitted by the use of high-speed steel and the increased feed and depth of cut possible on modern machines, work is finished more rapidly and a larger proportion of the time is expended in changing tools and moving the heads from place to place. This calls for increased effort on the part of the workman, and a rapid-power traverse enables this work to be done without fatigue and in less than one-third of the time required if the heads must be traversed by hand. For a power traverse to be of value, it must be so simple and easy of manipulation that no appreciable time is required to put it in motion. It should not be necessary to do anything beyond moving a single member controlling the part to be traversed. Otherwise, so much time is taken in the manipulation of the mechanism that little saving results from the increased speed of head movement. Above all things, it is important that a workman should not be required to perform a series of steps before moving a head, if a serious accident to the machine may occur when one of these steps is neglected.

Accordingly, in designing the power traverse for the planer being described, the following points were borne in mind:

1. There must be only one handle for each movement required.
2. The movement of this handle must automatically perform all the functions necessary to disengage the feed, engage the power-traverse mechanism, and energize the source of power.
3. The direction in which this handle is moved must correspond to the direction in which the head controlled by it is moved.
4. It must be possible to move any head in either direction while the planer is in operation.
5. The moving of a head must not disturb the operation of any other head.
6. No part of the rapid power-traverse mechanism should run when it is not being used.
7. The mechanism must not revolve the handles or the handle shafts on account of the danger involved.
8. A power traverse must be provided for the side-heads, where it is sometimes even more important and desirable than it is for the rail-heads.

In addition to the requirements stated in the foregoing, which are vital to the operation of the machine, a number of other requirements had to be met relative to the manufacture and assembly of the mechanism. The device must be simple and compact, or it cannot be placed in the limited space available in the side-heads. A number of designs which filled the operation requirements were unsatisfactory because they did not lend themselves to the system of unit assembly which finds so large a place in modern machine tool practice.

Operation of the Rapid Power-traverse Mechanism

The design finally evolved is shown in the heading illustration and in Figs. 3 and 4. The mechanism is driven by an electric motor mounted on the top brace, which may be of either the alternating- or the direct-current type. The motor receives its current through a reversible controller. A gear-box, also mounted on the top brace, contains the necessary reduction gears which run in oil, and in addition serves to support the rail-elevating device. Power from the gear-box is transmitted to the power-traverse clutch mechanisms located at the end of the rail, and on the side-heads. The handles seen projecting from the power-traverse box at the end of the rail, and from the bottoms of the side-heads,

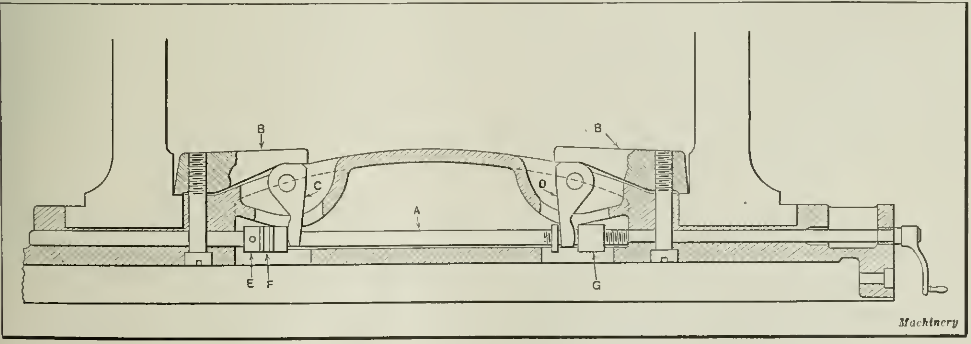

Fig. 5. Diagrammatic View of the Rail-locking Arrangement on the Gray Planer

are connected with rotary cylindrical cams which have an endwise motion and are concentric with the rail or side-head screws, as the case may be.

A movement of one of the handles rotates its cam and shifts it endwise, causing the unclutching of the corresponding screw from the feed mechanism and clutching it positively to the power-traverse gearing. The same movement causes the handle to engage and rotate a collar, the movement of which is transmitted to the controller. The direction in which the handles are moved determines the direction in which the controller rotates, and hence governs the direction of rotation of the motor and of the head movement. When one handle is moved from neutral to the operating position, all other handles are automatically prevented from moving so that the mechanism cannot be injured by carelessness on the part of the operator. The motor stands still except when the handles are moved. A lubricating system, which requires no attention except the filling of two reservoirs on the rail and one on each side-head every morning, carries oil to all parts of the power-traverse mechanism.

Rail Elevating and Clamping Devices

When the rail is clamped to the housings by means of a pair of cast-iron clamps bearing against ledges on the outside edge of the housing faces and drawn up by two bolts, in order to move the rail, it is necessary for the operator to take seven distinct steps as follows:

1. Loosen the two bolts on the right-hand clamp.
2. Walk around the planer.
3. Loosen the two bolts on the left-hand clamp.
4. Operate the lever controlling the elevating device while watching the height of the rail.
5. Clamp the two bolts on the left-hand clamp.
6. Walk around to the right-hand side.
7. Clamp the two bolts on the right-hand clamp.

In contrast to the foregoing the new Gray planer has a rail-elevating and a rail-clamping device, the operation of which involves only three simple steps that can all be performed without requiring the operator to move from his normal position.

The rail is clamped by means of the device illustrated in Fig. 5 in which two steel clamps *B* are fastened to the rail by heavy screws. These clamps engage ledges on the inner edge of the housing faces and are capable of slight rotation due to play of the screws in the rail. Bellcrank levers *C* and *D* bear against the inner end of the clamps, and are secured to the rail by pins. A collar *E* is pinned on shaft *A*, and interposed between this collar and the projecting end of lever *C* is a ball thrust bearing *F*. The longer end of bellcrank lever *D* engages a nut *G* on shaft *A*. The latter is parallel with the rail screws and projects from the operator's end of the rail, where it has a squared end similar to the rail screws. When it is desired to unclamp the rail, it is only necessary to remove the crank handle from one of the rail screws, place it on the end of the rail lock-shaft and give this shaft three turns. This causes nut *G* and collar *E* to separate, which results in rotating levers *C* and *D* about their pins and moving clamps *B* away from their ledges. Turning the handle in the opposite direction with a moderate effort draws the longer ends of *C* and *D* together, and clamps the rail securely to the housing.

The two clamps *B* bear on the ledges with exactly equal force, since the same pull is exerted upon each of the levers *C* and *D;* this prevents slippage of one side of the rail and resulting inaccuracy of the work. Moreover, it is impossible with this device to neglect to clamp or unclamp one side of the rail. By clamping the rail at the inside, the length subject to torsion is reduced, and the increased power of the clamp makes it unnecessary to use four clamps to hold the rail.

The rail-elevating mechanism is operated by a lever placed on the right-hand side of the machine. From this lever, a stirrup is suspended by a universal joint, as can be clearly seen in the heading illustration. The lever is normally locked in position, but a quarter turn of the wrist unlocks it, permitting it to be pushed up or pulled down. Moving the lever, clutches the elevating shaft to the reduction gears previously referred to, and simultaneously starts the motor. The operator, when holding the stirrup, stands in front of the housings where he can plainly see both the rail and the work. If the operator wishes to raise or lower the rail, he has only to turn the rail-locking shaft three turns to the left, push up or pull down on the stirrup, and then turn the rail-locking shaft again three turns to the right.

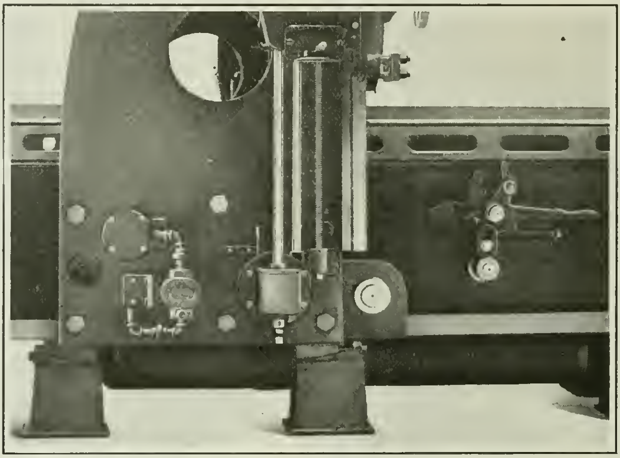

Fig. 6. View of Left-hand Side of Machine, showing Lubricating Pump and Filter

Provision for Lubrication

The accuracy and durability of a machine tool depend greatly upon the system of lubrication provided. If an oil film is always maintained between bearing surfaces, the surfaces are subjected to less wear and the machine will maintain its accuracy longer. The Gray planer is provided with a system of forced lubrication, a Brown & Sharpe geared pump being bolted to the left-hand housing and driven from the pulley shaft by means of a flexible coupling. The pump takes its supply of oil from a large cast-iron reservoir bolted to the bottom of the bed, and discharges through a filter in the housing. The filtering material can be readily removed and replaced by taking off the hand-hole cover shown in Fig. 6. Piping leading from the filter passes to the various bearings so that they are abundantly supplied with filtered oil, the used oil draining back into the reservoir from which it is pumped.

The oil supply is maintained at the proper pressure by a combination pressure relief valve and an accumulator placed in the line. Piping from the filter also leads to two holes drilled into the vees of the bed at the center of its length. Each table vee has a large oil-channel from which the numerous supplementary oil-grooves carry oil to all parts of the bearing surfaces. These oil-channels run the length of each table vee, and are closed at the ends. By this means the oil pressure is maintained constant throughout the entire length of the table. This design has the advantage that the oil supply is equal at all points, no matter what the relative position of the table and the oil supply in the bed may be. If short stroke work is being done near one end of the table, for instance, the oil does not have to flow through a long groove of limited area to reach the far end of the table. The surplus oil dripping from the vees and table rack flows through a heavy screen into a settling basin at each end of the bed and returns to the central reservoir through piping contained in the bed. In order to support the table when it is in its extreme position and to prevent the dripping of oil from the vees to the floor, the bed is made twice the length of the table. This prevents the table from springing, as there is no overhanging weight, and thus prevents the end of the bed from cutting the under side of the table. It also makes unnecessary special projections for catching the dripping oil, and constitutes a safety feature, since the table never extends beyond the bed.

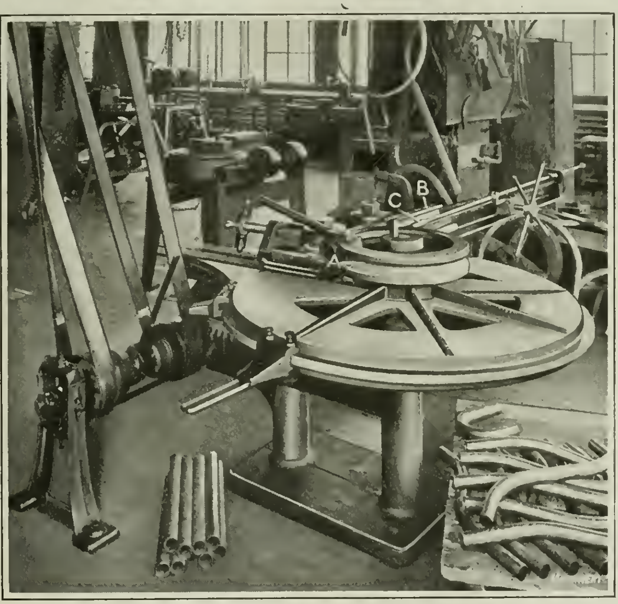
BENDING LOCK-SEAM TUBING

The Lock Joint Tube Co., of Mishawaka, Ind., manufactures what is known as "lock-seam" tubing, which is made with a folded seam. This concern realized that there was a market for its product in making automotive exhaust manifolds, but the tubing could not be bent to the forms required for this purpose without opening the seams. It might have been possible to make the necessary bends by first filling the tubing with melted lead or rosin, but that method would be too expensive for commercial production.

This problem was submitted to the Wallace Supplies Mfg. Co., of Chicago, Ill., and a special form was made for the purpose for use on this company's No. 5B pipe-bending machine. This equipment is so designed that the work is continually supported around the complete circle, both inside and outside, at the point of bending. The form *A* around which the work is bent, is grooved to embrace half the circumference of the pipe, and a similarly grooved follower *B* embraces the other half of the pipe. There is a mandrel *C* of the same size as the inside diameter of the work to be bent. As the pipe is bent around the form, both the follower and the mandrel move with it, so that they always support the work at the point of bending, and the metal is made to flow. With this equipment, it was found possible to bend lock-seam tubing without any tendency for the folded seam to open, and many new applications for this product were developed.



Pipe-bending Machine equipped with Special Form for bending Lock-seam Tubing

* * *

The Bureau of Standards, Washington, D. C., has published a booklet known as Technologic Paper No. 198, by A. H. Stang and L. R. Strickenberg, containing information on the strength and properties of rope of different kinds. This publication contains formulas and rules for determining the strength of rope made in different ways, and other information that would be of value to the user of rope for handling loads with proper safety.

SAFE PACKING FOR MACHINERY

The railroads, steamship lines, express companies, and Post Office Department have combined in a movement to awaken nation-wide interest in careful and secure packing of shipments. The aim of the "Perfect Package Campaign" is to bring American shipping methods to such a high standard that the great economic losses due in part to careless packing by shippers will soon be a negligible factor in the transportation industry. The transportation lines in the past have suffered losses in excess of $150,000,000 a year, due to poor packing, and this loss amounted to a great deal more during and immediately after the war. The carriers do not wish to dictate to shippers just how they shall pack their commodities, but they feel that their experience enables them to make suggestions that should be of value. Generally speaking, shipments should be so prepared or packed as to insure safe transportation with ordinary care on the part of the carrier. A recent study by transportation men of the packing methods of machinery has developed the suggestions given in the following:

The proper preparation of machinery and machine parts for shipment should, as a rule, be assigned to an experienced mechanic, except when standard packages are used. When articles are small, such as portable typewriters or small talking machines, and properly braced in their own case, corrugated and fiber board are satisfactory as outside containers, if of standard construction. When packed in wooden boxes or crates, all fragile parts should be protected from direct contact with cleats, etc., and all loose parts secured to prevent shifting and possible damage. Wooden cleats covered at point of contact with pads of felt, in addition to securing the stand of the machine to the bottom of the box by means of screws, offer protection against damage in transit and possible damage in removing the part from the case. Large machines and their parts are frequently secured to skids or to a platform that will not withstand the strain caused by the weight of the machine being concentrated on the center when the ends only are supported, as, for instance, when a shipment is being transferred from a car to a truck. The bearings or cast-iron frames are often left uncovered so as to prevent injury from hard knocks incident to handling unwieldy objects of this kind in the limited time allowed at small stations.

* * *

Drop-forged automobile wheels have recently been developed. At present they are used mainly on lower-priced cars. As compared with wooden wheels, the forged wheel has the advantage that it consists of a single piece, and even the brake-drum can be made in one piece with the wheel. It is practically unbreakable, and all trouble due to the shrinkage of wood is eliminated.

POINTS TO BE OBSERVED IN MACHINE TAPPING

By H. H. ARMSTRONG

It is the purpose of this article to call attention to the general need for more careful supervision of machine drilling and tapping operations, and to give suggestions concerning satisfactory methods of handling this class of work. As the operators of drilling and tapping machines used for quantity production work are usually paid on a piece-work basis, it naturally follows that various expedients are employed to obtain high production rates. If every piece is required to pass a thorough inspection, no fault can be found with any method that gives the desired result, but unfortunately the work in many cases is not properly inspected when it comes from the tapping machine. In an endeavor to obtain high productive rates, a considerable amount of inferior work is often put through which may, or may not, be thrown out when it arrives at the assembling department. If inferior work is passed by this department, it will in all probability cause the purchaser annoyance and give an unfavorable impression of the company's product.

Cause of Poor Threads

The question of drilling and tapping castings is therefore an important one, particularly when the material to be tapped is cast iron. In order to show some of the causes of inferior work, let it be assumed that a load of clean rough castings has been delivered to the machine shop, bearing a red ticket with the word "Rush" printed across it in heavy type. The foreman directs the load to an operator, who obtains the blueprint called for and immediately sets up his machine for the job. Before beginning work the operator usually ascertains the piece rate, and then decides whether the price is high or low. If the price seems too low, he knows that he will have to speed up his work in order to obtain a fair day's wage. He also knows that taps will be broken off in the work if the tapping machine is run too fast when tapping holes drilled with a regular size tap drill. The result is that a larger size of drill is often used, and this, in turn, results in a thread of shallow depth.

Generally the first piece tapped after setting up the machine is submitted for inspection, and if this piece is approved the whole lot may be passed, but if each piece were to be properly inspected with a limit plug gage it is more than likely that a number of pieces would be thrown out, because the gage would fit too loosely in the tapped hole. The castings then go to the assembly floor where the piecework system is also employed. The assembler puts in the screws, and if in tightening them down he finds that some of them do not set or hold, he knows that the thread is stripped and he will either put the defective piece to one side or attempt to fix it by some makeshift method.

Tap Drill Sizes

It may seem strange that over-size drills are used in jigs which are supposed to be equipped with bushings of the proper size. Nevertheless it is a fact that bushings become worn under continual use, so that they will easily admit a larger size drill than that for which they are intended. The writer knows of some cases in which shop foremen have requested the tool department to enlarge the bushings of a new or changed drill jig slightly, claiming that the taps were over-size and were being broken too frequently. This is often due to the fact that the tapping machine is run at too high a speed, and if it is slowed down the trouble would be eliminated. The tool department should not comply with requests to enlarge the hole in a drill bushing, and no bushing should be changed from the dimensions called for by standard clearance tables unless the change is approved by the designing engineer.

In observing tapping machines in operation, it will be noticed that the spindle reverses its direction of rotation in backing out of the tapped hole, and that sometimes the tap is brought down again while the spindle is running in the reverse direction. This causes the threads of the tap to tear the metal at the mouth of the hole to a depth of perhaps 1/8 inch or more. On noting this, the operator will invariably pull up the tapping head, and by the time he finally gets the tap running in the right direction some of the thread will have been torn out, so that the screw will only hold in the section of the thread below the stripped portion. If, in addition to the stripping of the threads, the tap drill happens to be too large, the thread will be practically useless. The tap drills used in tapping machines are always larger than the ones used when tapping a full thread by hand, so that if the operators use still larger tap drills in order to speed up the machine tapping, it is sure to result in the stripping of threads in the assembling department.

Trouble from Sharpening Taps and Clogging of Chips—Need for Thorough Inspection

Another source of trouble may be mentioned here, namely, that resulting from the sharpening of the end of the tap by the operator. This is done by grinding a new taper on the tap, and while this may prove satisfactory for tapping operations on thin work, such practice should not be followed when tapping work in which the tap cannot pass entirely through, as the bottom of the hole will not have full threads. For the latter type of work, bottoming taps should, of course, be used, which permit cutting practically a full thread to the bottom of the hole. Recently the writer's attention was called to some work in which the assembler could not enter the screws to the required depth. On examining the pieces it was found that the tapped holes were filled with the chips from the tap that had lodged in the thread and become firmly attached by a coating of rust. These pieces had to be sent back to the machine shop to be retapped. In this case the operator was required to do the work on his own time. Had he used compressed air to blow the chips out, this trouble would not have been encountered.

If a steel screw is set down too tight in a cast-iron piece, the threads are likely to become crossed and stripped, especially if the thread in the iron piece is shallow. Success in tapping holes depends chiefly on having conscientious operators who are willing to follow instructions and set their machines up properly for each job. If trouble is encountered, it should be brought to the attention of the foreman, and not covered up to be discovered at some later period. All machine tapped holes requiring any considerable degree of accuracy should be given a thorough inspection with a limit plug gage. The operator can do this if there is no inspector, and the foreman should keep in touch with the work. It has been proved by experience that the quality of a man's work will invariably be higher if he knows that the work is to be inspected. When excessive tap breakage is experienced, it is well to investigate the cause; in many cases it will be found that breakage is due to inefficient holding methods, the work being allowed to move during the tapping operation.

BRITISH MACHINE TOOL TRADE

Statistics covering the import and export trade of machine tools to and from Great Britain during the first six months of 1921 show that the imports amounted to 2243 tons, as compared with 2040 tons in the same period in 1913. The value of the imports in 1921 was approximately $2,000,000, as compared with $725,000 in 1913. The exports also show a great increase in 1921 over the corresponding period in 1913. The exports amounted to 12,977 tons in the first six months of 1921, as compared with 8545 tons during the same period in 1913, and the value increased from approximately $2,500,000 in 1913 to $7,400,000 in 1921. The exports of machine tools from Great Britain in the first six months of 1921 are the highest on record for that country for any similar period.

A Railroad Shop Organized for Efficiency

A Description of the Angus Shops of the Canadian Pacific Railway Co., Montreal, Canada
First of Two Articles

EFFICIENCY in railroad operation is a matter of great importance, not merely to the stockholders of the railway companies, but also, and in an even greater measure, to all classes of business enterprises served by the railroads. Efficient freight and passenger service rendered at reasonable cost is one of the essential conditions upon which the return of business prosperity depends. There are many phases of railroad management. The one in which the readers of MACHINERY are most directly interested relates to the handling of railroad shop work. In dealing with this subject, it is important to emphasize the two general causes of inefficiency in railroad machine shops. These are, first, the inefficiency of railway shop labor, and, second, the use of equipment, in many railroad shops, which is of obsolete design, inadequate capacity, and in poor condition. To re-equip a railroad shop requires a large investment, but in the case of many shops it would be an expenditure from which the railroad would derive an adequate return in the reduction of the cost of handling the shop work.

Returning to the question of the inefficiency of labor, American railroad shops have failed to turn out work at a reasonable cost, largely because of the provisions of the National Agreement on Working Conditions, which was entered into between the United States Railroad Administration and the railway shop workers during the period of government control. After an extended hearing of both railway executives and labor leaders, the United States Railroad Labor Board decided to abrogate the provisions of this agreement; but the labor unions are now making demands upon the individual railways for agreements specifying exactly the same undesirable conditions governing the work of shop employes, and pending the settlement of these controversies, the objectionable terms of the National Agreement remain in effect.

The Need of Better Equipment

With the return of labor to a normal state of efficiency, the railroad shop problem would be about half solved. Then the final solution would lie in the provision of more adequate machine tools and other equipment. Some of our railway shops are fairly well provided with machinery, but there are many in which the equipment is composed largely of obsolete machines incapable of producing results that could be obtained with modern machines. In addition, many machines are in such a poor state of repair that they are unable to give satisfactory results, as regards either the rate of output or quality of workmanship, and their use makes the cost of the work very high.

The experience in railroad earnings during the latter part of 1921 indicates that the railroads are about to enter upon a period of better financial conditions. Railroad managements generally look forward to brighter days provided labor troubles do not seriously disturb present favorable tendencies. As far as the problem of shop work is concerned, however, a state of "normalcy" cannot be expected until the standards both of labor efficiency and of shop equipment have been greatly improved.

It is safe to say that in the majority of American railroad machine shops, it will be necessary to increase the efficiency of both the men and the machinery in order to obtain pre-war results. New shop rules must be established that will make it possible to get work done in a way that will insure normal costs. Equally important is the question of machinery. Much of the machine tool equipment in some of the railroad shops is of obsolete design and in such a poor state of repair that the money lost by its continued use would pay a fair rate of interest upon the investment required to provide new machines. There are a few modern railroad shops, however, and the present article describes the layout and methods of operating one of them—the Angus shops of the Canadian Pacific Railway Co., Montreal.

How One Road Solved its Shop Problem

It is believed by many that the work in a railroad shop does not lend itself to being handled on a quantity production basis. Jobbing shop work is always costly, and unless a determined effort is made to break away from such a method of railroad shop management and to apply modern manufacturing methods of setting up work in multiple, it is futile to expect efficient results. In discussing this question of shop efficiency, it will be of value to explain the results that have been obtained by the Canadian Pacific Railway Co. at its Angus shops in Montreal.

This railway formerly maintained what were known as the Delorimier shops located near the center of the city of Montreal. Gradually this plant became inadequate for existing requirements, and the high value of the real estate on which it was built placed a heavy overhead charge on all of the work. As a result, it was decided to construct an entirely new plant, and for that purpose the site of the Angus shops was purchased on the northeast side of the city. This plant is noteworthy as a railroad shop on account of the fact that it was completely planned on paper before any construction work was started. Henry L. Gantt was retained as consulting industrial engineer to make a complete study of the problem, working in cooperation with H. H. Vaughan, who was then assistant to the vice-president and in charge of the Canadian Pacific Railway Co.'s motive power and rolling stock. The final result assures the inter-relationship of departments and an arrangement of equipment in each individual department which will permit the work to be performed with a maximum degree of efficiency.

Fort Williams represents the point at which the Canadian Pacific Railway lines are subdivided into the eastern and the western systems, and on each of these systems there are four divisions so that the entire road is subdivided into eight districts, each of which is served by a local shop where minor repairs and some general work are handled. The facilities of these district shops are supplemented by the Angus plant at Montreal, which serves the entire Canadian-Pacific Railway system. On the eastern lines, the heaviest work is sent to Montreal; and the Angus shops also manufacture many small parts in quantities and ship them to store-rooms of the different districts, where they are available when necessary. In this way, advantage can be taken of the increased efficiency resulting from handling the work on a quantity production basis, instead of setting up single pieces on machines which have sufficient capacity to handle a number of parts at a time, thereby placing a greater machine time charge against each individual job.

Classes of Work Handled at the Angus Shops

Under normal conditions of operation, the Angus shops provide employment for as many as 9500 men. With this force the plant is operated for the double purpose of making repairs on engines and cars, and building both these classes of equipment. The capacity under full operation is about as follows:

Engines, Pacific or Mikado type................4 per month
Engine repairs (complete overhauling)......40 per month*
Steel frame, single-sheathed freight box cars.....15 per day
Steel frame automobile cars......................10 per day
Refrigerator cars.................................. 9 per day
Steel sleeping cars................................ 1 per day
Compartment sleeping cars................1 every two days
Car repairs (complete overhauling)..100 per summer month†
Car repairs (complete overhauling)...230 per winter month

*This represents average operation: from 45 to 70 engine repairs per month have been made when no locomotive building work was being put through the shops at the same time.

†The average capacity on car repair work is 230 per month, but in summer the heavy passenger travel makes it impossible to withdraw the necessary number of cars from the system and the repair work is so arranged that the majority of the cars are placed in the shop during the winter months.

Lay-out of the Angus Shops

The accompanying diagram shows a general plan of the lay-out of the Angus shops. As this plant was constructed with the idea of increasing efficiency by handling work on a quantity production basis, careful provision was made for the routing of all work so that no time and labor need be spent in the unnecessary moving of heavy engines or cars and the parts of such equipment. The general scheme of the plant lay-out is to bring locomotives and cars in from the main tracks which run along the southwest end of the property, and to carry them over tracks leading to the various departments.

In examining the lay-out of the plant with especial reference to the elimination of lost motion in handling the work, it must be borne in mind that the locomotive shop, the passenger car shop, the freight car shop, and the steel car shop are distinct units, so that no provision need be made for the transfer of work from one of these departments to another. On the other hand, it is necessary for each of these divisions to be served from the general stores, the blacksmith shop, the gray iron foundry, etc., and with that idea in mind it will be noticed that the buildings in which these three departments are grouped, are centrally located so that deliveries may be conveniently made to each of the main departments of the plant.

Arrangement of Equipment in Individual Departments

In order to see the way in which individual departments have been laid out to facilitate handling the work, let us consider first the freight car shop. Here it will be noticed that the wheel foundry is located in line with and southwest of the truck shop. The wheel castings made in this department are bored and turned and pressed on their axles, so that they may be easily rolled on tracks leading into the truck shop. Here the wheels and axles are assembled on the trucks which, in turn, are rolled out of the northeast end of the shop where they can be picked up by a midway crane and carried over opposite the end of the freight car shop. Here they are again dropped on tracks running through this shop. The building of freight car bodies is handled by a method similar to the progressive assembly used in some of the most progressive manufacturing plants.

It has been mentioned that as the trucks come out of the shop in which they were assembled, a midway crane carries them to tracks running longitudinally through the freight car shop. To the right of this crane, is the planing mill in which all timbers for the box cars are cut ready for assembly. This material is simply carried across by the midway crane to the freight car shop and there it is ready for use, the various parts being distributed along the shop so that as the cars are moved down the tracks, the different parts such as sills, flooring, walls, and roofing can be secured in place.

Arrangement for Handling Passenger Car Work

Passenger cars used on the Canadian Pacific Railway have either steel wheels or cast-steel wheel centers with steel tires. These wheels are purchased outside the plant, and in the passenger car shops there are truck departments where this material is assembled and prepared for the passenger cars. It will be noticed that the planing mill is so located that heavy timbers can be handled with almost equal facility for use on either passenger or freight cars. There is a difference of procedure in handling passenger car work, however, as a large part of the material used in such cars is hard wood, which must be kiln-dried and then placed in storage ready for delivery to the cabinet shop as required. A kiln is provided in connection with the hard wood storage which is located at the northeast corner of the plant; and this storage building is located adjacent to the cabinet shop, where the finer interior finish of various types of passenger cars is completed ready for assembly.

From this department, finished sections of the interior finish are drawn and taken direct to the cars in which they are to be assembled. Unlike the freight car work, the passenger cars remain stationary in the shop until they have been completed. Each car is mounted on tracks running crosswise in the shop, and upon completion it is pushed out to what is known as a transfer table which runs along the space between the two passenger car shops. A car placed on this transfer table is run down into alignment with a track at one end, from which it is moved out to the sidings and thence to the point of destination on the railway.

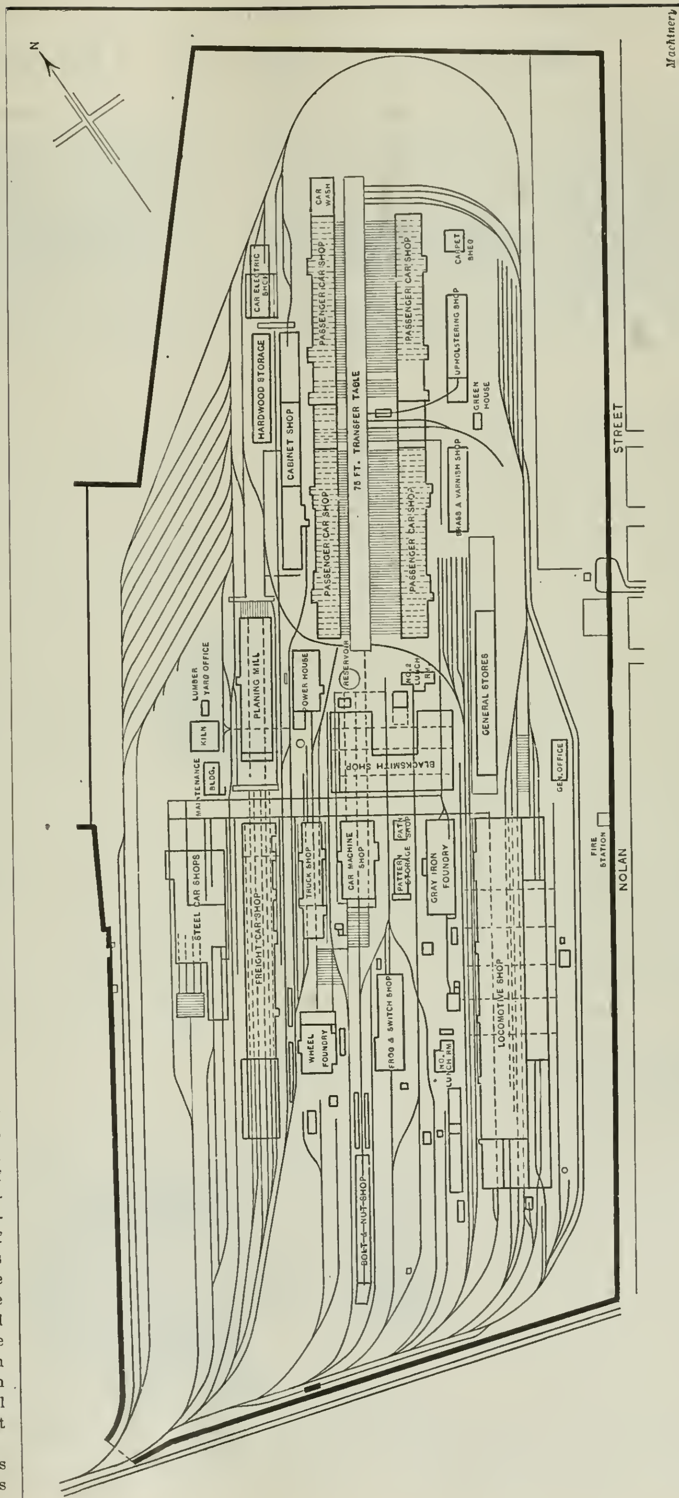
Manufacturing Car and Locomotive Parts for Stock

In line with the policy of adopting quantity production methods, as far as possible, the Angus shops are furnished with a general stores building measuring 600 by 85 feet. This building is equipped with the most approved arrangements of bins and other forms of containers, in which all classes of finished parts are stored pending their delivery to the plant on production orders or their shipment to one of the division shops of the system. In this connection it may be mentioned that a completely organized system has been evolved for the salvaging of the many classes of scrap material which accumulate on a railway, and these reclaimed parts are delivered to the store-room to await withdrawal for use in the shop departments. This subject will be discussed in detail in an article which will appear in a subsequent number.

Equipment of the Machine Shops

The same principle of stream-line production that has been followed in locating adjacent departments of the plant in such a way that the work can be handled to advantage, has been observed in laying out the sub-departments of each of the shops. Another important point in expediting production is the maintenance of open aisle spaces with white lines painted on each side, and the strict enforcement of the rule that no material must be allowed to project beyond these lines (see heading illustration.) With such a lay-out, electric trucks which are used for conveying material can be run at high speed without danger of interference.

The second installment of this article will deal with special tools used in the Angus shops.



General Plan of the Angus Shops of the Canadian Pacific Railway

Reducing Costs by Die-casting

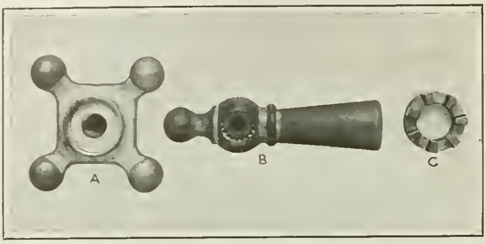


Fig. 1. Faucet Handles and Roller Bearing Cage made by the Die-casting Process

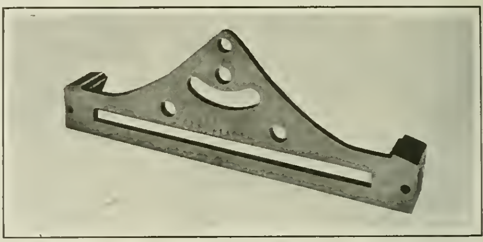

Fig. 2. Two-stand Bracket for an X-ray Apparatus, also produced by Die-casting

THE die-casting process offers many opportunities for reducing manufacturing costs, when the metals from which die-castings can be made are satisfactory for the parts required. By this process holes, recesses, etc., can be cast directly in the part being made with such accuracy that in most instances subsequent machining is unnecessary. The elimination of machining operations therefore constitutes one of the main savings in the use of die-castings. Even the first cost of the dies is negligible, as compared with the first cost of the machining equipment that would be required for making parts from steel, cast iron, or brass. In any line where die-castings can be used, therefore, their application should be investigated. Many manufacturers of specialties have found that not only is it possible to start a business for the manufacture of a new article with less capital, when the drop-forging process is employed (as the dies are cheaper than machine tool equipment), but it is also possible to get under way faster, as dies can be made in a fraction of the time that would be required for fitting up a machine shop.

How To Reduce Production Costs ?

It has been estimated that dies for making a given part on which a number of machining operations would be required would not cost more than 10 per cent of the cost for machinery and tools. The manufacturing of the article then reduces itself mainly to an assembling proposition and to the machining and making of such parts as cannot be advantageously die-cast.

Examples of Die-castings

The accompanying illustrations show a number of die-castings that have been manufactured by the Superior Die-Casting Co., Cleveland, Ohio, and figures indicating the saving resulting from their use will be given. Fig. 1 shows at *A* a star-shaped faucet handle. This handle costs, as delivered by the die-casting company, including the tapping operation, 65 per cent of what it cost when made from a brass casting. This includes the cost of dies distributed over a six-month period. The die-cast faucet handles are made from a zinc base alloy, having a tensile strength of 24,000 pounds per square inch. The composition is 88 per cent zinc, 4 per cent copper, 6 per cent tin, and 2 per cent aluminum. This metal is less expensive than brass, and in addition there is a saving of six machining operations, including a counterboring operation and two facing operations on each side. To prepare the brass casting for nickel-plating, it is also necessary to grind and buff it, while the die-casting needs to be buffed only. The only operations that need to be performed on the die-casting after it comes from the dies are to trim it and to tap the central hole. The counterbores on each end and the surfaces come so accurately from the dies that no further work is required except that of buffing before nickel-plating.

Faucet handles made in this manner have been used for a period of one year and have been found to be fully as satisfactory as brass handles. In fact, they have some advantages over those made from brass. They will take a heavier plate of nickel, and hence will wear longer, and if the nickel-plating wears off, the metal underneath will not show yellow, but the die-cast metal, being in the white metal class, will look more like nickel.

At *B* in Fig. 1 is shown another faucet handle, delivered at a cost of less than 5 cents, including the cost of the dies distributed over six months' production. No machining work needs to be done on this die-casting whatever. Formerly these handles had to be faced on one side, the center hole drilled and broached, and the hole for the button at the end counterbored.

At *C* is shown a roller bearing cage. In this case the die-casting costs more than the malleable iron casting that was formerly used, as there was no machining required on the malleable iron casting. However, the use of a die-casting meant a saving to the manufacturer of the roller bearings, as the die-cast cages all are uniform while the malleable iron cages are not. Therefore, in assembling the various parts, it was necessary, when using malleable iron cages, to try to fit a number of cages, which was found unsatisfactory for production work. Every one of the die-cast cages will fit, because it is possible to die-cast a part of this design within an accuracy of 0.001 inch. Thus the experience of this roller bearing manufacturer indicates the accuracy of die-castings, and shows that even in cases where the die-castings may cost more than a part made in some other manner, it might, nevertheless, be economical to use them because of other savings resulting

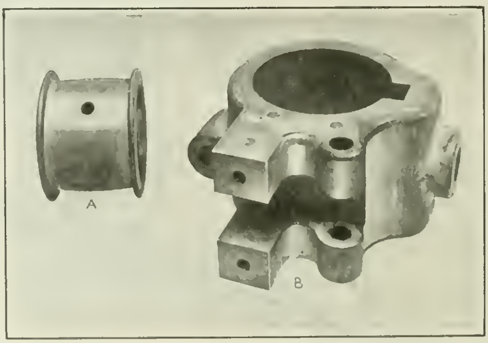

Fig. 3. Die-cast Pulley and Printing Press Part

from their uniformity and accuracy. The high rate of production obtainable in die-castings, assuring a supply of parts at all times, is also a point to be considered.

Bracket for an X-ray Apparatus

Fig. 2 shows a die-cast tube stand bracket for an X-ray apparatus. This bracket was formerly made from brass and nickel-plated. When made in this way, the holes had to be drilled and the various flat surfaces milled. The lines shown on the front of the bracket had to be produced by a graduating tool. Now this part is produced by the die-casting process, and no machining is required except the tapping of two of the holes. The large holes in each end of the bracket are in line with each other, and come accurately enough for the apparatus directly from the die-casting machine. All the holes formerly drilled are cast in place. The small holes are accurate within ± 0.0005 inch, and the rest of the holes within ± 0.001 inch. Lengthwise, an accuracy of ± 0.001 inch is assured for each two inches, and the width of the long slot is accurate within ± 0.001 inch. When zinc base metal is used for die-castings, it is generally possible to obtain a greater degree of accuracy in practically every dimension than can be obtained by ordinary machining methods, when producing work on a general commercial scale in interchangeable manufacture.

The total cost of this piece is less than the manufacturers' former cost for performing only one of the machining operations. On a comparatively small production, the cost of the die would be, say, from 20 to 25 cents per piece; but this figure is much less in comparison than the cost of the machine and tool equipment that would be required for machining a brass casting.

At *A* in Fig. 3 is shown a die-cast pulley, which was formerly made from bar stock. By die-casting, the cost was reduced 20 per cent. The feed-roll clamp *B* was formerly made from a gray-iron casting and required the boring and reaming of the large hole through it, the broaching of the keyway, the facing of both ends, the milling of the slot between the lugs, the facing of the lugs, the facing of two bosses, and five drilling operations.

These parts are now being die-cast; all holes are cast in place with sufficient accuracy without further machining, and the cost per piece is 55 per cent of the cost when a gray-iron casting was used, not including the die cost. The latter cost, however, is insignificant as compared with the cost of the machining equipment formerly required, because with a production of less than 2000 a year, the die was paid for by the first 1000 pieces through the difference between the cost of the die-casting and the machined gray-iron casting. Consequently, after 1000 pieces had been made, there was a clear saving of 45 per cent on every piece made thereafter.

The Cost of Dies

Many people do not realize that the first cost of the dies for a die-casting, when distributed over the number of parts to be made, is insignificant. The die cost that should be charged to each piece is, of course, proportionate to the quantity to be made. A die, when once made, will last almost indefinitely. The Superior Die-Casting Co. has had dies in operation for two years which have produced several hundred thousand castings, and which are still in good order. A die, for a piece of average design, would cost, say, $250. If there is a production of 5000 pieces a year, it will be seen that the die cost per piece distributed over a period of five years would be only one cent a piece.

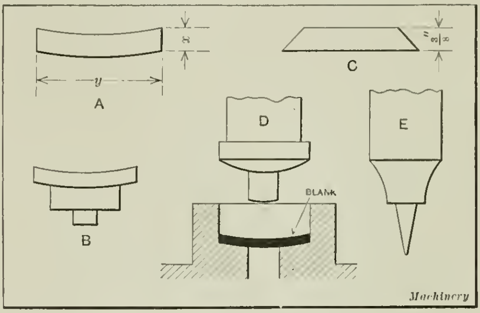
* * *

A small gas producer has recently been brought out by Gasmotoren-Fabrik Deutz in Germany, of a size suitable for yielding gas sufficient for from four to thirty-five horsepower engines. Even when not utilized to its full capacity, the power obtained by means of this small gas producer will, it is claimed, compare favorably with power obtained from central electric power stations.

MANUFACTURE OF COLLAPSIBLE TUBES

Collapsible tubes, such as are commonly used for artists' colors, are usually manufactured by the cold extrusion process. The metal from which these tubes is made is of either tin or lead composition and there is a large variety of alloys suitable for this class of work. These tubes are also often made from pure tin, and such tubes are considered superior to those made from the various compositions. The tubes are extruded from blanks of the shape shown at *A* in the accompanying illustration, punches and dies of comparatively simple design being employed. If a blank is to be drawn direct, the punch may be of the design shown at *D*. However, if a punch such as shown at *E* is to be used, it is necessary to perform a preliminary operation of forming the blank to the shape shown at *B*. Collapsible tubes vary in thickness from 0.005 to 0.010 inch, and the maximum size produced is 2½ inches in diameter by 9 inches long.

A blank of the type shown at *A* when x equals ¾ inch and y 4½ inches, can be drawn to a tube ¾ inch diameter by 4½ inches long, and will require a pressure of approximately 30 tons. When x equals 7/32 inch and y 1 inch,



Blanks from which Collapsible Tubes are extruded, and Types of Punches used

the size of tube will be 1 by 6 inches, and the pressure required, 42 tons. For a 1½- by 7-inch collapsible tube, x should be 5/16 inch and y 1½ inches, and an applied pressure of 84 tons should be used. In extruding a 2- by 8-inch tube, x equals ⅜ inch and y 2 inches, and the pressure required is 130 tons.

Caps for bottles, such as catsup bottles, are made from soft metal blanks, sometimes by the extrusion process and sometimes by rolling and forming the blanks. The usual method is to cast the blanks into the shape shown at *C*, and then to roll the metal to 0.078 inch in thickness and to cut out from this rolled material a 1-inch diameter blank. From this blank the cap is drawn to a wall thickness of approximately 0.010 inch and to a thickness of head of about 0.014 inch.

An alloy which will be found suitable for both collapsible tubes and soft metal bottle tops, consists of 4 ounces copper, 6 ounces antimony and 16 ounces tin, melted together, the resulting alloy being used with varying quantities of pig tin. For collapsible tubes 50 ounces of the alloy and 200 pounds of pig tin are used; for bottle tops, 134 ounces of the alloy and 200 pounds of pig tin. Any one of the three following compositions may also be used successfully in the manufacture of collapsible tubes: (1) antimony 14 per cent and tin 86 per cent; (2) antimony 5 per cent and tin 95 per cent; (3) copper 2 per cent and tin 98 per cent.

Of the forty-one tractors shown at an exhibition of agricultural tractors and accessories in Paris in the earlier part of the year, 19 were American, 18 French, 1 Italian, 1 English, and 2 Czecho-Slovakian.

Saving Time in Assembling

Examples Showing Savings Resulting from Investigation of Assembling Methods

By ALBERT A. DOWD, President, and FRANK W. CURTIS, Chief Engineer, Dowd Engineering Co., New York City

How To Reduce Production Costs?

IN quantity production, it is possible to perform manufacturing operations on parts at a comparatively low unit cost, yet the time consumed in the assembling department may be so great that the cost of the complete mechanism is increased much more than it should be. The efficient factory investigator makes a special study of methods used in the assembling department in order to reduce costs and increase production. If the production costs are high, the investigator may conclude to start his survey in the assembling department and work backward from this point, being governed more or less by conditions as he finds them. For example, as the various parts of the mechanism come to the assembling department and the workman starts to put them together, a certain piece is found to be a little too tight, and therefore must be touched up with a file before placing it in position; another piece has a burr along one edge, which must be scraped or filed off before assembling; the alignment of certain holes is not accurate enough and a line-reaming operation is required; or one surface of a part is not square with another, and the part must be refinished or scrapped, depending upon the seriousness of the error. Often parts must be scraped to a fit at assembly when proper machining would avoid the necessity for this.

Examples Showing Sources of Expense and their Remedies

In order to illustrate this point and bring it home more forcibly, several examples are here given with the remedies that were applied. An aluminum gear-case is fitted with a cap held down by six nuts placed on studs inserted in the case. The studs are assembled in the case by a workman using a stud setter, and formerly when the cover was applied and the nuts were put in place, some of the studs turned as the nuts were tightened, because the studs were too loose a fit in the tapped holes. This condition caused much annoyance and delay. An examination to determine the source of the trouble revealed a difference of from 0.002 to 0.004 inch in the stud diameters, some being made on one machine and some on another. One machine was producing work within the required limits, while the other turned out undersized studs. The remedy here was a more careful inspection which resulted in changes in the dies that produced the small studs. A matter of this sort would often be neglected and a great amount of time consumed in removing and replacing studs, which represents a needless expense.

Another case in point is that of a shaft assembled in a gear-box and running in bronze bushings. Although the hole in the bushings was inspected with a plug gage and found to be within the required limits, when the shaft was assembled it did not turn freely. In order to remedy the trouble the workman was obliged to ream one of the bushings with a hand reamer. This is a peculiar instance, yet an examination showed the reason to be that the holes in the bushings were slightly eccentric with the outside diameter. In some cases the bushings were assembled in the box with the eccentric portions in the same relative positions, and under this condition the shafts would enter all right and turn freely; but, when the eccentricity of the two bushings was in opposite directions, too tight a fit was the result. The remedy for this condition was found to be a change in the method of producing the bushings so that concentricity was obtained.

Another example of high cost remedied by a careful investigation of methods employed in the assembling department was a printing press platen which was scraped to alignment in the assembling department after being placed in position on the machine. The time consumed for this operation appeared to be excessive, and a careful inspection showed imperfect alignment and a surface slightly warped. Tracing the various operations back through the manufacturing departments it was found that the trouble originated in the planing department, the planers being old and inaccurate so that untrue results were obtained. The method of holding the work during the operation was also found to be incorrect, causing distortion and inaccuracies. The planers were overhauled and trued up, with the result that a saving of two days' time on each machine was effected when assembling, and much fitting was avoided.

Other matters that affect costs can be found by a careful investigation in the assembling department. Some of the points referred to may seem to be small matters, yet they are important on account of the time that can be saved by attending to them properly. For example, racks for screws, bolts, and other units used, and the placing of parts convenient to the workman, are matters of importance. Much time is saved by good arrangement of parts, and as the workman does not become so tired, he does more work. Accessories such as stud-setters, power-driven screw-drivers, and socket wrenches save time and help to obtain maximum production.

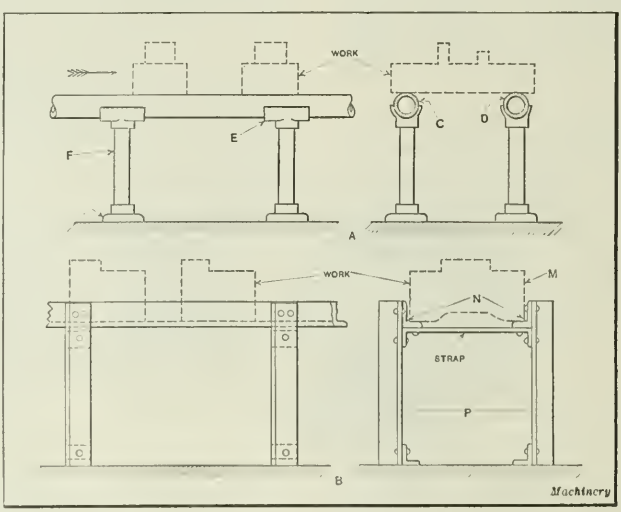

Fig. 1. Two Simple Designs for a Plain Assembling Conveyor

Matters Affecting Assembly

In determining the best method for assembling a given unit, several important factors must be considered. Conditions are quite different in a small shop with a low production from those in a large factory having a high production. The number of units to be produced is, therefore, an important factor, yet it does not necessarily follow that the assembling department should be neglected when only a small production is to be handled. On the contrary, "trimming the corners" by saving labor in assembling will reduce costs and stimulate production.

The amount of final fitting in assembly must be reduced to a minimum, as otherwise work will be done which should be taken care of in the manufacturing departments. The final fitting of parts should be watched closely by the assembling department foreman, and work which requires unnecessary fitting should be sent back to the inspection department with a notation as to the requirements. The inspection department should return the work to the department responsible, in order that it may be refinished to the size called for on the drawing. It is possible that the gages used in the inspection department may be worn or sprung out of shape so that parts made incorrectly pass inspection. In rare cases the engineering department may be at fault due to an incorrect setting of limits on the drawings. This trouble is not commonly found until the final test of the mechanism, at which time the necessary recommendations can be referred to the engineering department.

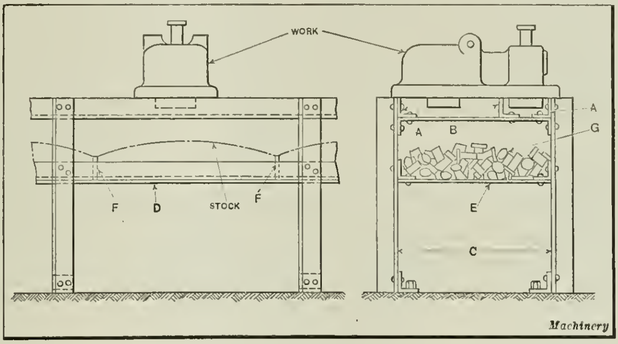

Fig. 2. Plain Assembling Conveyor having Compartments for the Stowing of Parts

Methods Used in Assembling

Many manufacturers do not consider the assembling of their product important enough to devote much study to improvement of methods used in this department, and there are numerous cases where workmen are left to their own devices and methods. One man out of ten may develop a good method, while the other nine work more or less profitably, according to their ability and general knowledge of the work. Progressive manufacturers realize the importance of keeping down assembly costs, and study the problems involved. A system of assembling is fully as important as an efficient method of production. When an investigator attempts to put into practice knowledge gained by experience, he is likely to meet with opposition from the men who should give him assistance. It is natural that any man familiar with a certain job of assembling should consider that he knows more about it than another man who sees it for the first time. He should not forget, however, that an investigating engineer is examining his work from a different angle and trying to devise means for doing it in an easier way and with less consumption of time.

In considering the various operations in an assembly department, an analysis of the number of movements a man makes, the number of times he is obliged to turn the mechanism over and his methods of inserting various units and holding them in place while putting in locating pins, nuts, or bolts should all be the subject of careful observation. It may be found that though a man is working conscientiously, he is handling the unit unnecessarily, so that often economies can be effected by the use of an assembling stand to assist in turning the device into different positions to make it easier of access. The need for a stand depends on the number of units produced, the size of the parts, and the difficulty in handling. For moderate production of small units, assembling stands are seldom necessary, but on larger work they may be found an advantage. When production is high, assembling stands or conveyors can be used to increase production. Assembling stands for various units are more or less expensive, but in some cases a simple wooden frame made at a nominal cost, will materially help production.

Assembling by the Conveyor Method

The advantages of conveyors and racks in the assembling of various products are not appreciated by many manufacturers, and when a conveyor is suggested for purposes of assembling, the manufacturer generally thinks of the large cost of installation and believes it necessary to reorganize and change his methods completely with a loss of considerable time. He also thinks of the possibility that the system may not prove successful after installation. In many large factories, however, the system has been developed to a wonderful degree, and there is no question as to its efficacy. A few specific cases which bring out the principles of the various types of conveyors for assembling, their use, application and advantages, will be given to show how important conveyors are and how easy it is to install the simpler types. It is evident that a conveyor system would hardly be needed in a factory where two or three men are sufficient to do all the assembling; yet even here there are possibilities of changes which would relieve these men for perhaps a part of their time so that they could work on some other operations. The points of importance to be considered when planning a conveyor or assembly line are as follows: Nature of the product, production, number of men needed in assembly, and time of each operation. The nature of the product determines the size of the conveyor and its general shape in accordance with the number of units or pieces which are to be assembled. It may be better to use two conveyor lines rather than one in order to avoid the length taken by too long a conveyor. The speed of a power-driven conveyor should be governed by the production required. It would not be good practice to design a conveyor to run at such a speed that a single operation would require an operator to move ten or fifteen feet, as this would be tiresome and the greatest efficiency would not be obtained. The number of men required is dependent upon the product and the spacing and apportioning of the operations so that they will time up with each other. The speed of the conveyor should be such that the operators do not interfere with each other, nor should one man have more work to do than another. The time of each operation is generally predetermined by the old method, although by the conveyor system there may be a slight gain in time, as the operator has only one thing to do, and consequently he becomes exceptionally expert in doing this particular thing.

Plain Type of Assembling Conveyor

A conveyor for assembling is usually designed to suit a particular product, although it is possible to standardize the construction so that it can be adapted to a number of kinds of work. The principal types which will be considered are the plain, roller, and power types. Fig. 1 shows at *A* one of the simplest forms of conveyors for assembling. This type is made up from pipe of suitable size and simple fittings which can be easily made and require little machining. The work rests on two lines of pipe C and D, which are spaced a suitable distance apart according to the width of the product. The pipes rest in cast-iron sockets E that are screwed to the upper end of short lengths of pipe F. Substantial cast-iron bases hold the lower end of the pipe, and these castings may be fastened to the floor or made heavy enough so that their weight is sufficient to hold them in position. The spacing of the uprights is determined by the size of pipe used and the weight to be carried. In using this type of conveyor, the assembler finishes a given operation on the part and then pushes it along the pipe to the next workman who does another portion of the assembling. This type of conveyor is suited to work of fairly good size not likely to be pushed off one side. There are no protecting guides, the workman being required to exercise sufficient care so that they are not necessary.

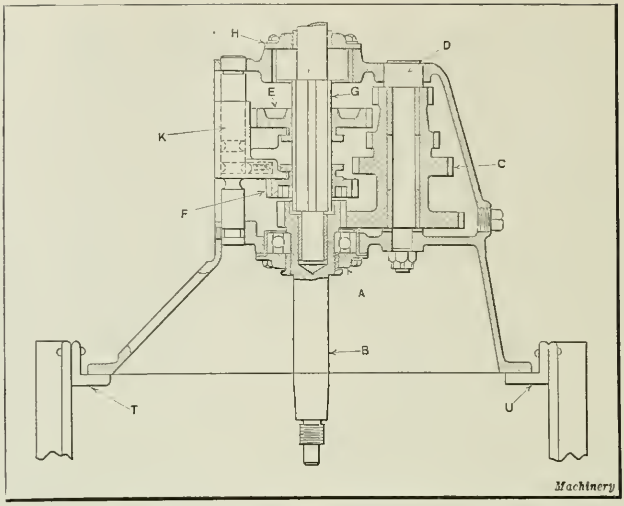

Fig. 3. Sectional View of Transmission Case assembled by the Conveyor Method

Another simple type of conveyor is shown at B; this form is composed entirely of angle-irons and straps. The dotted lines M indicate the piece of work to be assembled. The work is slid along from one operator to another in the guides formed by the legs of angle-irons N. These are set far enough apart so that the work will slide easily and yet cannot fall off. The uprights P are also composed of angle-irons with suitable reinforcements at the foot to allow them to be bolted to the floor if desired. When the work rests on a finished surface it may be found advantageous to place a strip of fiber or leather on top of angle-irons N for the purpose of keeping the finished surface from marring.

In order to obtain the greatest efficiency from the conveyor method of assembling parts, the operators' convenience should be carefully studied in order to make their movements as few as possible. In Fig. 2 is illustrated an angle-iron type of conveyor somewhat similar to the one previously mentioned. In this case, however, the work rests on the edges of the angle-irons A, a guide strip being placed at B to prevent it from being pushed off the conveyor. Uprights C are also angle-irons and between these, angle-irons D extend longitudinally and carry a plate E on which are placed a number of parts used in assembling. Suitable partitions F are inserted so that each workman's parts are kept separate from the others. In assembling, an operator simply reaches down and selects a part from the pile G, while the next operator has a similar pile of other parts which he uses when the work is pushed to him. This method allows an operator to work rapidly, and a high production rate is obtained.

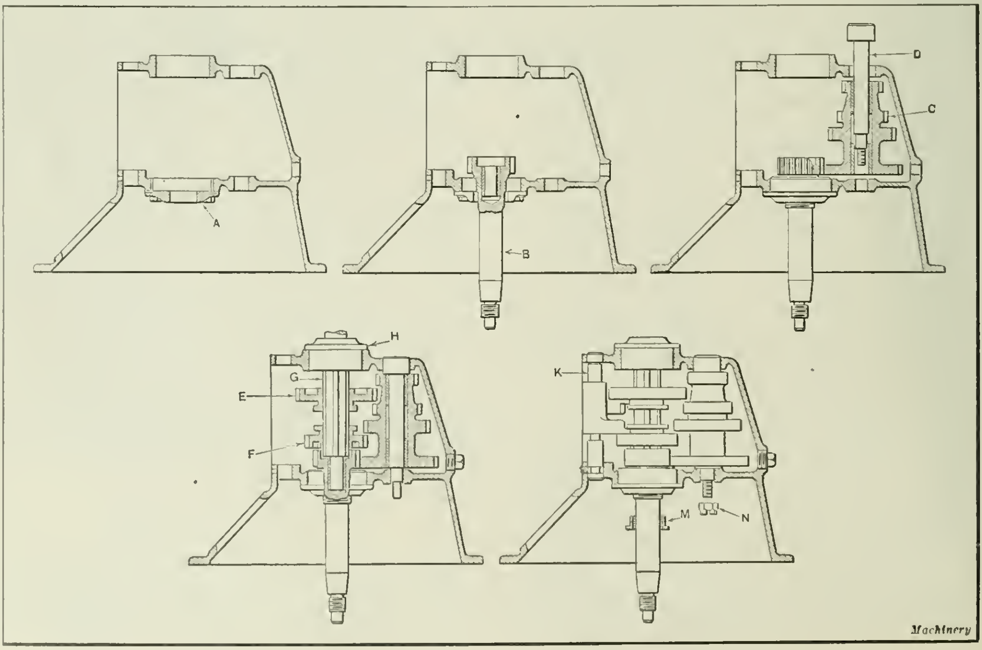

Fig. 4. Various Stages in the Assembling of the Transmission Case shown in Fig. 3

Roller and Power Types of Assembling Conveyors

The roller type of conveyor is not used much in actual assembly but rather for conveying parts from one position to another. For heavy work rollers having ball bearings allow the product to be moved very easily. The cost of such a conveyor is higher than that of a plain type, but its advantages for certain kinds of work offset the difference in cost. This form of conveyor is not generally used in assembling, as it is hard to keep the work steady enough so that parts can be placed in position with certainty.

The power type of conveyor is most commonly used in large manufacturing plants. In this type a chain or belt carries the work along at a uniform speed, and the workman who does the assembling walks with it when placing the various parts in position. The speed of the conveyor is so arranged that each workman has a given amount of time to do a certain operation, and the various jobs are carefully proportioned so that one man does not have more to do than another. The advantage of this form of conveyor is that the manufacturer knows exactly how many units he will obtain in a given length of time, as the parts are not moved with respect to the conveyor and they travel at a uniform speed. When this method of assembling is adopted, each operator is obliged to keep up with the speed of the conveyor, as the next man is always waiting for the part to come to him.

A conveyor of this sort can be designed to hold a considerable amount of stock in various locations. Provision can also be made for turning the work over in order to assemble units on either side. In cases where it is necessary to perform a machining operation after a certain amount of assembling has been done, the conveyor can be designed so that the work can be slid on a sheet-metal table at the level of the machine table on which the operations are performed. After the machining operations, the work can be slid back on the conveyor for further assembly. If the length of time necessary for assembling is such that a conveyor would be required longer than the length of the building, it can be turned around corners and returned in the opposite direction.

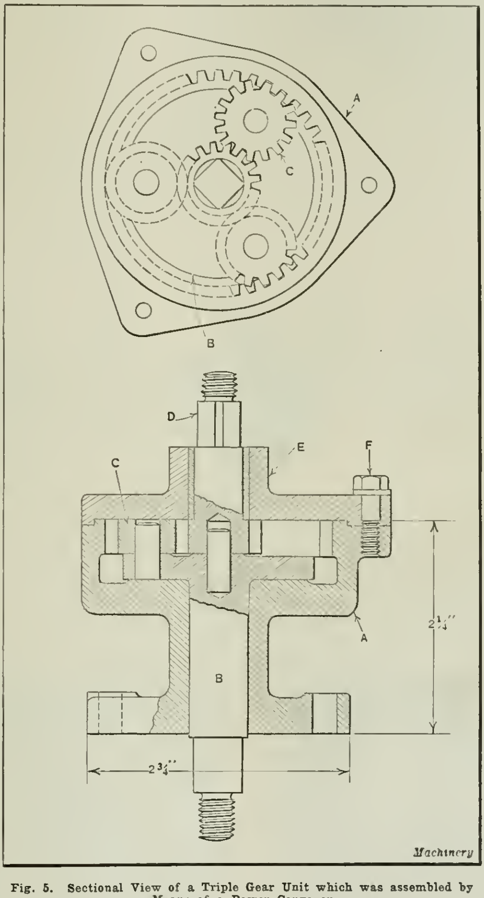

Fig. 5. Sectional View of a Triple Gear Unit which was assembled by Means of a Power Conveyor

Examples Showing Savings Resulting from Conveyor Assembling

In order to make the actual savings obtained by the use of a conveyor system of assembling more apparent, two specific examples will now be presented. Fig. 3 illustrates a transmission case assembly which had in times past been assembled on a bench. A number of men were employed on this work, and each man assembled and tested a complete unit. The work was picked up from the floor and placed on a bench, after which the different parts were taken from conveniently placed racks and assembled in the case, one at a time, bolts being tightened by hand and all adjustments made so that the unit, when finished, was ready for the final inspection. The time necessary for assembling a complete mechanism was twenty minutes.

An investigating engineer decided that this method was entirely too slow and, therefore, installed a conveyor arranged with angle-irons as shown at T and U which served to support the work and acted as guides. The work is placed on one end of the conveyor in the form shown at the extreme left of the top row in Fig. 4, the bearing cap A having been assembled in a previous operation. The first workman places the combination shaft and pinion B in position and pushes the work along to the next man, who assembles the shaft in its bearing and makes a superficial test to see that it runs properly. The next man places the gear C in the case and sets shaft D in position. After this, another operator drives the shaft D home and makes sure that the gears mesh correctly and revolve freely. The next step is the assembling of sliding gears E and F on shaft G by an operator who simply places the parts in position but does nothing more. The next man adjusts the parts, sees that they move freely, and places the bearing cap H in position, at the same time placing the bolts in the holes to secure the bearing cap. The next workman uses an electric drill provided with a socket wrench and rapidly screws the bolts into the nuts, the work being then passed to another operator who tightens the nuts by hand. The next operation is placing the gear-shifting shaft K in position and testing the gears to make sure that they move freely. After this has been done, another operator turns the work over and places bushing M and nut N in position. The last workman adjusts bushing M and tightens nut N, thus completing the assembly. A comparison of the two methods shows that it required twelve men using the new method to produce sixty pieces per hour, while the old method required twenty men for the same production. The cost of the conveyor was nominal, as the construction was very simple and standard angle-irons were used.

Assembling a Gear Unit

An investigation was recently conducted in a shop in which a triple gear unit was one of the products. A sectional view of this part is shown in Fig. 5. The production wanted was six hundred per eight-hour day. After carefully inspecting the methods of machining and improving these where it was found desirable, the assembling was considered. It was found that three men assembled the parts at the required rate of production and that the superintendent considered that this was satisfactory. One man assembled the parts while the others tightened the nuts, the average total time consumed for one piece being 2.4 minutes. The mechanism consists of a body *A* in which a flanged shaft *B* is contained. Three gears *C* are assembled on pins equidistantly spaced in the flange of shaft *B*, these gears meshing with an internal gear cut on the inside of body *A*. Shaft *D* has a pinion cut on one end, and this also meshes with gears *C*. A cover plate *E* is fastened to the body by means of three bolts *F*, each of which has a spring lock washer. The assembling is quite simple and no fitting is required.

After studying the old method, it appeared that a conveyor could be easily applied with a distinct gain in production, and so a study was made of the length of time necessary to assemble each of the parts by the old method. This gave a basis for comparison and an idea as to the speed at which the conveyor could be run. A preliminary sketch of the idea was made, and as it appeared worth while, the idea was put into practice as illustrated in Fig. 6. The two pulleys *G* and *H* were mounted in a wooden frame set on the floor, and motor *K* was connected to drive pulley *H*, the reduction being such that the surface speed of the canvas belt *L* permitted time for each man to assemble his portion of the work. Belt *L* was furnished with a series of blocks *M*, spaced at intervals of 3 feet. In each block a hole was bored to allow space for the central shaft of the unit when assembling. The work is located on studs projecting from blocks *M*, which hold it in position so that assembling can be done readily. The belt slides over the top surface of table *Q* which eliminates sag.

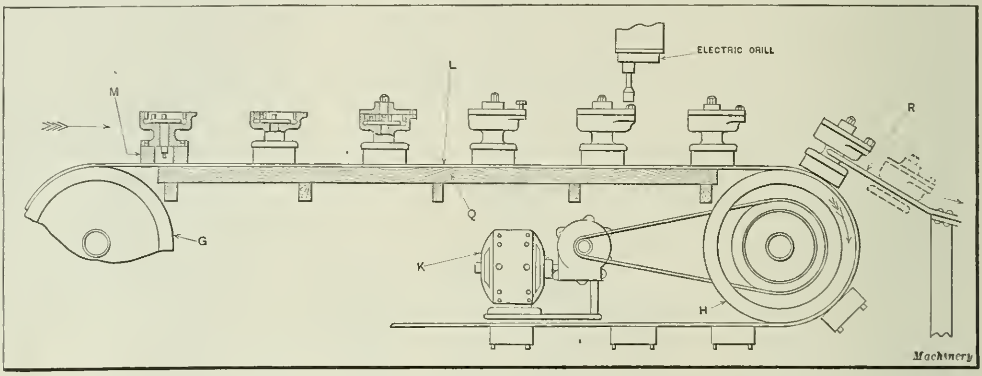

Fig. 6. Motor-driven Belt Conveyor used in assembling the Triple Gear Unit shown in Fig. 5

In the first operation a man places the work on the two studs and assembles the part *B*, Fig. 5, in position. The next workman places the three triple gears *C* in place, while in the third position, the central pinion *D* and the cover *E* are assembled. In the fourth position the three bolts *F* and their lock-washers are put in place, and in the fifth position an electric drill suspended over the conveyor is brought into place to tighten these bolts loosely by means of a socket wrench. In the sixth operation, a workman tightens the bolts by hand. Immediately after this operation the work passes over the pulley, at which time it is guided between the plates *R*, Fig. 6, and slides down an incline ready for inspection.

In addition to the mechanism shown a bench was provided on one side so that any defective parts could be set aside and replaced by a new part. The percentage of defective parts, however, was small, due to accurate machining. After the workmen had become familiar with the new method it was found that by running the conveyor one hour a day and employing six men, the desired production was obtained and the men liked the change from their work at the bench. The amount of space required was small, and the total cost of the equipment moderate.

By comparison, the time required per piece in the old method was found to be excessive, as is clearly shown by the following figures: Old method, 2.4 minutes per piece; new method, 0.60 minutes per piece; old method, 600 pieces required 1440 minutes; new method, 600 pieces required 360 minutes. The saving in time equals 75 per cent. This is a good example of the economies which can be effected by the judicious use of conveyors in assembling. The small manufacturer should not attempt to install a complicated system of assembling conveyors, but he can save a great deal of money by using simple forms like those described.

MOVING PICTURES OF MACHINE TOOLS

The educational value of motion pictures for teaching students of trade schools and colleges is coming more and more to be appreciated, and this is emphasized by the fact that the United States Government is now having motion pictures of machine tools taken, which are to be used for educational purposes in twenty-seven vocational schools throughout the country. The pictures are being filmed by the Society for Visual Education, and a ten-thousand foot film relating to milling machines has been taken in the shops of the Kempsmith Mfg. Co., Milwaukee, Wis. This film shows the assembly of the different parts of a milling machine into units, the assembly of the units, and the complete assembly of a machine. Then follow pictures of various milling operations, ranging from those of a simple nature up to complex operations requiring the use of a dividing head or special attachments. The cutting of gears is also presented. Close-up views of the revolving cutter in ultra-rapid pictures indicate clearly the manner in which the cutter tooth cuts into the metal and removes a chip. A series of such pictures should be of considerable interest to the student of machine shop practice.

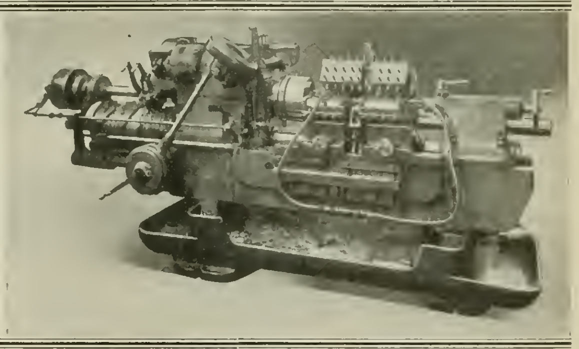
STANDARDS FOR TESTING WELDS

The American Welding Society, 33 W. 39th St., New York City, has issued a bulletin entitled "Standards for Testing Welds," consisting of a report of the Committee on Standard Tests for Welds of the American Bureau of Welding, which is a joint advisory board of the American Welding Society and the Engineering Division of the National Research Council. Differences in the procedure of testing welds in the past have caused widely divergent results, and comparisons are frequently impossible, with the result that the usefulness of much of the research work on record becomes limited, and in many cases the results are actually misleading. The committee feels that the need for some immediate standards is great, and the universal use of the specifications contained in the bulletin is urged upon all those who have to do with the testing of welds.

Cost-reducing Tooling Equipments



Tooling Equipments Employed for Machining Steering Knuckles and Other Automobile Forgings at a High Rate of Production

By RALPH E. FLANDERS
Manager, Jones & Lamson Machine Co.
Springfield, Vt.

MACHINE tool developments, during the last decade, have been influenced to a remarkable degree by the automobile industry in the establishment of the high productive and efficient manufacturing methods now followed by most of the concerns connected with the industry. The present-day trend in the design of machines for performing lathe operations is either to provide the machine with several work-spindles and a corresponding number of tool positions, as on multiple-spindle automatic screw machines, or to provide one spindle and as many tools for taking simultaneous cuts as the work will stand without chattering or springing. The present article describes the turning of forged parts according to the second method referred to on automatic lathes produced by the Jones & Lamson Machine Co., of Springfield, Vt.

How To Reduce Production Costs ?

The machining of steering knuckles is typical of the jobs handled on the Fay automatic lathe. The tooling equipment used on this machine for one type of steering knuckle is illustrated in Fig. 3. The knuckle is centered on the axis of the wheel-spindle. The center at the large end is drilled to a uniform depth, as gaged in the centering machine from any support on the forging which will locate the bosses for the holes. The front tool-holder of the lathe feeds in at an angle, until the proper depth of cut is reached, and then feeds straight toward the left, the three tools finishing the two ball seats of the knuckle, ready for grinding, and the small end, ready for threading. Meanwhile, the two tools in the rear tool-holder take a roughing cut on the tapered portion, the length of the cut being divided between them, so that what would otherwise be the longest feed of the operation is considerably shortened. A supplementary holder beneath the rear holder also rocks into place so that the two tools held in it bevel and neck the small end to prepare it for a threading operation. All the tools on the machine work simultaneously.

Fig. 1 illustrates a similar job except that the small end is not necked and the bevel on this end is produced by a tool in the front holder. A designer can usually arrange to omit this neck, and so simplify the tooling for an operation of this sort. Only a roughing cut is needed on the steering knuckle, because the two ball seats are ground later. The forging shown in the machine in Fig. 1 is machined at the rate of about forty per hour, so that over 700 parts are produced in a nine-hour day by one

operator running two machines. The steering knuckles shown are of the forked type used with a T-headed front axle, but the tooling of the machine and the production would be the same with a T-type knuckle for a forked axle.

Tooling Equipments for a Transmission Shaft

Transmission shafts are also readily turned on Fay automatic lathes. The example shown in Figs. 4 and 5 is a lower or jack shaft having an integral pinion. With close-forged blanks of mild steel, a single cut over each surface is all that is necessary to prepare the part for the grinding and threading operations. With inaccurate forgings, however, and particularly with those made of tough alloys, roughing and finishing cuts must be taken over each surface. When two cuts are necessary and only two machines are available, it is best to run a lot through both roughing operations first, and then, without changing the camming of the machine, through both finishing operations.

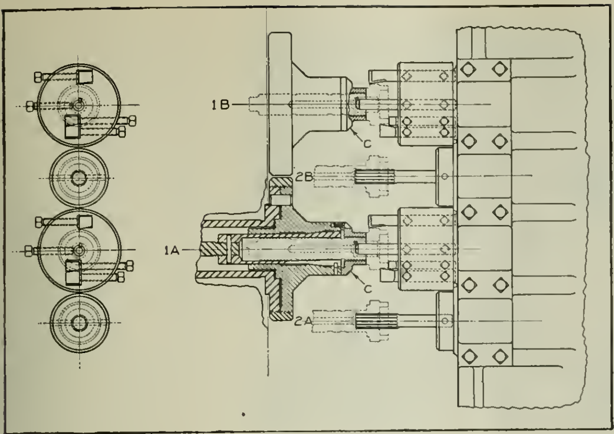

Fig. 9. Equipment provided on a Double-spindle Production Lathe for machining Transmission Clutch Shaft

All such parts as these are best handled if the ends are straddle-milled to length in a preliminary operation, gaging from the pinion blank, and then centered to a standard depth. This procedure saves facing into the centers and provides a smooth surface to center into as well. A rugged inexpensive machine for straddle-milling the ends of such work as forged shafts should find a ready sale in automobile factories. A simple gage for determining the depth of centers was shown at *C*, in Fig. 1 of an article describing the production of tractor camshafts, which was published in May, 1920, MACHINERY. The use of this gage in connection with straddle-milling permits work of ordinary accuracy to be put into the machine, taken out, and turned end for end in a second operation, without altering the positions of the shoulders. Longer forgings may be machined in the same manner as the shaft described, although it may be necessary to provide additional support at the middle of the work by the use of a steadyrest.

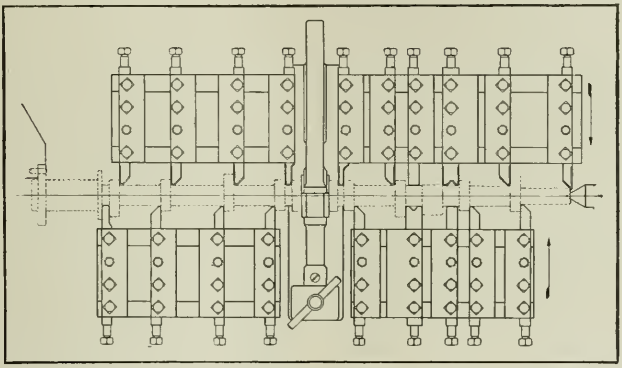

Fig. 10. Tooling provided on a Fay Automatic Lathe for squaring the Shoulders of Camshafts

Machining a Transmission Clutch Shaft

The first operation on a transmission clutch shaft is performed on a double-spindle production lathe equipped with the tooling shown in Fig. 6. Both spindles are fitted with an air-operated chuck for holding duplicate pieces of work, and two sets of tools simultaneously finish the two pieces in practically the same time as would be required for machining one piece in a single-spindle machine. When the carriage is fed forward, after the work has been chucked, the holes are drilled and counterbored and the two outside diameters of the large end are rough-turned, as shown at positions 1A and 1B. The carriage is then withdrawn and an automatic mechanism shifts the tool-slide over to bring the second set of tools, shown at positions 2A and 2B, into alignment with the work. As the carriage is again fed forward to its stop, two tools bevel the bottoms of the counterbores to form centers. Then, the tool-slide is fed toward the rear for a distance of about 3/16 inch to bring two tools into position to rough-face the end of each piece of work, the cut being divided between them as one tool works toward the outside and the other toward the center of the part. Meanwhile, a tool recesses the bottom of the drilled hole. If the forgings are straddle-milled prior to this operation, the facing tools can be omitted.

Figs. 7 and 8, respectively, show the roughing and finishing cuts on this part, which are taken in a Fay automatic lathe. The point of particular interest is the method of supporting, locating, and driving the work. The work is centered on a spring plunger *A* which recedes as the tail-center is advanced, until the bottom of the counterbore in the work comes in contact with the end of part *B*. All the cuts are thus gaged from the bottom of the counterbore, which is the logical place. Set-screw *C* is then clamped to hold parts *A* and *B* in the proper relation to each other. Attention is also called to the arrangement of the tools in the front holder; it will be seen that the machining of the shank is divided between four tools, so that the rough-turning is completed in about one-quarter the time that would be necessary with one tool.

Rigid support of the work at the headstock end is an essential feature in withstanding the pressure of these multiple cuts. On most work, it is advisable to use a revolving ball-bearing center in the tailstock, as otherwise the center hole will wear so badly as to

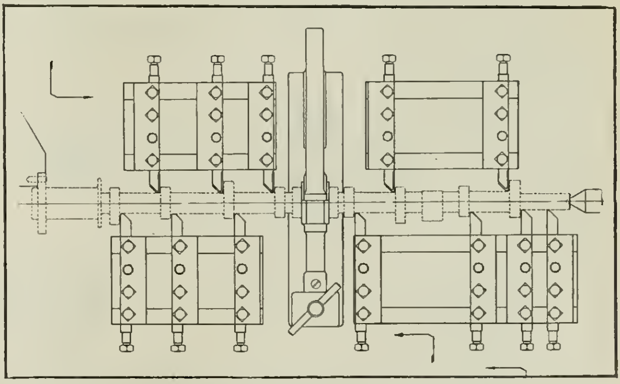

Fig. 11. Turning the Camshaft, the Cuts being divided between Tools in the Front and Rear Holders

allow the work to shift, with the result that it will be turned inaccurately and, perhaps, cause the tools to break. The ordinary solid tailstock center has a limited usefulness in intensive turning operations. A copious supply of cooling compound is also essential for the satisfactory accomplishment of such operations, and Fig. 2 shows to what extent coolant is furnished in practice.

In the finish-turning operation illustrated in Fig. 8, the tooling is obviously determined by the finished dimensions of the work. Much higher speeds and finer feeds are used than in the roughing operation, and the result is an accurate and well finished piece that is produced in the same time as that required for rough-turning. The tools in the rear tool-holder produce grooves on the shank, and finish-turn, bevel, and neck the small end. On this job one man operates two machines, and the production ranges from twenty-five to thirty completely finished pieces per hour.

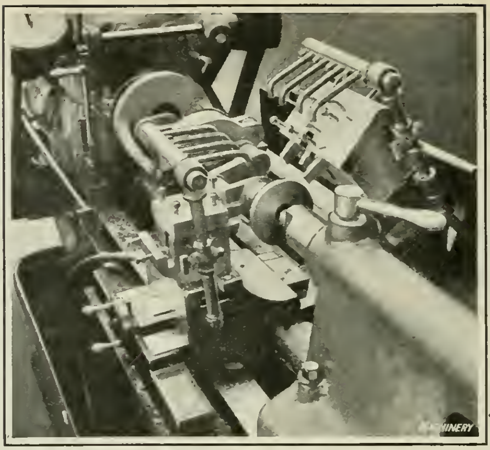

Fig. 12. Crankshaft End Bearings being machined with the Part supported by a Spindle Fixture

The part next goes to a drilling machine to have a long central hole drilled, although in some cases this operation is left until after it has been ground and gear teeth cut on one surface, as this provides a better means of holding. The final lathe operation then consists of finishing the large end on both the inside and the outside. For this purpose, the work goes to a second double-spindle production lathe equipped with the tooling shown in Fig. 9. The tools shown in positions 1A and 1B finish-bore the bearing seat, finish-turn the outside diameter of the gear and clutch portions, and finish-butt-face the end. A tool for recentering the bottom of the counterbore may also be provided, but this is not usually necessary, because the shank is finished true with the center and the work is held by the shank in an air-operated expansion collet.

Since the diameter of the shank may vary, the longitudinal position of each collet is not fixed and it is therefore necessary to stop the work against collars *C* which are fixed longitudinally. The holes in the shafts are reamed to size, ready for grinding, by the tools shown at positions 2A and 2B. The total time for this operation is but little more than would be required for producing one piece at a time.

Operations on Camshafts

The lathe work on camshafts can be performed on double-carriage Fay automatic lathes provided with tooling equipments as shown in the heading illustration and in Figs. 10 and 11. The particular forging shown in those illustrations comes to the machines with the end flange finished and drilled and the center bearing turned. It is necessary to have the center bearing turned previously, to provide bearing surface for the steadyrest. The flanged end is held in hardened and ground jaws in an air-operated chuck, the camshaft being driven by a dowel in one jaw engaging a bolt hole in the flange. There are two general methods of machining and hardening to obtain hardened cam and bearing surfaces and a soft body. One way is to machine the part completely and then carburize it, the surfaces to be left soft being copper-plated so that they will be protected during the carburizing process. The other method is to square the shoulders, rough-grind the cams and bearings, carburize the part, turn the body and other surfaces to be left soft, and then harden. In this way, the carbon is removed from the surfaces which have been turned, and consequently they will be left soft in the hardening process.

Fig. 10 shows the tool set-up used in squaring the shoulders, both the front and rear tool-holders being fed straight in. The camshaft is complicated by a pump cam located between the second and third valve cams from the right end. There is danger on a wide forming cut that a slender shaft will catch on the tools, ride up on them, and spring off the centers. For this reason, the cuts taken on both sides of the pump cam are divided into three chips by using alternate double and single tools at the front and rear of the work as shown. This arrangement tends to balance the stresses and makes heavier cuts possible on slender work of this sort. Fig. 11 shows the tooling equipment for the turning operation, the cuts being again balanced between the front and rear tool-holders. The rear tools are fed to the work at about the center of the space between the cams until they are cutting to depth, after which they are fed toward the tailstock. The operation of the front tools is similar except that they are fed toward the headstock. This permits the cuts to be overlapped somewhat so that surfaces of different lengths may be turned with one length of feed. It is also possible, as shown at the extreme right, to turn an extra long surface with two tools.

The heading illustration shows a machine set up for a job very similar to that shown in Fig. 10, and the production with one man running two machines is twenty-five camshafts per hour. The automatic feature of the machine is important in taking these short multiple cuts, as it saves the physical and nervous strength of an operator. All machine movements are automatic, with the exception of the opening and closing of the chuck and the changing of work. Six-cylinder camshafts are handled in a similar manner, except that, owing to their greater slenderness, it is often

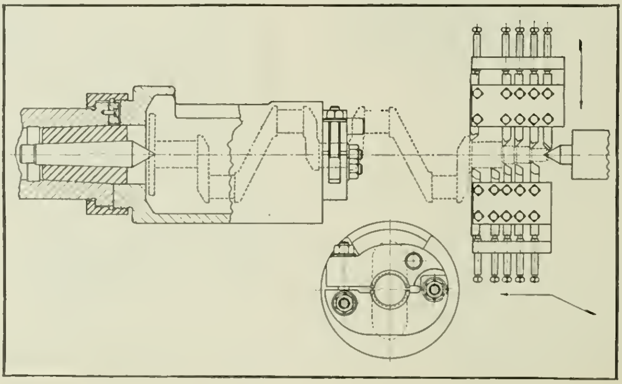

Fig. 13. Tool Set-up in which the Spindle Fixture used in Fig. 12 is also employed

necessary to divide the cuts into three operations and use fewer tools in each. It is important in shaft work to have all shoulders squared in one setting if possible, because this gives greater accuracy than when the work is transferred to another machine and, perhaps, turned end for end. It cannot be expected, of course, that the design of an automobile engine can be based on machining problems alone, but if it so happens that a designer can use a camshaft having the turned portions of approximately equal length and no form cut more than ½ inch in width, tooling problems will be considerably decreased.

Finishing Crankshaft End Bearings

Machining the end bearings of crankshafts bears a general resemblance to camshaft work, although it is simpler and heavier. An example is shown in Fig. 12; this is an ordinary three-bearing, four-cylinder crankshaft. The main bearing is supported in a clamp bushing mounted in a spindle fixture. The latter will be more clearly seen in Fig. 13. Of especial interest are the form of the spindle end and the means used for holding the overhanging fixture. The production obtained on these machines is twenty crankshafts per hour, with both ends machined, and one man running two machines.

IMPROVEMENTS IN LOCOMOTIVE DESIGN

By ARTHUR GORE

The railroad companies who are anxious to put their roads back on a paying basis realize the necessity for reducing their operating expenses as well as increasing efficiency in every way possible. The motive power is, of course, one of the principal sources of expense in the operation of a railroad. The price of coal has increased enormously in recent years, and it is therefore of the greatest importance that every available means be employed to cut down the fuel consumption.

The locomotive in its present form is very wasteful. Steam is used at the boiler pressure for 75 per cent of the piston stroke before being expanded, and is exhausted into the air when still at a high pressure. This practice is anything but economical, and some means of utilizing this exhaust steam for tractive purposes should be adopted. It may be said that it is general practice to shovel coal into the furnace by the ton, and allow a large percentage to be ejected at the stack in the form of smoke and cinders. A large proportion of the heat energy of the coal—sometimes as much as 50 per cent of the total amount—therefore does no useful work.

Coke as a Fuel

The purpose of this article is to suggest improvements in the design and method of operating locomotives that will not necessitate material alterations or changes, yet that will be of such a nature as to result in substantial reductions in the operating expense. With this idea in mind, attention is directed to the successful operation of by-product coke ovens, which has made it possible to solve many of the problems that at one time seemed unsurmountable. It is proposed that this vast industry and especially its new developments be studied carefully with a view to utilizing some of its products as locomotive fuel.

Motorizing Locomotive Tender

It is proposed that the present tender of the locomotive be changed to permit of the installation of a high-pressure steam turbine between the frames. This turbine would be coupled to the axle by suitable gearing. The exhaust from the main cylinders would drive the turbine, and the exhaust from the turbine would be directed to the uptake. Coke and tar would be the fuels utilized in the furnace, the latter being fed through suitable injectors by steam, and the former fed by hand in the usual way. A good draft and a very incandescent fire should result from this combination of fuels. Tar has been used as a fuel for a number of years by some of the European railroads and has given excellent results.

In the case under consideration, tar, being one of the chief by-products of the coke oven, would be a cheap fuel. It has given great satisfaction in steel furnaces in conjunction with coke oven gas. The use of the locomotive tender as a motor is not a new idea, but the introduction of a steam turbine seems original in locomotive practice, although there is no mechanical reason why it will not adapt itself to that service, and at present this plan is being tried out in Europe by one of the leading locomotive builders. Undoubtedly, the most economical method of using coal as a fuel is to extract its constituents in the by-product coke oven and use them separately, and not shovel it into the furnace as at present in an indiscriminate mass. It is understood that the present average consumption of coal on our railroads is about sixty pounds per mile.

Turbine-driven Tender

Objections will doubtless be raised against the use of turbines for railway work, but it should be remembered that some of the largest and fastest ships are driven by reciprocating engines which exhaust into low-pressure turbines. However, objections will undoubtedly be made against any radical change in the present design of locomotives. It may be recalled that when Parson's turbine was first introduced, it was rejected by the leading engineers of the day.

The Mallet type of articulated locomotive, while in use for many years in Europe, did not find favor in this country until the railroad managers were forced to find a means of hauling the ever-increasing train loads without injury to bridges and road-beds. The tender has always been a cumbersome element to deal with, and if it can be utilized for hauling or tractive purposes much expense may be eliminated. It would not be necessary to change the present design of tender materially in the improved type. A simple engine with two high-pressure cylinders equipped with the Walschaerts valve gear could also be employed. The boiler could, in the writer's opinion, be shortened without decreasing the efficiency of the heating surface.

* * *

SPECIAL LIBRARIES IN MANUFACTURING PLANTS

The increasing importance to the industrial executive of accurate facts and information is illustrated by the rapid growth of industrial research libraries, with trained library experts in charge. As the result of a survey recently made by the Special Libraries Association, it was found that there are over 1300 special libraries throughout the country, and of this number more than 200 are directly concerned with industrial and manufacturing subjects. Special libraries have demonstrated their value in all the more important lines of manufacture. Such collections are maintained by companies producing metal products, electrical supplies, explosives, rubber, oil, paper, textiles, shoes, office appliances, firearms, etc. While industrial libraries are maintained primarily to aid the executive officers of the concern, they have frequently rendered valuable service in the education of company employes. In some cases the central library has extended its facilities to factory branches in various parts of the country by the establishment of branch libraries and information departments. Many of the industrial libraries have interesting special features. In several instances bibliographical or news bulletins are issued. During six months, 1790 reference questions were answered by one library. The complete findings of the Special Libraries Association's survey have recently been published in the form of a "Special Libraries Directory," edited by Dorsey W. Hyde, Jr., president of the association, 3363 Sixteenth St., Washington, D. C.

Combination Dies for Finishing Parts in One Stroke

How To Reduce Production Costs ?

By J. BINGHAM, President, Bingham Stamping & Tool Co., Toledo, Ohio

COSTS may be reduced and the production of various styles of drawn covers for such articles as tobacco cans, etc., may be readily accomplished in one power-press operation, provided the machine is equipped with some type of combination die. Fig. 1 illustrates a combination blanking and drawing die employed in the manufacture of the cover shown at the bottom of the illustration, this part being made from 0.011-inch sheet iron, commonly called "tin." In the operation of this die, a strip of metal is placed on die ring *A*, the top of draw-ring *B* being raised to the same level as the cutting edge of ring *A* through the action of the rubber buffer which actuates the block upon which pins *C* rest.

When the punch descends, the face of ring *D* is advanced ahead of the face of section *F* by coil springs placed between the ring and section *E*, and cuts the blank to a diameter of 5⅝ inches as it enters die ring *A*. The draw-ring then holds the blank firmly against the face of ring *D* and retards the movement of the latter, so that the coil springs are compressed and the relation between the faces of ring *D* and section *F* is changed, permitting section *F* to draw the part to the desired shape on ring *G*. The operation is completed when ring *D* and section *E* come into contact. The draw-ring ejects the work from the die when the punch ascends while ring *D* forces it from the punch.

Although this job would be a difficult one if an ordinary solid punch were employed, it was accomplished satisfactorily by means of the sectional punch. The coil springs are made of 1/32- by 3/32-inch flat wire and are about ½ inch in diameter. Attention is called to the provision of a block *H* in a counterbored hole in the bolster plate. This arrangement eliminates the necessity of machining holes through the bolster plate to accommodate draw-ring pins, because they can be located in the special block. Therefore, the bolster plate does not become ruined after a number of dies on which the diameters of the draw-rings vary are mounted on the machine, because a suitable block may be provided for each die. The only holes required on the bolster plate are those for bolting the die-shoe to it. This construction has been used for years with complete satisfaction.

Drawing a Canister Top by the Inverted Method

The die shown in Fig. 2, which is used for producing canister tops, cuts the blank and then performs two distinct drawing operations, the part being first drawn as shown at *A* and then as shown at *B*. This method is known as "inverted drawing." The material used for the part is 0.028-inch sheet iron. Normally, the top of draw-ring *C* is held in the same plane as the top of die-ring *D*, by a stud and rubber buffer arrangement which functions similarly to that on the preceding die. The blank is cut to a diameter of 6½ inches by ring *E* of the punch as the latter enters the opening in ring *D*, after which the draw-ring holds the blank firmly against ring *E* as this member continues to descend, and draws the part on ring *F* of the die to the shape shown at *A*.

As this step is concluded, pad *G* and the spring-actuated ring *H* come in contact with the work and cause it to be drawn to the shape illustrated at *B*, during which time ring *H* is retarded so that the springs placed above it (not shown in the illustration), become compressed. By this construction ring *H* functions in the same manner as a draw-ring. Upon the return stroke of the punch, the springs

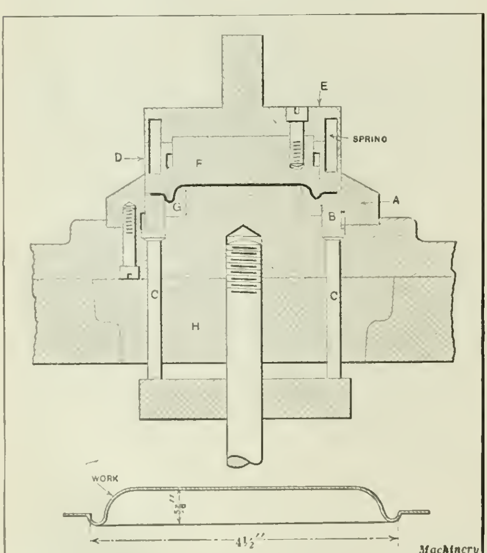

Fig. 1. Making a Tobacco Can Cover in One Operation by Means of a Combination Blanking and Drawing Die

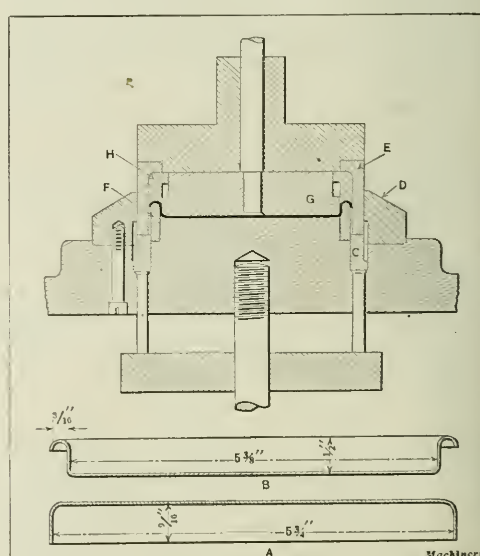

Fig. 2. Another Combination Die which produces a Canister Cover by the Inverted Method of drawing

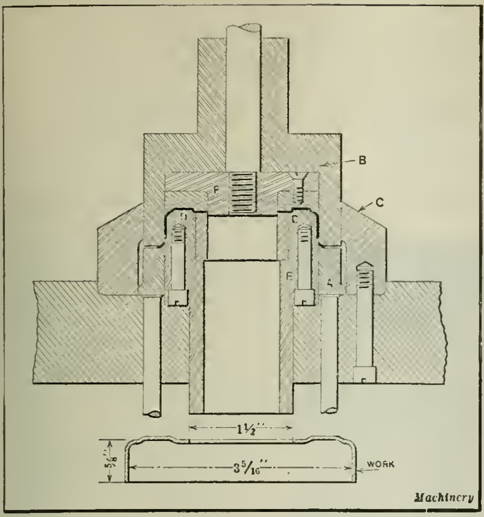

Fig. 3. Performing Blanking, Drawing, Trimming and Punching Operations in a Single Stroke of the Press

expand and cause ring *H* to eject the work from the punch. Ring *E* is secured to the punch-holder by means of machine screws. As indicated by the view of the work at *A*, the face of ring *E* projects 9/16 inch plus the thickness of the metal beyond pad *G*.

Die which Blanks, Draws, Punches, and Trims

Another interesting combination die is illustrated in Fig. 3. This die blanks, draws, punches the hole, and trims the lower edge of the part shown beneath the die, the material being 0.035-inch cold-rolled steel. Draw-ring *A* of this die serves in the same capacity as those on the dies previously discussed. The blank is cut as punch *B* enters ring *C*, and is drawn upon ring *D* as the punch continues to descend. During the lower portion of this stroke the bottom edge of the work is sheared off as the punch face passes the upper edge of die-sleeve *E* due to the outside diameter of the latter being the same as the internal diameter of the punch. As soon as this trimming step has been completed, section *F* comes in contact with the work and cuts the hole as the stroke of the ram is concluded.

Section *F* enters the die only a slight amount approximately equal to the thickness of the metal. If the section entered the hole much further, a perfectly round hole would not be obtained. The scrap from the operation falls through the die and an opening in the rubber buffer, which in this case is supported by two studs. Although the trimming step really consists of "pinching" off the metal rather than cutting it, the method has been satisfactory on metal up to 0.065 inch in thickness and is probably practical up to a thickness of 3/32 inch.

* * *

STANDARD PATTERN PRACTICE

Last year the American Society for Testing Materials requested the American Foundrymen's Association to sponsor an effort to standardize patterns, core-boxes, etc. A general committee was organized, consisting of two members from each of the following organizations: American Society for Testing Materials, Institute of Metals Division of the American Institute of Mining Engineers, Steel Founders' Society, American Malleable Castings Association, and the National Association of Pattern Manufacturers. Vaughan Reid of the City Pattern Works, Detroit, Mich., is chairman of the committee, and any suggestions on this subject will be welcome.

DEAD CENTER DRIVE FOR BENCH LATHE

The dead center drive shown in the accompanying illustration was designed to fill the need for an attachment not ordinarily included in the equipment of a bench lathe. Referring to the illustration, *S* is a hardened and ground sleeve made to fit over the tapered end of the hollow spindle of the lathe. This sleeve serves as a bearing for a light weight pulley *P* which may be made of cast iron but preferably of aluminum. The pulley is held securely between the flange on the sleeve and a hardened steel washer *W* which is tightened against a shoulder on the sleeve by the collar *C*.

In order to prevent oil from being thrown from the rims of the pulley, an oil-groove is cut into the corner which fits over the flange, and a series of holes drilled from the bottom of this groove, on an angle, so that centrifugal force will cause the oil to flow toward the collar *C*. The collar *C* is grooved in such a manner that a small lip *L* having a slight taper catches all the excess oil and allows it to drain off through a pipe *A* inserted at the bottom of the collar. The projection on the pulley, as shown in the illustration, enters the groove in the collar, and the holes through which the oil passes in the pulley break through in the projection so that oil which comes through them must be thrown from the lip *E* into the groove in the collar. Oil coming from the other end of the bearing is carried around the inner contour of the pulley projection and is thrown off lip *E* and caught by lip *L* in the same way.

The plug *B* takes the place of the draw-back collet and is threaded to suit the draw-back sleeve of the regular machine. The end of the plug is tapered to suit the taper in the sleeve. When the sleeve, pully, washer and collar assembly is placed over the end of the lathe spindle, the plug *B* is inserted and screwed into the draw-back sleeve. When the draw-back handwheel is turned up tight, the plug is drawn in so that the sleeve is firmly held on the spindle. The addition of a driving pin *D* in the pulley completes the attachment. Pin *D* should be slotted so that a screwdriver can be used to tighten it in the tapped hole in the pulley. Of course, an oil-hole is provided in the pulley which is plugged with a headless screw. The lathe center furnished with the machine may be used if desired, in which case it is driven into a tapered hole in the plug *B*. It is necessary to provide an extra pulley on the countershaft for driving the attachment pulley.

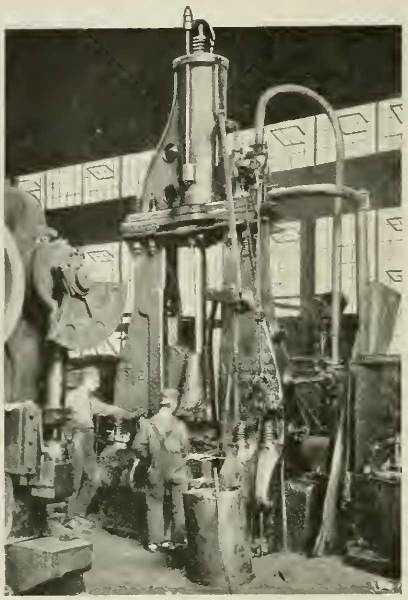
Dead Center Drive for Bench Lathe

Modern Drop-forging Practice

Trimming the Forgings—Forging Heats—Typical Examples of Drop-forging Work
Second of Two Articles

By FRED R. DANIELS

THE previous article on this subject published in November MACHINERY dealt with comparative characteristics of drop-forgings and castings, application, steels used for drop-forgings, and general methods of making drop-forgings. The present article takes up the trimming of the forgings and correct forging heats, and gives typical examples of drop-forging work.



Trimming the Forgings

After each operation has been performed on the drop-hammer, the flash, or surplus metal, must be trimmed from the forging, either while it is still hot or after it is cold. The percentage of metal lost by the trimming operation is necessarily great; the loss may be from 33 to 50 per cent, and is relatively greater on small work than on large forgings.

It seems to be best practice to use the cold-trimming process for small work. If a heavy geared press is used and the trimming dies are properly proportioned, rather large forgings can be trimmed cold, provided the flash is not excessively thick. On ordinary work where the design is not intricate, the flash should not be thicker than 1/16 inch, for cold-trimming, but on unusually large or intricate work the flash may be as thick as 3/16 or even 1/4 inch and still be cold-trimmed. A case where the formation of a thick flash seems unavoidable is the motor truck towing hook, the dies for which were illustrated in Fig. 9 of the article "Design and Making of Drop-forging Dies" published in September MACHINERY. The maintenance of a thin flash is, of course, the desirable condition.

Forgings which are to be cold-trimmed should first be pickled in a weak solution of sulphuric acid to remove the oxide scale. This practice will prolong the life of the cutting edge of the trimming dies. Drop-forgings, having a carbon content of 0.40 per cent or more should also be annealed before being trimmed.

For large work, the usual practice is to trim the forgings while hot. In fact, it is impossible to perform a cold-trimming operation on such parts as crankshafts. Whether the work should be trimmed hot or cold depends upon the steel used, the sizes of forgings produced, and the equipment available in the hammer shop. The question of cost is also a factor. Hot-trimming is more expensive than cold-trimming, because the drop-forger receives a higher rate of pay than the power press operator; an unskilled man, or even a boy, can operate a power press. Consequently, where it is practicable to make the trimming operation a separate one and trim cold, this should be done.

One reason that hot-trimming should not be done on comparatively small work, if it is possible to avoid it, is that the hammer man consumes so much time in transferring the forging to the hot-trimming dies and operating the press that the fires must be slowed down, and the entire cycle of operations is correspondingly affected. After the forgings have been hot-trimmed, they are usually placed in the finishing die again, and restruck to correct any distortions that may have been produced in the process of hot-trimming, and to remove irregularities at the parting line. In addition to this extra handling, it is necessary to crop off the sprue by means of which the forging is handled with the tongs. This may be done in a separate operation, after the forging is cold or it may be removed in the hot-trimming operation; in this case the forging is not restruck.

Hot-trimming dies will give much longer service, however, than cold-trimming dies. If the tools are properly hardened and drawn, they will last almost indefinitely, even though the steel from which they are made has 0.10 per cent less carbon content than that ordinarily used for cold trimmers. The design of the work to be trimmed and the composition of the steel from which the forging is made, rather than its size, affect the length of service of a cold-trimming die. On comparatively plain designs it is frequently possible to trim 20,000 parts without regrinding the cold trimming dies.

The process of drop-forging has been developed to a point where thousands of pieces are practically completed under the drop-hammer and require little or no further machining operations. As a cost-reducing method, drop-forging ranks high among metal-working processes. In the drop-forging plant itself, costs may be reduced by applying certain principles and methods making for economy—by selecting steel of the right quality, and by keeping dies and stock in such a manner that they are readily accessible and the required die and the right size and kind of steel may be easily located. Drop-forgings, when used in quantity, can sometimes be made as cheaply as castings, and are superior in strength. Actual costs are then reduced by employing them, because of the improved quality obtained at an equal price. Furthermore, a saving is usually made in the cost of machining, due to the fact that a drop-forging generally requires less finishing than a casting.

Forging Heat—Life of Dies

The determination of the proper heat to use in a forge furnace is under the general supervision of the forge foreman and is governed entirely by his experience. The pieces are placed on the hearth of the furnace by the furnace man,

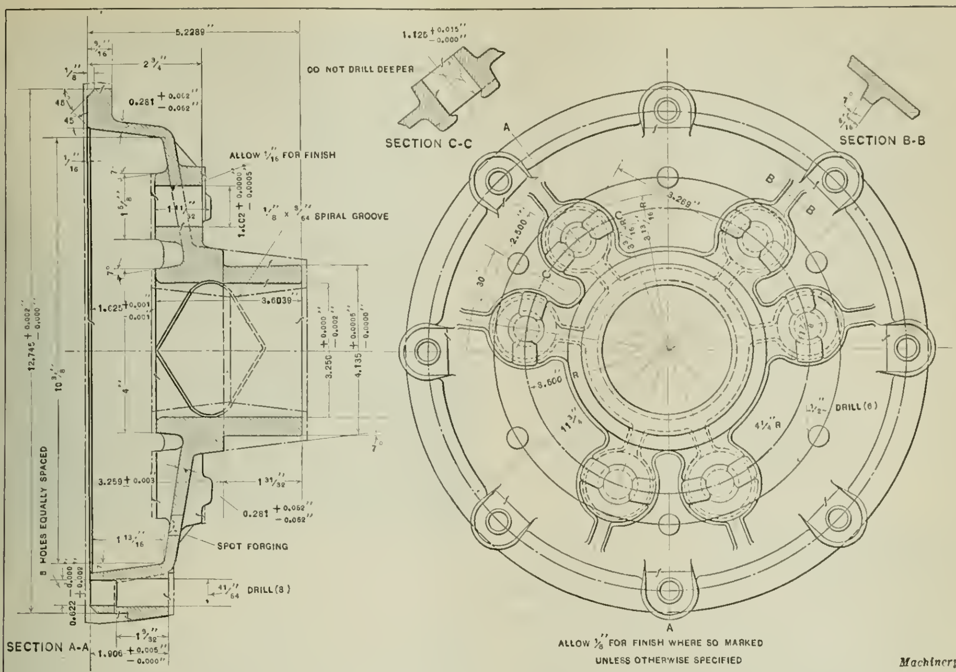


Fig. 1. Differential Gear-case for Motor Truck, which is produced by drop-forging

and arranged in a row with the tong-end protruding, in such order that they may be conveniently handled. If the forgings are made from bars, these are arranged on the furnace hearth in such a way that the one nearest to the hammer will always be the one to be withdrawn first and handed to the forger. After the forging has been made, the hammer man passes the remainder of the bar back to the furnace man, who places it at the head of the row and passes the next one on the opposite end to the hammer man. In this way, each bar will be heated equally, and there will be slight chance of the furnace man becoming confused and drawing a bar from the furnace before it has reached the proper forging temperature. On large work, which is hot-trimmed, three or more men constitute a gang instead of the two usually employed for handling small work, there being helpers in addition to the hammer man and furnace man. If the forgings are made from blanks cut to a predetermined size, there will not be room on the hearth for more than three, or possibly four of these at a time. These large blanks may be conveniently arranged to have the blank which is ready to be drawn nearest the hammer the same as in handling bars, or they may be reversed if the furnace man finds this to be handier.

The piece to be forged should be heated evenly throughout. There should be enough bars or blanks placed in the furnace at a time so that they will become thoroughly soaked with the heat before being withdrawn. If opposite ends of a large forging blank are unequally heated, the strength of the drop-forging is greatly lessened, and if this is frequently done, the dies will wear unevenly which will result not only in an inferior product, but may also lead to the hammer being seriously damaged. During the process of forging a quantity of parts, the impressions of the dies should be swabbed from time to time with crude oil to prevent the work from sticking in the impression.

If the forgings are of comparatively plain design and have no high or irregular projections, it is frequently possible to realize a production of 15,000 drop-forgings before it becomes necessary to resink the impressions. If the forgings are of rather intricate design, this quantity will probably not exceed 5000 forgings per impression. This data applies to dies having faces not greater than 14 inches square. Production on dies larger in face area than this, but of the same classification, will, of course, be proportionately less.

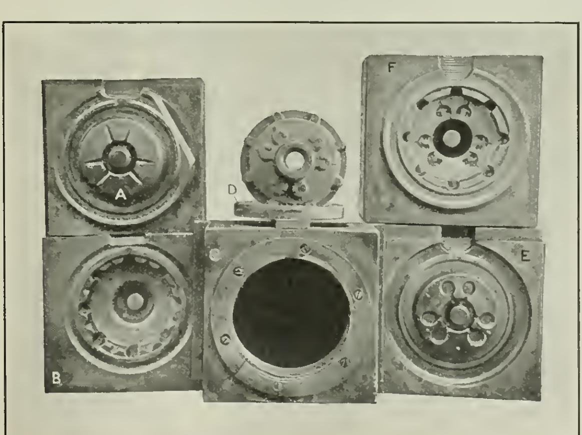

Fig. 2. Dies for producing the Differential Gear-case shown in Fig. 1

The life of drop-forging dies can be prolonged by working them while heated to a temperature between the hardening temperature of the die steel and the atmospheric temperature. Various methods may be used

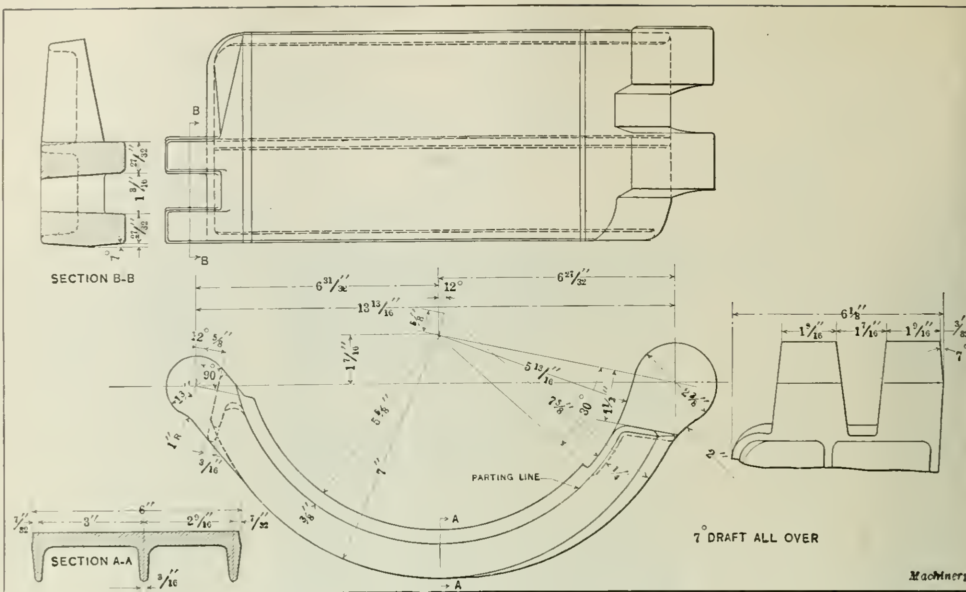

Fig. 3. Emergency Brake-shoe drop-forged from Low-carbon Steel

for heating the dies, one of which is to apply a jacket to the outside of the die-block, which is tightly packed with a suitable layer of infusible earth or fine molding sand, the packing being heated by the most convenient means available. For this purpose gas burners or an electric current may readily be utilized. Molten baths of lead or lead and tin alloy may be used if the die does not need to be heated over 600 degrees F., or use may be made of an oil bath if that is more convenient. For controlling the heat of the die-block, a heat-indicating instrument is set either into a recess in the block, into the packing, or in the bath.

For heating carbon steel blocks, the recommended temperatures vary between 300 and 1100 degrees F., but for certain grades of alloy steels, a higher temperature may be necessary, provided this is well below the hardening temperature. The heating temperature depends, of course, upon the composition of the die steel which can be determined from the manufacturers.

Straight carbon steels having a hardening temperature between 1400 and 1475 degrees F. will be given a high degree of resistance to wear if heated from 400 to 500 degrees F. while in use; and the lighter the falling weight of the drop-hammer (or the more easily the steel can be forged) the nearer can the lower limit—that is, 400 degrees F.—be approached. Dies made from alloy steels, such as chrome-nickel, carbon-chromium, chrome-vanadium, cobalt-chromium, tungsten or molybdenum require a considerably higher temperature than carbon steels. Heavy forging and trimming dies made of tungsten high-speed steel require a temperature of about 100 degrees F. which in some cases practically doubles the life of the dies, and for alloy die steels containing no tungsten a working temperature of about 850 degrees F. should be used.

Examples Illustrating Drop-forging Procedure

The automobile towing hook shown in Fig. 8 of the article "Design and Making of Drop-forging Dies," previously referred to, is made from a piece of 4- by 1¼-inch steel, 8 inches long, in two forging operations followed by a bending operation in an upsetter. The steel contains from 0.30 to 0.40 per cent carbon, and from 0.50 to 0.80 per cent manganese. On this job the waste of stock is great, the entire area between the arms being webbed before the trimming operation, in addition to carrying a heavy flash. The trimming operation could be performed cold, although the actual practice in manufacturing this hook is to trim it hot. This saves transporting the work to the cold-trimming department and back again to the upsetter for bending, which, of course, cannot be done until after the flash has been removed.

It is possible to produce parts such as wide yokes by drop-forging. In such work the die impressions are made so that the two arms of the yoke are parallel

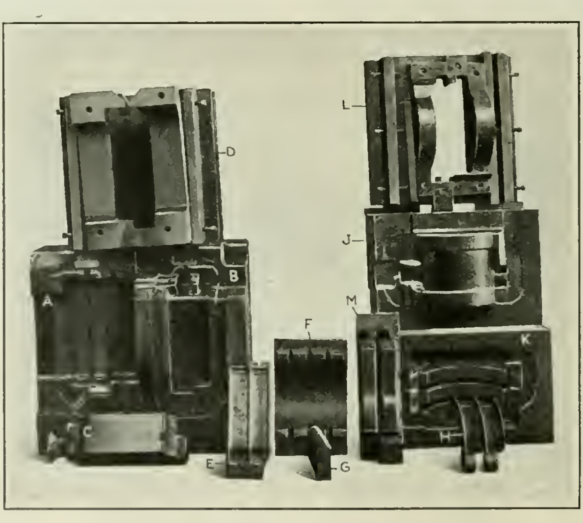

Fig. 4. Dies for Drop-forging the Brake-shoe shown in Fig. 3

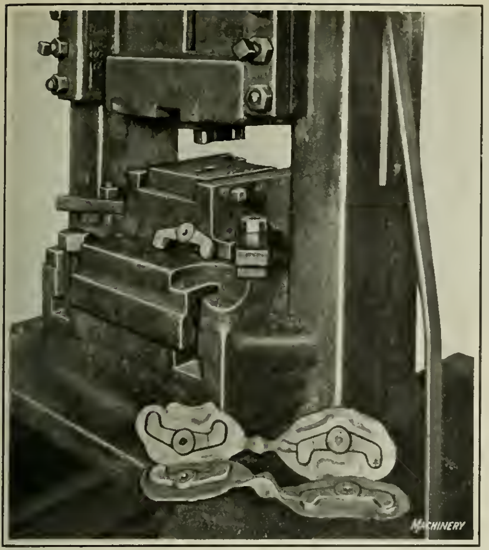

Fig. 5. Power Press equipped with Cold-trimming Dies

and close together; after the forging has been made from this impression, the arms are spread to the proper width, and if necessary, restruck in finishing dies. This permits a much smaller die-block to be used, and also enables the blank from which the yoke is to be forged to be of smaller size, which results in a considerable saving of material. This, in fact, is common forging practice, where the pieces are of such a nature that they can be drop-forged in one form and subsequently shaped to another by bending.

Another excellent example of drop-forging practice is that of the differential gear-case for a motor truck shown in Fig. 1. This illustration shows the rough forging on which there is 1/8 inch allowance for machining, wherever finish is required. The gear-case is made from a piece of open-hearth steel, 0.20 to 0.30 per cent carbon, high in manganese, the dimensions of the blank being 1 3/4 inches thick by 11 inches square. This piece, with its many bosses and projecting hub, shows the possibilities of the drop-forging process for producing parts that are of intricate shape.

Two operations are required to complete the job, exclusive of trimming. It is first blocked or broken down on a 5000-pound steam drop-hammer, and then after being reheated, is finish-forged in a 6000-pound steam drop-hammer. Both trimming operations are performed hot. The entire collection of dies, including trimmers and punches, is shown in Fig. 2. *A* and *B* are the upper and lower break-down dies, respectively, and *E* and *F* are the finishing dies. The trimming die is shown at *C*, and the punch (on which will be seen the finished forging) at *D*. The finishing dies are plug dies, designed to produce the hole in the hub. By employing this construction advantage is taken of the tendency for the hot metal to shoot up, in order to form the hub.

Still another example of what can be accomplished by drop-forging is shown in Fig. 3. This is a motor truck emergency brake-shoe, weighing 26 pounds. The forging is made from low-carbon open-hearth steel, and three operations are required to produce it. The blank from which it is made is 5 inches wide, 2 inches thick, and 15 inches long. It is first blanked, and then trimmed hot and bent, all these operations being done without reheating. The bending die is attached to the outside of the frame of the hot-trimming press, where the shear blades are ordinarily attached. The bending operation can then be done without much loss of time or heat. The forging is next reheated and finished in a double-impression die, after which the flash is trimmed hot. The blanking operation is done on a 3000-pound steam drop-hammer; the finishing on a 5000-pound steam drop-hammer; and the bending and trimming on a heavy back-geared press.

In Fig. 4 is shown the set of dies with which these machines are equipped to produce the brake-shoe. It will be noticed that the breakdown dies *A* and *B* are of comparatively plain design. The first-operation trimming die is shown at *D* and the punch at *C*. The drop-forging, as it comes from the first-operation trimmer, is shown at *E*, although the sprue has been knocked off the piece shown. The bending die *F* is a plain cradle member, and the bending punch *G* simply bears on the work at the center as it lies on the die *F*, contacting on the rounded end. The dies *J* and *K* produce the finished forging, which when trimmed by die *L* and punch *M* has the appearance shown at *H*.

Examples of Trimming Work

Examples of cold- and hot-trimming operations are shown in Figs. 5 and 6, respectively. The press shown in Fig. 5 is equipped with dies of the ordinary power-press type such as used for punching operations, although this type of die is not always used for cold-trimming. The function of the punch is simply to push the cold forging through the die opening, as in hot trimming. The small levers which are to be trimmed are made from open-hearth steel of low-carbon content and are shown in detail in Fig. 7. The forgings are produced in double-impression finishing dies, but the trimming must necessarily be performed singly, as will be understood by an inspection of the punch, the trimmed forging shown resting on the press, and the untrimmed work. The untrimmed forgings are likely to become bent at the gate, which makes it difficult to trim both parts simultaneously.

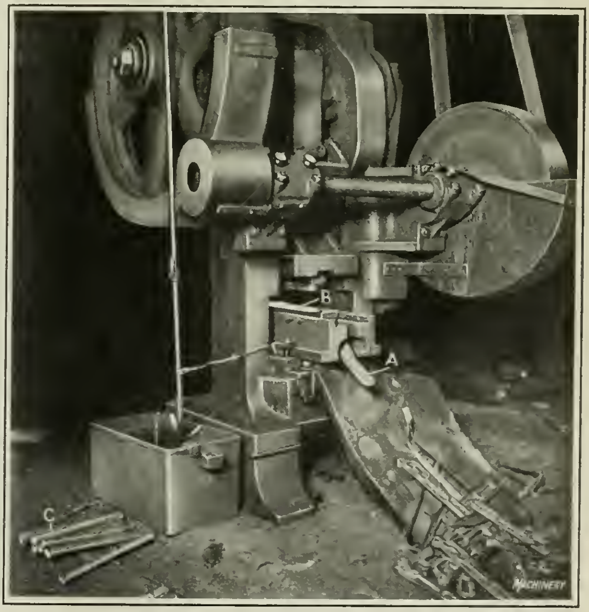

Fig. 6. Geared Press engaged in a Hot-trimming Operation

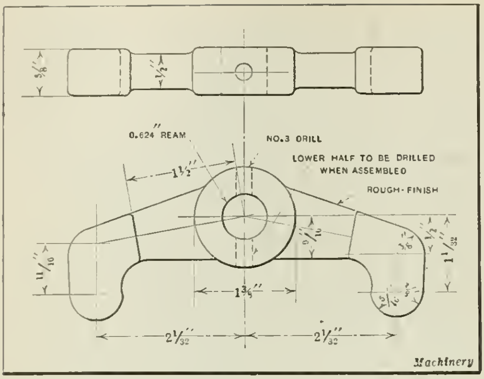

Fig. 7. Drop-forging trimmed with the Equipment shown in Fig. 5

In Fig. 6. a hot-trimming operation is shown in process and the work being trimmed is a small carbon-steel forging. The illustration shows the hot drop-forging *A*, with the flash removed, after being pressed through the die opening, and an untrimmed forging *B* resting in the die opening. There are also a number of trimmed pieces shown lying on the floor. This drop-forging is a latch cylinder locking link for railroad switch work, and is made from open hearth steel, 0.15 to 0.20 per cent carbon. The size of the blank is 1⅝ inches in diameter, and 18 inches long. A number of these blanks, which are cropped from regular bar stock, are shown lying on the floor at *C*, preparatory to being heated.

MACHINERY is indebted to the Union Switch & Signal Co., Swissvale, Pa., and to J. H. Williams & Co., Brooklyn, N. Y., for much of the information contained in this article. The concluding installment of this series of articles will describe modern drop-forge plant heat-treating equipment, heat-treating processes, and types of furnaces and fuels suitable for this work.

* * *

DELAMATER-ERICSSON MEMORIAL TABLETS

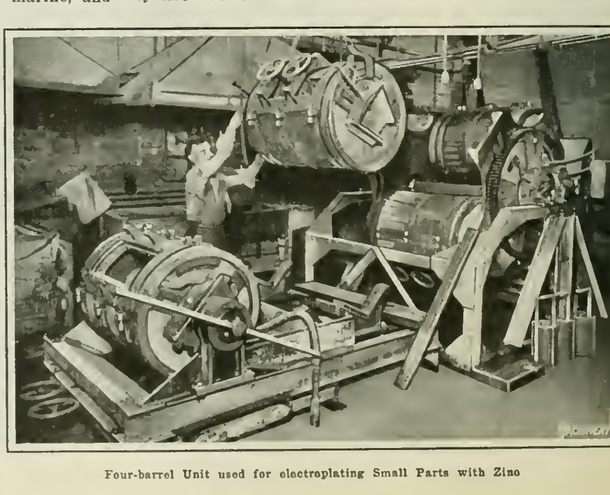
On March 9, 1922, which will be the sixtieth anniversary of the battle of the *Monitor* and *Merrimac* at Hampton Roads, Va., which demonstrated the merits of the turret battleship, invented and designed by Captain John Ericsson, tablets will be unveiled at four different places in New York City to commemorate the work of Cornelius DeLamater and Captain John Ericsson, who for fifty years—from 1839 to 1889—were pioneers in developing the naval, marine, and industrial interests of this country, and who at the time of the Civil War, without thought of personal reward, turned their mental and financial resources to account and applied their energy and experience to accomplishing what the Government had failed to do. One of the tablets will be erected where the Phoenix Foundry was located, at 260 West St., where the first iron boats in this country were built and where John Ericsson first introduced screw propellers for river and ocean steamers. A second tablet will be erected at the DeLamater Iron Works, at the foot of W. 13th St., where the first self-propelled torpedo, the first torpedo boat, the first submarine boat, and the engines for the original *Monitor* were built. A third tablet will be erected at the Continental Iron Works, Greenpoint, Brooklyn, where the hull of the original *Monitor* was built; and a fourth tablet will be placed at 36 Beach St., where Captain John Ericsson worked, lived, and died.

ZINC ELECTROPLATING UNIT

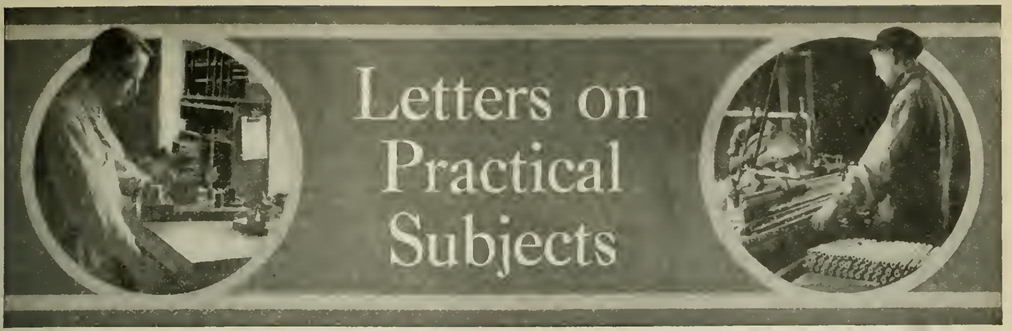
Confronted with the problem of increasing the output of zinc-plated parts used in electric controlling devices, the Cutler-Hammer Mfg. Co., Milwaukee, Wis., developed and patented the electroplating unit shown in the accompanying illustration. The apparatus consists mainly of a structural steel frame and a rotating member on this frame in which four wooden barrels are mounted. These barrels are filled with the zinc solution and the parts to be plated. They are stationary on their own axes, but, of course, revolve with their supporting member. The latter is driven by a 1-horsepower motor through two gear reductions, the first of which is a worm and worm-wheel, and the second a spur pinion and gear. The barrels are turned at the rate of three and one-half revolutions per minute. The electric current connections to the solution in the barrels are made by means of the V-shaped castings on their ends, these castings being copper-faced. The placing of a barrel into position in the carrier automatically makes the electrical connections.

It has been found desirable not to load and unload the four barrels at one time, but rather to replace one, run the machine a certain period, replace another, and so on. An extra barrel is provided so that little time is lost in changing barrels, the change being effected in one and one-half minutes. Each barrel remains on the apparatus for forty minutes, and as there are four barrels, this requires the changing of a barrel every ten minutes. During the removal and replacement of a barrel the current is not cut off from the other barrels; therefore, the plating is continuous. When a barrel is removed, it is placed on supports over an open bin at the left of the unit, and then the barrel with the unplated parts, which has been resting on vees at the front end of the bin structure, is lifted into place. An air hoist is employed to facilitate the shifting of the barrels.

After the apparatus has again been started, the operator removes the cover from the barrel over the bin and then revolves this barrel about 180 degrees so as to permit its contents to drop into the bin. Screens at the bottom of the latter allow the solution to drain off, after which the parts are dumped into suitable receptacles. The drained solution is used over again. When the barrel is empty, it is placed on the vees, filled with unplated parts and the plating solution, and after the cover is replaced, it is ready to be mounted on the apparatus once more. Approximately 300 pounds of parts can be loaded into a barrel, and so an average production of 6 tons per nine-hour day is obtained. The barrels are about 30 inches long and 24 inches in diameter. They are made of oak timber, and are secured on the unit by hook bolts. O. L. J.



Four-barrel Unit used for electroplating Small Parts with Zinc

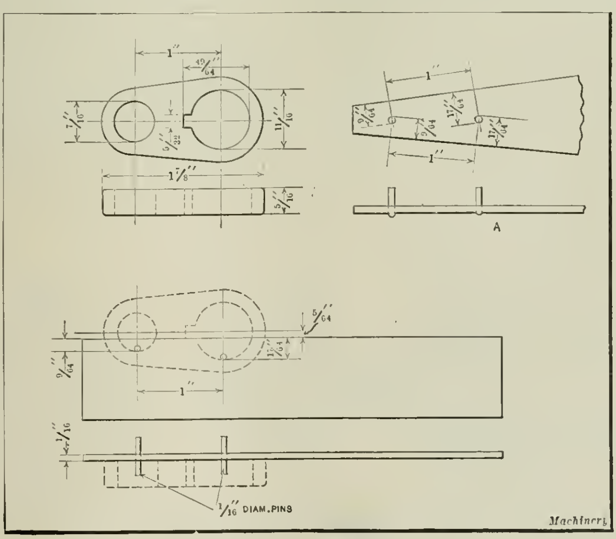


TEMPLET FOR LAYING OUT KEYWAYS

The accompanying illustration shows a templet that may be used advantageously for laying out keyways which must be symmetrical relative to a center line. A typical example of work on which a templet of this kind may be used is shown in the upper left-hand corner of the illustration. Ordinarily, in laying out the center line in tapered pieces such as this, considerable trouble is experienced, it being necessary to use plugs and resort to considerable calculation if a templet is not used. For accurate work, the outside of the part is seldom suitable to use as a locating surface.

The templet used for laying out the keyway in the work, and its method of application are shown in the lower part of the illustration. The templet is made from a strip of 1/16-inch sheet steel, in which two 1/16-inch pins are assembled. In laying out the centers of these pins, it is only necessary to locate from one edge of the templet, and make the center distance equal to the center distance of the holes in the work. The only calculations required are those for obtaining the 9/64- and 17/64-inch dimensions. It will be seen that these are the differences between the radii of the two holes in the work and one-half the width of the keyway. For example, 11/32 — 5/64 = 17/64 inch.

In use, the templet is placed on the work, as shown, so that the pins will seat snugly in the lowest part of the bores, and it is held in this position while a line is scribed along the upper edge of the templet to locate the lower side of the keyway. The pins in the jig project equally on each side of the 1/16-inch plate, so that by turning the templet over it may again be used for locating the other side of the keyway, the pins then being diametrically opposite the position occupied when scribing the first side of the keyway. After these two parallel lines have been scribed, an 11/64-inch plug is inserted in the hole and a strip of steel, 5/64 inch thick, is laid tangent to it and perpendicular to the center line, so as to furnish an approximate location for scribing the depth to which the keyway is to be cut.



Templet for laying out Keyways in Work which does not have Parallel Side

Perhaps the greatest time-saving feature of this simple templet is the provision for using both sides by simply permitting the pins to extend through the plate. Referring to the view at *A*, it will be seen that if this method of assembling the pins is not followed, a tapered templet is required so that the pins may be located perpendicularly and equidistant from both angular sides. The calculations involved in laying out the center distance of the templet would also be more complicated. A templet of the type described will be found to effect a considerable saving in time in laying out a keyway, as it requires only about thirty seconds per piece.

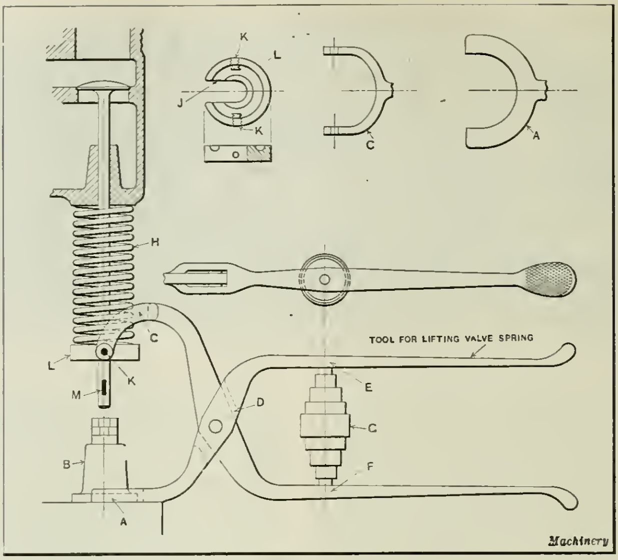
Wilkinsburg, Pa. WILLIAM S. ROWELL

TOOL FOR LIFTING ENGINE VALVE SPRINGS

The valve spring lifter shown in the accompanying illustration has proved useful in removing the valves from gasoline engines. It is easily made and differs somewhat from the conventional type of valve spring lifter, which is often found to be more cumbersome than convenient. The tool consists of a pair of tongs, the two halves of which are forged from steel. A fork *A*, which will straddle the valve tappet guide *B*, is forged at the end of one member. The other member is also made with a forked end *C*. It will be clearly seen from the illustration that this half, owing to the forked end, will not pass through the slot at *D*, and must therefore be made in two pieces and welded after the tongs are riveted together. After assembling, the handles are filed and checked at the ends as indicated in the illustration.

Pins are fitted into the handles at *E* and *F* which position the spring *G*. A steel pad *L*, grooved to fit the end of the valve spring *H*, and slotted as shown at *J* in the detail view, is placed in fork *C*, where it is held by two pins *K* which allow it to swivel. To remove a valve it is only necessary to compress the handles and insert the tongs under the valve spring H as indicated. When the handles are released, spring G causes the tong ends to be forced apart, thus compressing spring H. This permits the valve cotter-pin M to be easily removed, as both of the workman's hands are left free for this work. By assembling pad L in the fork so that it can swivel, it will automatically align itself with the valve spring H, so that there is no danger of the tongs slipping or flying out of position due to the pressure exerted by the spring. It is a simple matter to release the tongs and remove the valve spring after the cotter-pin has been removed. By the use of this tool, valves can be quickly and conveniently removed.

Cleveland, Ohio C. F. GEORGE



Tool for lifting Valve Spring to permit Removal of Valve

WORK-HOLDER FOR THREAD-MILLING OPERATION

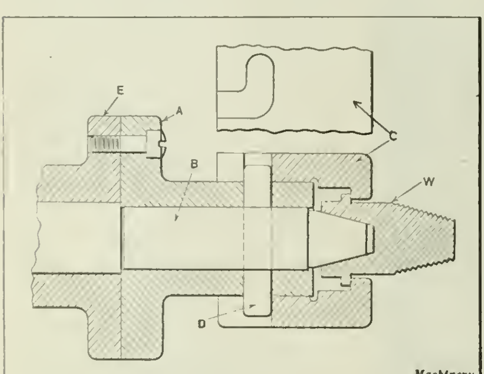
The work-holder described in the following was designed as a special holding means for the brass plug W which is shown located in the holder in the accompanying illustration. The operation performed on this brass plug was the milling of taper threads, the holder being attached to a thread-milling machine, although the design lends itself to application to other machines. In the present installation it was impossible to make use of the tail-center as a support, so that other means had to be employed to chuck the work securely. Consequently in the design of this special holder advantage was taken of the surfaces which were previously finished true with the portion on which the threads were to be milled, and these surfaces are those by which the work is shown located in the illustration.

The spindle of the thread-milling machine is indicated at E, and the adapter or body of the holder, which is attached to the spindle by means of fillister-head screws, at A. This adapter extends out from the head of the machine a sufficient distance to to allow clearance for the operation of the cutter-head of the machine. The construction also provides a rigid support for the tapered plug B which locates and helps to drive the work. Pin D is a driving fit in the adapter and plug, and holds them together. The projecting ends of this pin form lugs which engage bayonet lock slots in ring C. By this construction the locking ring C can be readily slipped in place, and brought up against the collar on the work, a slight turn securely holding it on the tapered end of plug B. The bayonet lock slots in which pin D engages are so machined that they have a slight angle relative to the face of the ring, and so enable the ring to be drawn in and securely bind on the collar of the brass plugs W. All that is necessary, then, in chucking work with this special holder is to first place the work on plug B and slip the locking ring over the work until the slots engage the ends of pin D, after which by a slight rotation of the ring, the work is securely held by the pressure exerted on the flange of the work.

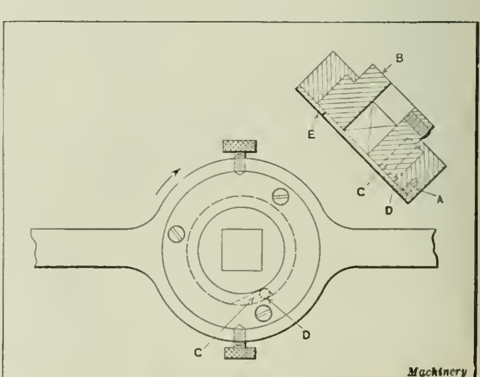
B. S.

REAMER WRENCH

There is a tendency for boys and semi-skilled men, especially if they have ever performed any hand-tapping work, to back a reamer out of a finished hole the same as they would a tap. It is, of course, known to all mechanics that a reamer should be rotated in the same direction, both in reaming the hole and in withdrawing the reamer from the work. If this is not done, the reamer quickly becomes dull, and the surface which has just been finished is likely to become scratched. A reamer wrench which was designed to prevent this occurrence, and which is extremely simple in construction consists of a die-stock in which a suitable



Work-holder for Thread-milling Operation



Slip Wrench for Hand Reaming

holder A is held by means of two thumb-screws. The holder is bored to fit a bushing B which is provided with a square hole for about two-thirds of its length and with a round hole for the remainder, so that it may fit the end of the hand reamer. The reamer is secured in bushing B by a headless set-screw. The periphery of the bushing contains a tangential slot C which is milled to a sufficient radial depth so that roller D may be housed between the bushing and the holder A and be free to revolve when located in the deepest part of this cut-out. The holder is provided with a plate E, screwed to the face to hold the parts together. The wrench is designed to operate similarly to a roller clutch, it being at once evident that after the wrench has been slipped over the end of the reamer and the set-screw which holds it to the shank tightened, rotation in a clockwise direction will cause the roller to bind in holder A and drive the reamer; also, reversal of direction of rotation will result in the roller becoming pocketed in the cut-out section of holder A and thus prevent movement of the reamer. The device is simple and fool-proof, it being absolutely impossible to back the reamer out of the hole when roller D is not wedged against the bore in the holder.

Rosemount, Montreal, Canada — HARRY MOORE

PATTERN CORRECTIONS

While it is impossible for the patternmaker to foresee all the difficulties that the molder may encounter, it should, nevertheless, be possible to minimize these difficulties by encouraging closer cooperation between the molder and patternmaker. An effective method of promoting such cooperation, even when the foundry is situated at a considerable distance from the pattern shop or even in another city, is to see that all pattern changes made at the foundry, and all reasonable suggestions that the molder can make to improve each pattern, be recorded on the pattern drawing and given to the patternmaker. By this practice the patternmaker will obtain a more intimate knowledge of actual foundry practice, and as a result, be able to construct better and more practical patterns. Where this practice has been followed, excellent results have been obtained, and the possibility of making the same mistake twice is eliminated.

Kenosha, Wis. — M. E. DUGGAN

DIMENSIONING SPLINE MILLING CUTTERS

Cutters used for milling splines must be very accurate in order to yield the required results. To furnish a toolmaker with dimension A, at the left in Fig. 1, and the included angle of the cutter teeth is not sufficient, since the usual gaging equipment does not make it possible to measure these accurately. The simplest way for a toolmaker to measure the cutter teeth is to use a vernier gear-tooth caliper and work to dimensions B and C, these dimensions being, respectively, the greatest width and depth that the cutter mills to. The method of computing these figures trigonometrically will be given in the following. As a check on the calculations it is advisable to lay out half a spline and space as shown in Fig. 2, either ten or twenty times actual size.

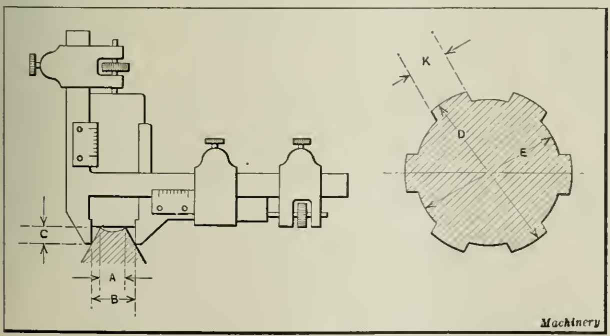


Fig. 1. Dimensions which should be furnished on Drawings of Spline Milling Cutter, and Part to be milled

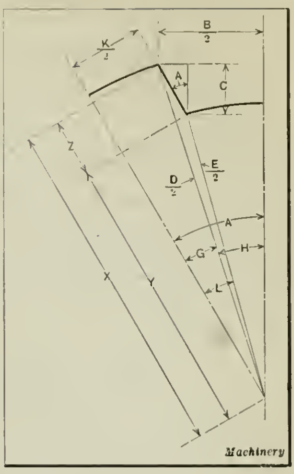

Fig. 2. Diagram used in computing Dimensions B and C, Fig. 1

From reference to Fig. 2 it will be evident that if N = the number of splines to be cut on a part, $A = 360 \div 2N$. Also,

$$\sin G = \frac{K}{D},\ \sin L = \frac{K}{E},\ \text{and}\ H = A - G.\ \text{Therefore,}$$

$$B = D \sin H.\ \text{Again,}\ X = \frac{D}{2} \cos G,\ Y = \frac{E}{2} \cos L,\ \text{and}$$

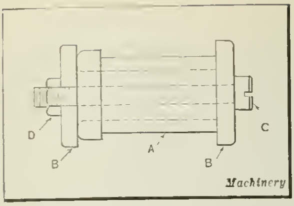
$Z = X - Y$. Thus, $C = Z \cos A$. While this computation involves a little more work for the drafting-room, it will be much appreciated as a time-saver by the toolmaker. The data given on the drawing of the part for which a cutter is intended should consist of the dimensions D, E, and K, on the sectional view shown at the right in Fig. 1, and the number of splines.

Detroit, Mich. — H. P. LOSELY

SHRINKING DRILL BUSHINGS TO DECREASE SIZE OF HOLE

Every toolmaker has undoubtedly had the misfortune to grind or lap the holes in a set of drill bushings to a size larger than was intended. In most cases this means that new bushings must be made to replace the ones having over-size holes. This, of course, results in a loss of time and material. The general procedure in making a drill bushing is to drill, and ream or bore out the hole; then rough-turn the outside diameter. The bushing is next hardened and put through a grinding and lapping process, which usually consists of first lapping the hole and then grinding or lapping the outside to the right size, care being taken to keep the outside concentric with the finished hole. If it should happen that too much stock is removed during the inside grinding or lapping operation, and this is discovered before the final outside finishing operation is performed, there is still a way to save the work if the error is within reasonable limits.

The method is to shrink the bushing to a size which will permit the grinding and lapping tools to be used again for finishing the hole to the correct size. The accompanying illustration shows the method of preparing the bushing for the shrinking operation. The bushing A is covered at both ends with thick washers B, which are tightly clamped to the ends of the bushing by means of screw C and nut D. The whole assembly is next brought to a red heat and then plunged in a cold bath. The cooling liquid is prevented from entering the hole in the bushing by the



Drill Bushing Ready for Shrinking

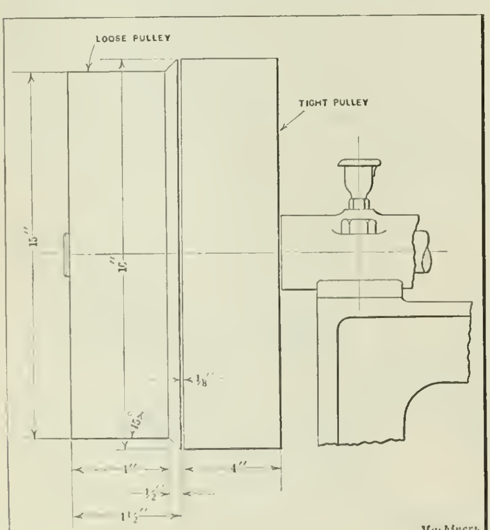
washers. As a result, the inner portion of the bushing shell, while still hot and soft, is contracted by the outer portion of the shell which is more quickly cooled and contracted by the cooling liquid. If required, this operation can be repeated, but the washers must be tightened each time. Bushings 1/4 inch in diameter and up may be shrunk in this way so that the holes will be 0.002 inch smaller in diameter.

New York City C. G. Youngquist

LOOSE PULLEY DESIGN

Belt-driven machines equipped with loose pulleys are seldom in operation all the time that the power is on. Under the most favorable conditions of continuous production, the idle time of the machine is usually in excess of 10 per cent of the total working day. Certain machines, which, from the nature of the operation, must be frequently stopped and started, are often idle 50 per cent of the working day. Under the best conditions, then, the drive belts of nearly all machines are running on the loose pulleys for a considerable part of every day.

Loose pulleys have long been recognized as necessary evils. Their bearings run hot, wear bell-mouthed, and quickly become a loose fit on the shaft. They are difficult to oil, and are generally avoided when an installation will bear the expense of a good friction clutch. A few manufacturers, recognizing these troubles, have adopted the pulley design shown in the accompanying illustration. It has the advantage of relieving the belt tension while the belt is on the loose pulley, thereby saving, not only the belt, but the bearing as well. The bearing pressure is lowered to such an extent that overheating is rare with this type of pulley, and the oil film is more readily maintained. A reduction in diameter of the loose pulley of 1 inch ordinarily reduces the belt tension about 150 pounds per square inch for a 25-foot belt. The resulting bearing pressure is usually low enough to permit the use of the so-called "oil-less" bushings of impregnated wood on pulleys which have previously been considered to be subjected to too severe service for this type of bushing.



Loose Pulley Design that relieves Tension on Belt

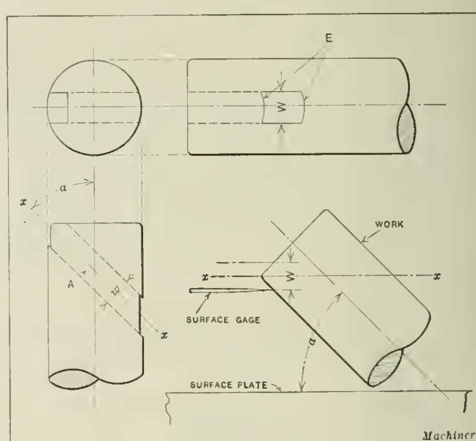
The difficulty of belt shifting is but little greater with this type of pulley than with straight-faced pulleys of equal diameter. To aid in shifting the belt, the conical portion of the pulley face should be inclined at an angle not greater than 45 degrees. Some designers use angles as small as 30 degrees, but the difference is hardly noticeable. The increased pulley face necessary to procure the lesser angle is not warranted by the results.

The loose pulley here described and illustrated is not new. It has been used for many years on the Universal Winding Co.'s machines and doubtless on many machine tools. Its adoption, however, has not been as general as its good features would seem to justify. A reminder of its purpose may result in its more general use on many machines now equipped with loose pulleys of the regular type, and thereby eliminate much of the trouble common to this type.

Philadelphia, Pa. John L. Alden

FILING SQUARE HOLES IN BORING-BARS

When a square hole such as indicated in the accompanying illustration at *A* is required in a round boring-bar for



Method of filing a Square Hole in a Round Boring-bar

the purpose of holding a square tool bit at an angle with the axis of the bar, it becomes necessary to file the hole square by hand if a slotter or some other suitable machine is not available. In filing holes or slots of this kind where the holes are held at an angle *a* with the axis of the bar, unsatisfactory hit-and-miss methods of procedure are often employed which can be eliminated if proper guide lines are scribed.

The view in the lower right-hand corner shows how the elliptic guide lines *E* can be easily scribed. Clamp the work to an angle-plate, with the axis x–x of the hole for the tool bit held horizontal and parallel to the face of the surface plate. Next set the scribing point of the surface gage at a point 1/2 W below axis x–x and scribe the lower lines. The scribing point should then be set at a distance of 1/2 W above axis x–x and the upper lines scribed in a similar manner. Care should be taken to keep the base of the surface gage in contact with the surface plate while scribing the lines. It will be noted that the upper line, in one instance, will be scribed on the end of the bar, while the lines on the opposite side will be located as shown at *E* in the upper view.

Cincinnati, Ohio J. F. Thornton

Industrial Conditions in Germany

From MACHINERY'S Special Correspondent

Berlin, November 9

GERMANY today presents a picture of millions of people working hard in consequence of the peace treaty and the London ultimatum, apparently with the aim of building up a great German market in competition with all other manufacturing countries. This aim is being realized due to the trade advantages offered by the continual lowering of the exchange value of the mark, which is seriously hampering the industries of surrounding countries and aiding the disposal of German-made products. In Holland there is practically no industry that is not suffering greatly because of the impossibility of competing with German manufacturers, and in some cases, notably in the machine-building line, the very existence of the industries is threatened. The number of working hours per week is generally less than in Germany, while the wages of employes are approximately three times as much. Recently the Dutch Indian colonies ordered materials for bridge and railway construction from German dealers. Conditions in Belgium and Switzerland are the same as in Holland. Swiss exports have dropped to one-half what they were a year ago, the watch, machine, and metal industries being particularly affected.

Italian and Russian Trade Relations

The Italian Government, in order to protect home manufacturers, has adopted a new high tariff. Of especial interest to machine tool builders is the fact that the tariff on machines weighing less than 10 meter-quintals (about 2200 pounds) is now 268 lire per meter-quintal (about 5 cents per pound, present exchange) instead of 9 lire per meter-quintal (about 0.17 cent per pound) as has been the case until recently. This increased tariff appears, at the present writing, to have put an end to German competition in Italy.

Arrangements made by the German Government with Soviet Russia have greatly improved business relations with that country. During 1920, Germany ranked second to Sweden in exports to Russia, but now Germany shows the strongest gains in that trade. Russian dealers and German manufacturers are cooperating to promote business between the two countries.

General Business Conditions

The manufacture of machine tools for home consumption is considerably less than for the export trade, although domestic demands have been satisfactory. Plants in the machine-building industries have orders for their products for months to come. However, production has been hindered by an insufficient supply of coal. American firms offered coal in September at 850 marks per ton F.O.B. Hamburg, while English coal was offered at 520 to 550 marks per ton F.O.B. Berlin. Iron and steel, automobile and railway car plants are all busy. Locomotive builders have sufficient work to last until January 1, but it is said that no orders are in prospect for completion after that date. It has also been reported that German locomotive builders have been underbid in South American countries by American concerns who also are able to extend credits for a longer period of time. Precision machines, optical goods and cameras are especially in demand in some countries.

Among the leading machine tool builders in Germany should be mentioned Ludw. Loewe & Co., Berlin, which firm has modernly equipped shops, and produces machinery well known not only in Germany but generally in the world's markets. This company is at present employing about 2600 workmen and 600 office employes. The plant has 3900 machines running, two-thirds of which are of the Loewe Co.'s own make. The total number of machines built in a year by the company is about 1600, and during the past year it declared a dividend of 24 per cent. Other plants reported as fully occupied are the Schubert & Salzer Ltd. of Chemnitz, which company paid 25 per cent dividends last year. The Wotanwerke Ltd. of Leipzig, specializing in shapers, paid dividends of 40 per cent, and the R. Stock & Co., Ltd. of Berlin-Marienfelde, twist drill manufacturers, have paid in the last three years, 25, 15 and 25 per cent dividends, respectively.

Owing to the large amount of business being done, the dividends paid out by machine tool builders generally vary from 8 to 25 per cent. Many concerns have increased their capital and some firms are combining their sales organizations. The Association of German Machine Tool Dealers has united with the Berlin Tools and Machine Tools Trade. In former days some antagonism existed between these two societies. The total amount of machine tools exported in 1920 reached 949,212 meter-quintals (about 104,632 tons) and was valued at 1,325,093,000 marks (about $5,300,400). About 190,500 meter-quintals were exported to Holland, 136,700 to France, 117,600 to Switzerland, 75,500 to Italy, 74,500 to Belgium, and 16,200 to Great Britain. The imports of metal-working machinery into Germany during the same year amounted to 10,105 meter-quintals (about 1115 tons).

The Labor Situation

Labor conditions have improved considerably. While the unemployed on the first of August amounted to about 358,000 workmen, this number was reduced to about 232,000 by September 1. There have been several strikes that interfered with regular production, but most of these have been settled without much difficulty. In a Dresden metal-working establishment a strike affecting 6000 workmen and lasting five weeks resulted in a failure for the employes. During that period the unions suffered a weekly loss of 5,200,000 marks (about $21,000) and the manufacturers, 65,000,000 marks ($260,000).

The Aluminum Industry

Experiments conducted during the war showed that aluminum could be obtained not only from pure clay, but from many inferior grades subjected to certain treatment. As a consequence the aluminum industry has been developed extensively in southern Germany where hydro-electric power is used in its production. Prior to the war the output of aluminum amounted to around 800 metric tons annually, while it is now about 32,800 metric tons.

Influence on Industry of Recent Fairs

The vast importance of the Leipzig fair is shown by the fact that more than 2,000,000 workmen are now occupied in filling orders obtained at this exhibit. The recent automobile exhibition in Berlin has also resulted in sales reaching into billions of marks. Some concerns received orders for more than 200 cars, and Belgian and Dutch dealers endeavored to reserve for themselves the entire production of a number of concerns. This industry employs about 150,000 workmen, and the total exports in 1920 amounted to between 21,000 and 22,000 cars and motorcycles.

Hanson-Whitney Semi-automatic Universal Thread Milling Machine

THE production of threads by milling has developed rapidly since 1900, and the single-cutter thread milling machine has become a standard tool, especially for external threads. Although the single-cutter type of thread milling machine has been used to a certain extent for internal work, it has not become as universal as the machine employed for milling screws. Even before the time mentioned, threads were made on gun work by a hob milling process; that is, a hob having concentric teeth corresponding in pitch with the screw to be milled was used in conjunction with a suitable lead-screw, and the screw was finished by setting the hob to the proper depth in the work and then feeding it endwise by means of the lead-screw; when the work had made one revolution, a thread was completed which was fairly accurate. There have been several developments along this line for such work as tap making and for cutting short threads on automobile parts, and also in places where a short thread only is wanted. Special machines have been made for internal as well as for external work.

The Hanson-Whitney Machine Co., Hartford, Conn., has produced a semi-automatic universal thread milling machine, designed to meet various conditions and to produce work of different types having external or internal threads especially when large quantities are required. Figs. 1 and 2 show front and rear views of this machine, which is of a very rigid design. The spindle is of a hollow type, and has a capacity for holding work up to 2 inches in diameter, but different headstocks can be used for larger diameters when necessary, and special holding devices are easily supplied to meet requirements. The illustrations show the machine with an ordinary cutting head, used especially for external work which can be held either between centers or in a chuck. Where the work is long and large in diameter, centers are used, and with the rapid adjustable footstock it is possible to hold the work very rigid.

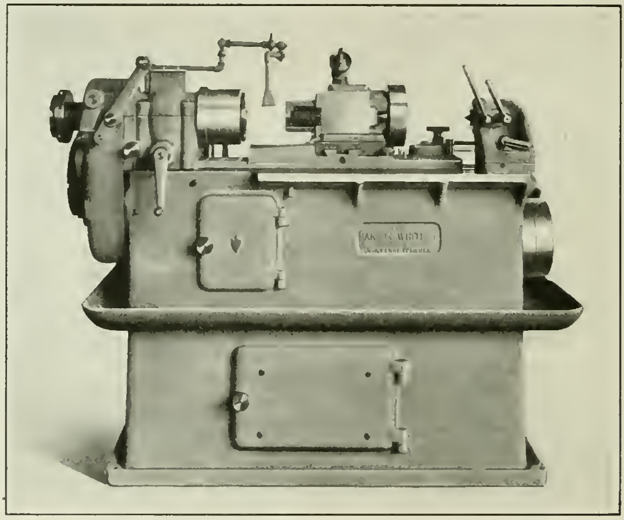


Fig. 1. Hanson-Whitney Semi-automatic Universal Thread Milling Machine

Operation of the Machine

The machine is partly automatic. The operator puts the work in the chuck and presses the button shown in front of the headstock; the carriage carrying the hob advances rapidly toward the headstock and then crosswise toward the work. When the hob almost touches the work, the motion is automatically changed to a proper feed motion; the spindle is revolving and the hob advances to the depth of the thread, and when the depth has been reached, the hob stays in the same position radially and advances according to the pitch desired. When cutting a right-hand thread, the hob moves axially away from the spindle, and when cutting a left-hand thread it advances axially toward the spindle. After the work has made a little more than one revolution, the hob automatically recedes a little more than the depth of the thread and traverses toward the tailstock a distance of about 3½ inches, leaving the work entirely free; then the machine stops automatically. The operator next releases the work and puts in another piece, and the machine repeats the sequence of operations. For internal work the hob has no outer support, but the process is the same. The hob automatically enters the hole, then feeds in to the proper depth; the work makes a little more than one revolution, the hob recedes, and traverses out of the hole, and the machine stops ready for the next piece of work to be milled.

General Features of Construction

Taper threads can also be produced by using taper hobs, and a compensating device can be employed for the taper desired. The capacity of the machine is for external diameters from 5 inches to ⅜ inch, and for internal diameters from 5 inches to 1 inch. All parts are well protected and well lubricated, and the slides are exceptionally long. The hob always rotates in the same direction whether machining internal or external work, or left- or right-hand threads. The direction is such that the hob tends to press the carriage down into the bed instead of lifting it. This prevents chatter, and is considered the principal reason for the smoothness of the work. On the right-hand end of the carriage, as shown in Fig. 1, is a knob handle by which the carriage can be adjusted longitudinally relative to the work. On the front of the headstock is a crank which can be used to operate the machine by hand when setting it up. Above the cutter-head there is a screw with a dial for adjusting the hob to the proper depth. The lead is controlled by a cam, and for different leads different sections are introduced into the cam. The cam is very accessible, being located behind the door on the upper part of the machine in the front. There are very few gears in the machine, and as the cams are cut with extreme accuracy, the lead of the milled thread is very accurate, especially when using a hob that has been finished after hardening. The lower door on the front has a tank attached to it for cutting lubricant, and the work is constantly flooded from a pump running at a constant speed.

Speeds and Feeds

The machine is driven by a single belt, and no slippage can take place that will alter the relation of the hob and the work. At the left in Fig. 2 is shown the speed-box for the hob, by means of which six speeds are obtained. At the right is another gear-box for the feed, and there are twelve feeds for each speed. This gear-box also includes the "hurry-up" motion, which is constant and is used for bringing the hob into engagement with the work, and also for withdrawing the hob. On the end of the machine there is a tappet disk which controls the slow and the fast feed. The slow feed, used while milling, is variable according to the material and diameter of the work. Where the thread is interrupted, as on a tap, the proper number of tappets may be applied to the disk, causing the spindle to move faster when crossing the flute, which saves considerable time, especially on taps of large diameter. All bearings in the transmission run in oil, and as ball bearings are used, very little power is required to run the machine.

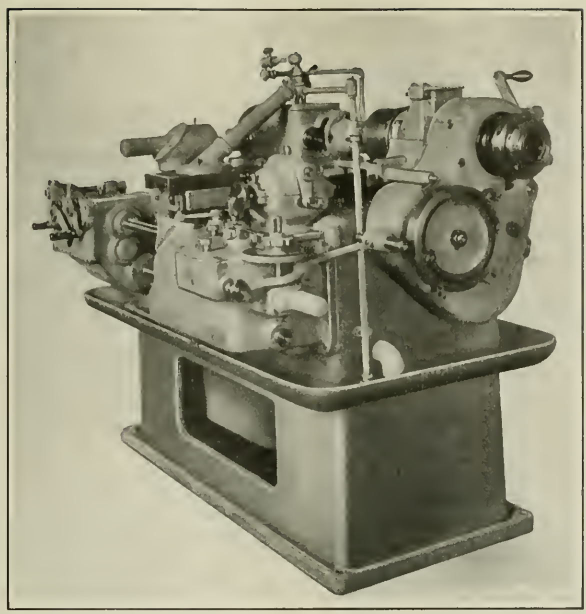

Fig. 2. View of Headstock End and Rear Side of Hanson-Whitney Thread Milling Machine

This machine is particularly adapted for threading parts such as are used in automobiles and airplanes, for cutting short threads on spindles, valve work, and for many other parts on which such threads are required. Excellent results have been obtained as to speeds and finish; for instance a machine steel bolt 2 inches in diameter with a thread 2½ inches long has been threaded satisfactorily in forty-eight seconds. The machine is also built with a simple method of changing the speed and the feed by so-called "selective change-gears." These are particularly useful when work is being produced in large quantities, and changes of work are not so frequent.

* * *

THE MACHINE TOOL SITUATION IN GERMANY AND HOLLAND

By H. DRESES, Dresee Machine Tool Co., Cincinnati, Ohio

The following paragraphs give some of the writer's observations during a visit to Holland and Germany this summer and fall, relating particularly to the conditions in the machine tool trade and industry in those countries. The most important dealer in Rotterdam, Holland, had an immense stock of American, German, Swedish, and Swiss machine tools on hand. The prices, size for size, of American and German machines were approximately as 3 to 1. While the quality of the German machines may have been somewhat inferior, the dealer stated that it was impossible to sell American machine tools against this competition. In Germany, especially in Berlin and Cologne, the principal dealers had large stocks on hand, but not a single American machine tool could be found, it being stated that all that had been on hand were sold during the war.

The general conditions in Germany are very peculiar. A machinist, when the rate of exchange was 1.25 cents to 1 mark, received about ten times the wages, expressed in marks, that he received before the war, his pay averaging, according to locality, from 8 to 10 marks an hour. At that time this would have amounted to from 10 to 12 cents in American money, but at the present rate of exchange of 0.4 cent to the mark, his hourly pay would only be from 3 to 4 cents an hour. The overhead expenses and the cost of raw materials are also in the same proportion, as compared with prices in the United States, except that bronze and copper cost about the same as in this country.

The German shops are still busy, and in addition to supplying the home trade, obtain business from the surrounding neutral countries, South America, and even from former enemy nations. However, the selling of German machines and goods at about one-third of the world's market price cannot last indefinitely, as it is a terrible drain on the national wealth, and it can be accomplished only with the lowest wage rate, the most frugal living, and small or no profits.

In some quarters it is believed that the German Government and financiers have forced this state of affairs to bring about a reduction in the reparation payment, but this would be a dangerous experiment, because the low purchasing power of the mark, with the consequent starvation of the people, may bring about a revolution or a Soviet Government, as in Russia. German business men, financiers, and economists all agree that the breakdown is unavoidable, and that the consequences will affect the whole world.

What the drop in the rate of exchange really means is clear to only a few people. Suppose that the German General Electric Co. had 10,000,000 marks in the bank with which to buy American copper. At an exchange rate of 1 cent per mark, this is only $100,000; but when the exchange drops from 1 cent to 0.4 cent a mark, which recently happened within a week, it means that the capital of this firm in the bank has shrunk to $40,000, and consequently, within a week, the purchasing power of Germany for American copper and the export possibilities for copper from this country have been reduced by more than half.

If Germany succeeds in passing through the present crises without a revolution, the people will still have to exist, and can do so only by producing and living so cheaply as to crowd everybody else out of the world's markets.

* * *

The American Drop-Forging Institute, with headquarters in Cleveland, Ohio, has entered upon a campaign of publicity and educational promotion relative to the use of drop-forgings. The purpose of the campaign is to impress upon buyers and users of all types of tools and machines the importance of knowing whether or not all the parts subjected to strain are drop-forged. A book has been prepared for distribution entitled "What is a Drop-forging?" which can be obtained without cost upon application to the American Drop-Forging Institute, Hanna Bldg., Cleveland, Ohio.

The British Machine Tool Industry

From MACHINERY'S Special Correspondent

London, November 14

FOR the first time in many months signs of returning activity are discernible in industrial circles. As a direct consequence prospects in the machine tool field are brighter. Several valuable orders have been received by machine tool makers, and important inquiries from both home and overseas sources are in an advanced stage of negotiation.

Small Tools

Small tool makers report a steady trade. One maker of machine tool accessories, in announcing substantial price reductions, received a flood of orders. To enable the reductions mentioned—an amount approximately equal to 45 per cent of what other makers are asking for similar articles—to be made, the firm has been engaged for the last eighteen months in developing a series of semi-automatic single-purpose machines, of a simple yet effective type. On putting these machines into commission, the immediate result was an enormous cut in productive labor costs, and this has been passed along to the consumer in due proportion, with the results stated.

Foreign Trade in Machine Tools

Among the overseas countries who are in the market for machine tools, India, Japan, Belgium, and Poland figure prominently, in about the order named. On the Continent British made goods stand high, and there is a strong demand for machine tools and machinery of all kinds. Customers have expressed themselves ready to buy, but, unfortunately, the demand is no measure of the capacity to pay.

As far back as 1919 legislation was passed designed to overcome this fundamental difficulty by the institution of a credit scheme whereby advances were made to the buying country. The total amount allowed for such advances was £26,000,000. The scheme has been disappointing in its results, credits amounting only to about £1,300,000 being advanced, chiefly to Czecho-Slovakia and Rumania. The scheme has now been considerably modified. All countries are to come within its scope, and instead of each transaction having to come up for consideration before an advance is made, a total credit sum is specified for any particular firm, after due investigation. The British Government holds the exporting firm responsible for 57½ per cent of the credit, the risk carried by the Government being 42½ per cent.

Exports and Imports

The reports of imports and exports of machine tools for this year show that imports fluctuate in tonnage at a low level, about equal to the pre-war level, but for the last three months they have dropped below that level. The exports fluctuate above the pre-war level and tend to keep above that level. Exports for September amounted to over 1200 tons, the value being about £175,000. Imports remained under 200 tons and £25,000 for the month. The ratio of total value of imports to exports is as follows: Pre-war imports, 100; exports, 290. Current year imports to end of September, 100; exports, 432. The export values for September included nearly £70,000 for lathes alone.

Labor Conditions

After lengthy negotiations the wage reductions proposed by the employers have been agreed upon, and the so-called Churchill award of 12½ per cent bonus is to be foregone by workers in three stages, which will complete the reduction by the new year. As a result, manufacturers have already been able to base their costs on a definite labor charge, and in some cases are prepared to supply machine tools based on these 1922 costs. There should now be no inducement to hold back orders in the hope of further price reductions, and it is generally expected that machine tool prices will remain stationary when demand revives. In connection with the voting by the men on this wage reduction it is interesting to note that where trade conditions have been better than the average the vote against acceptance was the heaviest.

Unemployment continues to be severely felt throughout the country, and in the engineering trades the total number claiming employment benefit at the end of September was very nearly a quarter of a million, the figure being but slightly less than for the previous month. In Johnstone—the Scottish machine tool center—distress among the employes is promptly dealt with by the firms themselves, who each contribute weekly to a special fund administered by a municipal official. Each case is dealt with on its merits, and in view of the small population it means that the position of practically every worker and the circumstances in which he is placed are known.

The working days lost through labor disputes have of late been relatively few; in September 150,000 days were lost, whereas for the same month a year ago over a million days were lost. How much a part unemployment has had in bringing about this result it is difficult to say, but the prospect of being without anything to do has no doubt presented itself forcibly to all classes of workers. Trade union restrictions still remain a great hindrance. To cite only one instance, on the Mersey, oxy-acetylene cutters cannot be used unless the job is large enough to necessitate twenty-five men being at work. As another instance of a shortsighted and disastrous policy, unions stipulate that in foundries the less skilled men who look after molding and other machines must be paid at the same rate as the skilled hand molder.

Prices of Material

Attention is being rapidly concentrated upon the vital question of the price of coal. Just now the coal market is in such a state of chaos that it is difficult to state a figure for the average price today. Reports are current that certain collieries are offering large spot lots at such prices as 10 shillings per ton (about $2, present exchange) or even less, while the price of coke in these districts has been reduced in a sensational manner from over 30 shillings ($6) per ton to 22s 6d ($4.50). Needless to say, all such prices must be regarded as abnormal, and due only to immediate lack of cash, since an average figure of the actual net cost of raising coal to the pit head would exceed them. However, the iron and steel smelting interests are very definite in stating that unless fuel can be obtained at less than 20 shillings ($4) per ton there can be no resumption of production on anything approaching an adequate scale. Taking these facts into consideration, there is no getting away from the fact that the miners' wages will have to come down again very shortly.

Iron and steel makers have announced drastic cuts in steel prices. Round bars 3 inches in diameter and over have been reduced from £14 ($56) to £12 ($48) a ton

Sheffield makers of high-carbon acid steel have reduced the price of billets, specially made for the file trade, from £19 ($76) to £16 ($64) per ton. This represents one of the biggest cuts recently made.

In finished steel products there is a brighter tone. Some crucible steel firms have considerable work on hand, and are running full time. It is stated that the Russian Soviet Government has placed large tool contracts in Sheffield, and an order for 200,000 saws has just been completed.

British steel works are again benefiting greatly by the condition of the industry on the Continent; it is extremely difficult to place orders for delivery before the beginning of next year with either Belgian or German works, and only a few French firms are prepared to sell for shipment before December. Therefore, taking into account the early delivery of British works, the prices quoted go a long way toward meeting foreign competition, and to many inland points, upon which heavy railway freight rates have to be paid, continental goods are at a disadvantage as regards price.

The associated makers of high-speed steel in Sheffield have reduced their prices considerably, and 18 per cent tungsten steel has fallen from 3s 9d (75 cents) to 3s 3d (65 cents) per pound, while 14 per cent tungsten steel has dropped from 3s (60 cents) to 2s 8d (53 cents) per pound. Foundries are feeling the present pinch to the extent that many are working practically at cost. As an example, identical castings for which £45 ($180) per ton was paid a few months ago now cost only £24 10s ($98) per ton.

Machine Tool Prices

The price of machine tools has been retarding sales, and even when big concessions are made on existing prices by firms who are badly in need of money and must realize on their stock, buyers will not accept the assurance that a special quotation has been put forward, and always decide to wait for a still lower figure. Stock machines are being offered at a reduction of 20 per cent on prices which are really necessary today.

The sales of government machine tools are still being held in various parts of the country. At the beginning of this month a sale was held in Birmingham, and some machines, particularly some of the highest grade American makes, were disposed of at prices lower than would be obtained if sold as scrap. A planer built by the G. A. Gray Co., of Cincinnati, with a 12- by 3½-foot table and three tool-holders, which was in nearly new condition brought only £150 ($600). Nine Pratt & Whitney plain hand milling machines, with a 16- by 3½-inch table and collet chuck, packed in the maker's case unopened, brought from £13 ($52) to £19 ($76) each, while eight Pratt & Whitney three-spindle vertical profiling machines, weighing 3500 pounds each, with 14- by 12-inch table, in the maker's case unopened, were sold at £20 ($80) each. A hexagon turret lathe, made by the same concern, taking 1½-inch stock, which was in practically unused condition, brought £30 ($120), while a nearly new Warner & Swasey No. 6 screw machine swinging 18 inches, with a 2⅝-inch hole through the spindle, was sold for £20 ($80). A No. 4 screw machine of the same make brought only £16 ($64).

The whole situation regarding the disposal of government machine tools is admittedly unsatisfactory, and calls for some concerted action on the part of machine tool makers and dealers.

* * *

We are not a nation of machines, and houses, factories, and railways. We are a nation of men, women, and children. Our industrial system and our commerce are simply implements for their comfort and happiness. When we deal with those great problems of business and economics we must be inspired by the knowledge that we are increasing and defending the standards of living of all our people. Upon this soil grow those moral and intellectual forces that make our nation great.—*Herbert Hoover*

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, November 12

There is hardly any buying in the machine tool market. The dealers have their stock-rooms full of machines which they are unable to sell in spite of the many concessions they make and the very easy terms they offer. Some manufacturers find themselves in the same position. A large firm in the vicinity of Paris actually has in stock more than 60,000,000 francs worth of machine tools, principally large machines. During the first six months of this year France imported about 22,000 tons of machine tools, while during the whole year of 1920 31,600 tons were imported. The majority of these imports came from Germany.

The machine tool industry, of all French industries, is the one which will be most affected by the recent agreement of Germany to deliver material in lieu of money. The situation is aggravated by the fact that the Government is bringing pressure to bear on the industries to make them buy this German material.

Very few orders seem to be given out by the railroads at the present time. This is due to the indecision concerning the management of the railroads as well as to the existing financial situation. Furthermore, the French railroads will receive 6200 repaired railroad cars and 4500 new cars from Germany. Two thousand of the new cars will be 20-ton freight cars, two thousand, flat cars of 20 tons capacity, and five hundred, cars of 40 tons capacity. This will tend further to retard manufacture in railroad shops in France.

An important association has just been formed which includes such companies as Cail, Fives-Lille, and Ernault, to manufacture locomotives for Rumania, and large shops are to be built in that country for the purpose.

It is to be hoped that, because of the tremendous success of the automobile show and the numerous inquiries obtained there, metal-stamping factories will start up again. Nevertheless, it is evident, when the productive capacity of the various manufacturers is taken into consideration, that very large orders would be necessary to maintain the factories in active operation.

In the foundry field there is hardly any activity, and there seems to be no hope for improvement. The importation of castings has increased considerably during the first six months of 1921, as compared with the same period of 1920. This seems abnormal, when the very low prices quoted in France for castings are taken into consideration. Probably this is due to the fact that parts of machines have been listed as castings. On account of the very few orders, prices of castings continue to fluctuate.

* * *

CONVENTION OF THE AMERICAN FOUNDRYMEN'S ASSOCIATION

The American Foundrymen's Association will hold its next convention and exhibit in the city of Cleveland during the week of April 24, 1922. The headquarters of the association will be in the new Cleveland Public Hall at Lakeside Ave. and E. 9th St., which is rapidly nearing completion, and the exhibits will also be shown there. The Institute of Metals Division of the American Institute of Mining and Metallurgical Engineers will hold a joint convention with the association, as has been the custom in years past. The next meeting promises to be of unusual interest, as there never has been a period when economy in production was so important as now, and the exhibition will show the latest improvements and developments in foundry equipment.

* * *

A recent Commerce Report states that there are twelve factories in Austria engaged in the manufacture of tractors; but most of these factories are only partially devoted to this branch of the industry.

The Metal-working Industries

TO review conditions in the metal-working industries at this time without reference to general industrial conditions throughout the United States would be misleading. Of all the industries, those devoted to metal-working have without doubt felt the business depression most keenly and are among the last to return to a normal state. But every indication points to the fact that the lowest point of the depression in these industries was reached during the summer, and that there is a definite improvement at the present time. The iron and steel industry shows this gain to a marked degree. In the small tool field, the improvement noted in this review last month continues, and while the machine tool industry as a whole does not present so marked a change, many manufacturers report that sales during the last two months have been considerably above the average for the preceding months; still the activity is very slight, and active operation of the industry is not looked forward to for several months to come.

Taking the business situation as a whole into account, the progress toward recovery was somewhat interrupted a month ago by the theartened strike on the railroads. Nevertheless, from all parts of the country there are reports of slightly better conditions. There is a great deal more optimism, and while very few people are looking for a rapid improvement in the situation, the present rate of progress, if continued without interruption, will bring us back to a normal condition in a reasonable time. The Federal Reserve Bank of Cleveland in its November statement sounds a definite note of confidence in stating ". . . the time is near when business can safely throw away its crutches. Nearly all reports agree that the improvement shown last month is holding up well, and in some lines the production throttle has been opened another notch to meet the increase in demand. While there are still too many smokeless stacks in the steel section, the blowing in of furnaces is reducing the number. About this time last year the weakness in iron and steel was casting gloom over all kinds of business, this industry being regarded as the barometer of business. Then the cancellation of orders was a common occurrence. Today this barometer indicates a steady improvement.

"A year ago automobile and tire manufacturers were overstocked, and sales falling off. Recent reports indicate that sales are holding up well. Production is now being determined by demand. Last fall, building was hesitating in anticipation of lower costs. Labor troubles gave out a jarring note. The recovery this fall has been even more rapid than was expected. These developments are only a part of the transition—a transition not yet completed, but gradually working toward dependable business."

The Second-hand Market in Machine Tools

Many manufacturers have expressed a belief that the second-hand machine tool market will seriously affect the sales of new machinery for some time to come. It is generally supposed that there are available large quantities of used machinery, most of which is almost new or in very good condition. This view is not supported by the dealers in second-hand tools. Most of the machine tools offered today are so old or worn that the dealers will not consider putting them in their stock. Most of the good machinery from dismantled plants has already been offered and absorbed, and while occasionally a few good second-hand machines are available, the volume of this trade is not greater than it would be likely to be under normal conditions.

The second-hand machinery market seems large at present because of the very small business in new machinery. One dealer in used machinery says there are fewer used machine tools sold now than under normal conditions, because the market for used machinery, as well as for new machinery, is greatly reduced. Just as soon as reasonably normal conditions return, the influence of the used machinery market on the sale of new machinery will scarcely be felt—at least it will be felt no more than during normal times in the past.

There is very little government machinery still to be placed on the market; and while there are instances where firms which, in the past, would never consider anything but new machinery, have been induced to buy used machines on account of the saving at this time, it is not generally believed that those who have been accustomed to buying only new machinery will consider anything else in the future. Their buying habits will reassert themselves when their buying power is restored.

The Tool Equipment Business

A considerable change has taken place in the tool equipment business during the past months. Some of the concerns engaged in the designing and making of jigs, fixtures, gages, and special tools have discontinued altogether, which has lessened the very keen competition in this field during the last year, enabling firms established in the field to obtain business at figures which at least do not entail a direct loss. Taking the business of designing and building special tooling equipment as a whole, the last two months have shown a decided improvement, and at least one firm could be cited that is working at full capacity.

The number of concerns in this line that have gone out of business in some of the cities of the Middle West has thrown a considerable amount of machine tools on the second-hand market in those cities, which, for the time being, makes the supply of used machines exceed the local demand.

The Automobile Industry

Dealers in automobiles report that business continues well up to expectations for this season of the year, and in many instances the sales during October exceeded those in September. Further price reductions have been announced by some of the manufacturers of passenger cars and trucks. The reports from the different automobile manufacturers vary considerably, but on the whole production is showing the usual seasonal falling off. October shipments, according to the National Automobile Chamber of Commerce, were 11 per cent under those for September, and 4 per cent under those for October, 1920.

The Railroad Situation

Some of the western and southern railroads have requested the Interstate Commerce Commission to approve freight reductions averaging as much as 20 per cent. All classes of labor employed on the roads operating east of the Mississippi and north of the Ohio will soon be asked to accept wage reductions of 10 per cent. in order to make freight rate reductions in the East possible. One of the railroads in the Middle West has authorized the purchase of 55 locomotives, 127 steel passenger cars, and 7300 freight cars, while two other roads have purchased 3500 freight cars. This activity in buying will doubtless have a stimulating effect upon the industry in general.

Railroads in the Middle West have placed some orders for machine tools, but the buying of shop equipment is still limited to absolute necessities, and cannot be said to meet the actual requirements of the roads for the economical operation of their shops.

NEW MACHINERY AND TOOLS

THE COMPLETE MONTHLY RECORD OF NEW AMERICAN METAL-WORKING MACHINERY

Triplex Combination Bench Machine

A COMBINATION bench type of machine which may be used for all operations done on regular bench lathes, millers, and drilling machines, thus reducing the amount of equipment ordinarily required in tool-rooms, has been developed by the Triplex Machine Tool Corporation, 18 E. 41st St., New York City. One of the unique features of this machine is the method of mounting the spindle head. It will be seen from Fig. 1 that the spindle head is mounted on an arm *A*, which has the form of an arc and which is graduated in one-half degrees to facilitate setting the head in any angular position between the horizontal and the vertical. The head may be clamped in position by tightening a single nut, and is balanced by means of a counterweight within the hollow column. The spindle is driven by a motor, which is attached directly to the head, and which, consequently, maintains the same position relative to the head regardless of the position of the latter. The drive to the head is by means of a belt running on two-step pulleys. The motor has a rating of ¼ horsepower, is reversible, and of the constant-speed ball-bearing type, its speed being 1750 revolutions per minute. As the motor is reversible, either right- or left-hand tools may be employed.

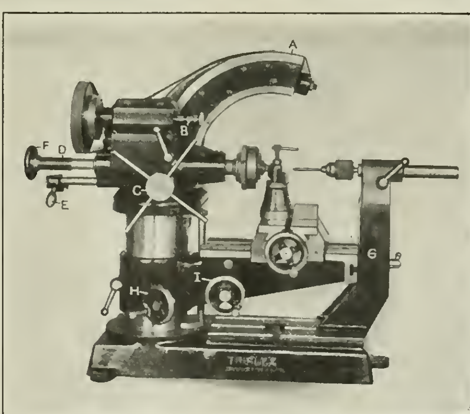

Fig. 1. Combination Bench Lathe and Milling and Drilling Machine brought out by the Triplex Machine Tool Corporation

Six spindle speeds are obtainable, the lowest of which is 90 and the highest 1150 revolutions per minute. These changes in speed are obtained by operating handle *B* which controls three shifting gears. The spindle can be fed a distance of 3 inches by turning the spider wheel *C*, and can be locked at any point by means of a clamping handle located above the spider wheel. The possibility of extending the spindle is particularly advantageous when some difficult milling and lathe work is being done.

The spindle is always fed by hand except when cutting threads, in which case it is fed by a master screw *D*, which engages a nut segment attached to handle *E*. The engagement is effected by swiveling handle *E*. The spindle is fed forward as it revolves, due to the engagement of the threads on the master screw and segment. At the completion of a cut, the nut segment is automatically disengaged by the beveled edge on the hub of handwheel *F*. Internal threads can also be cut in a similar manner when a proper threading tool is used. Either a faceplate, collet, or chuck may be attached to the front end of the spindle.

The bed of the machine swivels on the column, and may be swung to one side so that high work may be placed on the base, which is provided with three standard T-slots for bolting down the work. In Fig. 1 the outer end of the bed is supported by an upright member *G* which can be removed when not needed. This upright is provided at the upper end with a socket in which may be inserted a center for holding work between centers, or the shank of a chuck as shown. The bed is raised and lowered on the column by rotating handwheel *H*, and the carriage is fed longitudinally on the bed by handwheel *I*. The transverse feeding of the carriage slide is accomplished through the operation of the handwheel on the front of the carriage. The various handwheels are provided with dials graduated to 0.001 inch. The carriage can be clamped in any longitudinal position, and the bed in any angular position. By swinging the bed the required amount, any degree of taper, in either direction, can be turned on work. Graduations on the column bearing of the bed facilitate these settings.

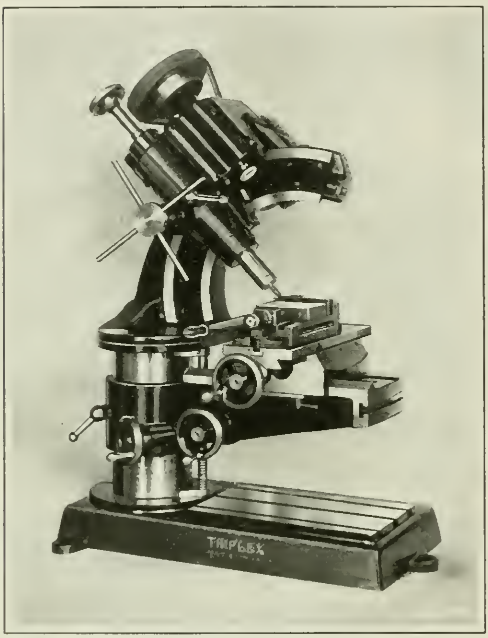

Fig. 2. Performing an End-milling Operation with the Spindle in an Angular Position

Milling operations can be performed by mounting a cutter on an arbor supported between the spindle and the tailstock center, or end-milling operations can be accomplished by inserting the cutter in a spring collet in the spindle, as shown in Fig. 2. The spindle head is shown in an angular position on its arm in this illustration. Fig. 3 shows the head in a vertical position, the machine being used as a bench drilling machine. A Jacobs drill chuck having a capacity for drills up to ½ inch in diameter is supplied. Some of the specifications of the machine are as follows: Longitudinal feed of carriage, 10 inches; transverse feed of carriage slide, 6 inches; vertical feed of bed, 4½ inches; maximum swing over carriage, 8 inches; maximum swing over bed, 14½ inches; maximum center distance, 14 inches; maximum height with spindle in vertical position, 43 inches; weight of machine, about 450 pounds; and bench space required, 16 by 25 inches.

COLBURN NO. 6 HEAVY-DUTY DRILLING MACHINE

The Colburn Machine Tool Co., 1038 Ivanhoe Road, Cleveland, Ohio, has recently added to its standard line of drilling and boring machines, a No. 6 heavy-duty drilling machine, designed especially as a production tool, a variety of work being accommodated due to the wide range of speeds and feeds obtainable. The machine is built with either a plain or a compound table in a single-spindle style, or with a plain table in gangs of two, three, or four spindles. Fig. 1 illustrates the single-spindle machine equipped with the compound table, while Fig. 2 shows a two-spindle machine having a plain table.

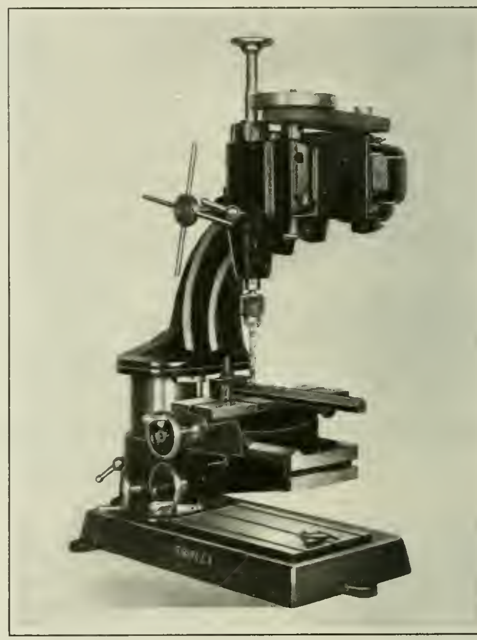

Fig. 3. A Drilling Operation in which the Spindle is placed in a Vertical Position

The machine has a column and base cast integral, to the top of which is bolted the head casting. The lower section of the column contains a storage tank for cutting compound, openings on each side of the column affording access to this tank. A flexible pipe returns the compound from the table to the tank. The head casting serves as an oil-tight box for the gearing. The speed and feed gearing run in oil, and all other gearing is lubricated by a splash system. All vertical bearings are lubricated by means of wicks. To suit work of such a height that it cannot be placed between the table and the spindle, a special extended base having two T-slots and a finished surface may be furnished. In order to place work upon this base the regular table must, of course, be removed from the machine.

The spindle has a No. 5 Morse taper socket, is double splined to equalize the working strain, and slotted across the lower end to provide a means for driving large boring tools. A small slot in the side of the spindle is employed for keying drills or other tools to prevent them from turning during an operation. The spindle is driven at its largest diameter and near the lower end, by a heat-treated chrome-nickel steel bevel gear. The spindle sleeve is bronze-bushed, and has rack teeth cut directly on its surface. A self-aligning ball bearing takes the thrust between the spindle and the sleeve.

The speed change-box is located on the left-hand side of the head near the back. It has an oil-tight cover which may be readily removed to enable the gears to be changed to give the desired spindle speed. Two speeds are obtainable with each pair of change-gears by transposing them on the driving and driven shafts, while two more speeds are obtained by means of sliding gears operated by a lever at the front of the machine. A set of change-gears may be furnished, which, with the combinations of change and sliding gears, will give forty-eight spindle speeds ranging from 30 to 375 revolutions per minute. The regular equipment consists of one pair of speed change-gears, giving four spindle speeds as described.

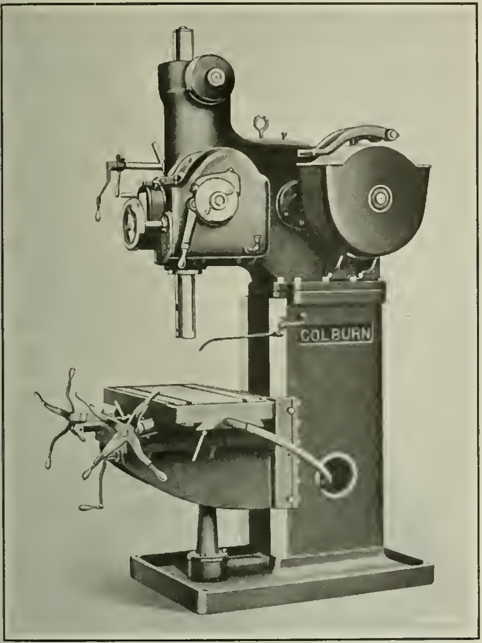

Fig. 1. Single-spindle Heavy-duty Drilling Machine made by the Colburn Machine Tool Co.

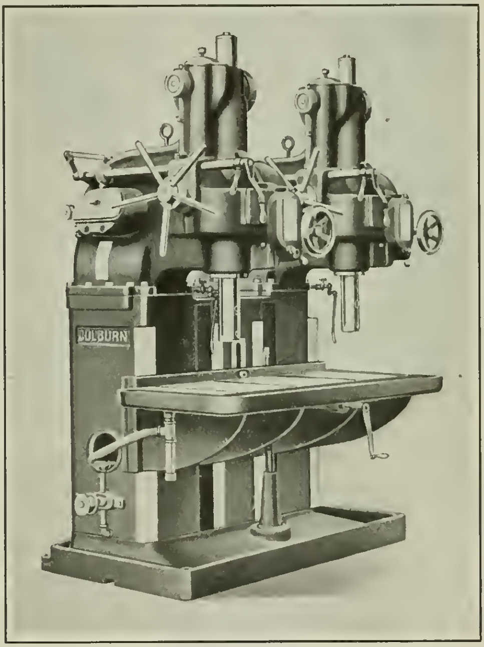

Fig. 2. Colburn Two-spindle Drilling Machine equipped with a Plain Table

The feed-box is located at the front of the head near the feed handwheel, as shown in Fig. 3. The various feeds are obtained in a similar manner to the different speeds, that is, by changing two gears in the feed-box. Two rates of mechanical feed are obtainable with each pair of change-gears by simply moving the handwheel either in or out. By moving the handwheel midway between the extreme inward and outward positions, the power feed is disengaged and the spindle may then be hand-fed by revolving the handwheel or the capstan wheel on the side of the head, the latter method being employed to obtain rapid movement of the spindle. With a complete set of change-gears, thirty-six feeds ranging from 0.005 to 0.134 inch per spindle revolution may be obtained. The feed mechanism is provided with a safety device, by means of which a pin is sheared, causing the feed to be stopped when the tool is operating under abnormal conditions, before any damage can result.

An interlocking device makes it impossible to change speeds while the machine is in operation, and this device also makes it impossible to start the machine until the sliding gears are fully in mesh. All control levers and handles are conveniently located at the front of the machine. An automatic tripping mechanism stops the feed when work has been drilled to the desired depth. The spindle is furnished with a spring counterbalance, the tension of which can be increased or decreased to suit the weight of different tools. The counterbalance also returns the spindle automatically after it has been tripped. A gear-driven tapping attachment having a ratio of 1½ to 1 is furnished when desired. This attachment is mounted on the driving shaft and driven by a pulley.

An oil-pan extends around the working surface of both the plain and compound tables. The elevating screw of the plain table is operated by a crank-handle, and is set off center to permit the boring of a hole through the table to accommodate boring-bar pilots. The compound table is mounted on a special knee and has rapid longitudinal and transverse movements, which are obtained through gearing actuated by the capstan handles. These are so arranged that the operator can readily manipulate the table in both directions while standing directly in front of the machine.

This machine may be equipped with a motor drive, provision being made for mounting the motor directly on the lower portion of the column at the rear. A motor of from 10 to 20 horsepower is recommended, the size depending on the work being done. The machine has a working capacity for driving 3-inch high-speed drills through steel. Some of its main dimensions are as follows: Distance from center of spindle to face of column, 14 inches; vertical adjustment of plain table, 13 inches; maximum distance between nose of spindle and plain table surface, 36 inches; compound table, 30 inches; and working surface of plain table, 20 by 24 inches, and of compound table, 18 by 30 inches.

On a machine of the gang type, each head forms a complete unit, this design permitting a number of heads to be mounted on a common column. All heads are interchangeable, a templet being used in drilling the bolt holes by means of which the heads are secured in place. Each individual unit is driven by a constant-speed belt from a lineshaft and connected with tight and loose pulleys on the head. Thus, any spindle may be stopped or started independently of the others. The machine may also be driven from a countershaft attached to the rear. The table on three- and four-spindle machines is elevated by means of two screws, one at each end. A large capacity pump supplies coolant to all spindles. This pump is attached to the side of the column, and is driven from either the lineshaft or the countershaft.

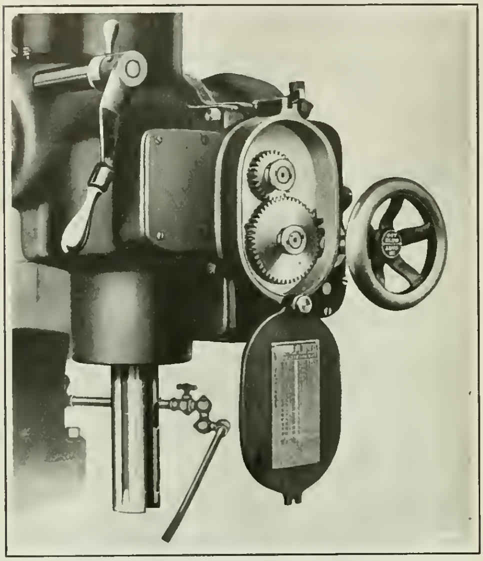

Fig. 3. Close-up View of Feed-change Box on Front of Spindle Head

The gang machine may also be equipped with a motor drive and tapping attachments. A ball-bearing countershaft is furnished with a motor-driven machine. The distance from center to center of spindles on gang machines is 35 inches The table is 20 inches wide, and, on a two-spindle machine, 59 inches long.

VAN NORMAN "RELIO" BENCH GRINDING MACHINE

To meet the requirements of garages and automobile repair shops, the Van Norman Machine Tool Co., 160 Wilbraham Ave., Springfield, Mass., has developed the bench machine shown in the accompanying illustrations, which is suitable for grinding pistons, valves, wrist-pins, etc., regrooving pistons, and for any other grinding or turning operation within its capacity. This machine is sold under the trade name of "Van Norman Relio." An individual motor drive is supplied for both the wheel- and work-heads, the wheel-spindle being connected to its motor by a belt, while the work-head spindle is driven through reduction gears direct-connected to the armature shaft of a motor mounted on top of the work-head. The wheel-spindle is equipped with ball bearings, and is located with its motor on a slide that may be moved transversely relative to the table.

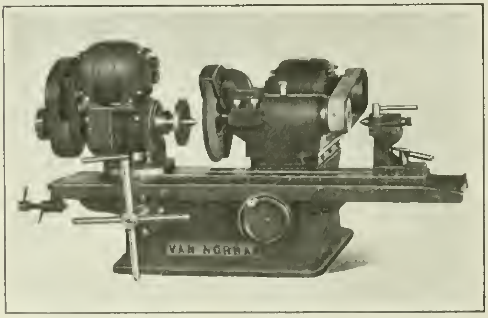

Fig. 1. "Relio" Bench Grinding Machine developed by the Van Norman Machine Tool Co.

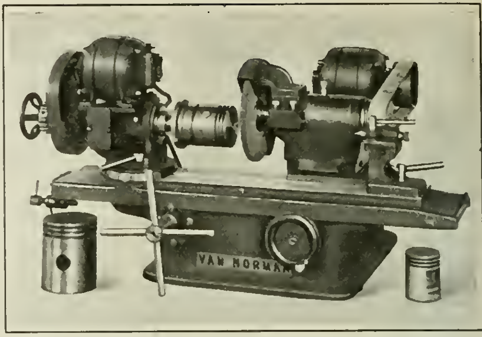

Fig. 2. Machine set up for grinding Automobile Pistons

The work-head spindle revolves in a taper bearing that may be adjusted to compensate for wear of the engaging surfaces. This head may be swiveled on the table and set at any angle from the center line of the table up to 50 degrees. Graduations on the base of the head facilitate these settings, and locating holes at 0, 30, and 45 degrees insure the same settings on subsequent pieces when grinding valves, reamers, etc. A tailstock is provided for holding work between centers when this method of support is desirable.

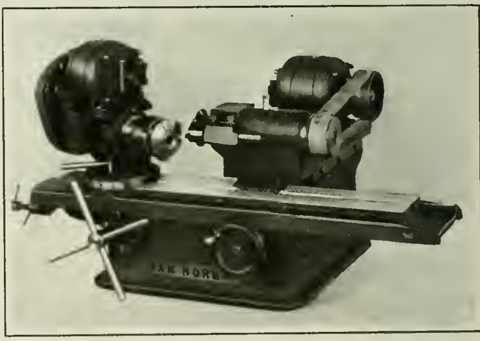

Fig. 3. Turning Angular Surfaces on the Van Norman "Relio" Bench Grinder

The table may be traversed past the grinding wheel through the rotation of a handwheel, and adjustable stops are supplied to limit this travel.

In Fig. 2 the "Relio" grinder is set up for grinding pistons, an attachment being mounted on the work-head spindle to enable the work to be quickly loaded and unloaded. Any standard piston with either straight or tapered sides can be accommodated. By removing the wheel and guard from the grinding head and inserting a special holder with a turning tool in a socket of the wheel-head in front of the wheel-spindle, the grooves for the piston-rings may be remachined. Another operation in which a turning tool may be effectively used on this machine is that of turning angular surfaces. This operation is illustrated in Fig. 3. The tool is fed over the face of the work by revolving the cross-

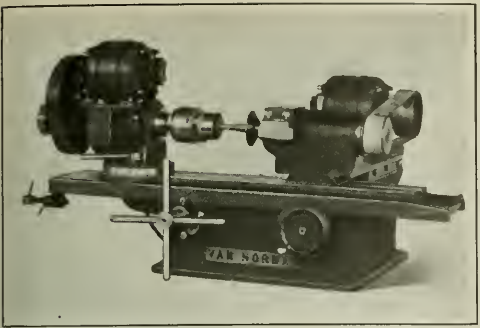

Fig. 4. An Internal Grinding Operation performed by attaching a Small-wheel Arbor to the Wheel-spindle

feed handwheel at the front of the machine. It will be seen that the work-head is placed at an angle to suit the angularity of the surface being machined.

Fig. 4 shows the machine set up for an internal grinding operation, a small-wheel arbor being attached to the front end of the wheel-spindle. Taper holes may be ground by setting the work-head to suit. Internal and external grinding can be performed at one setting of a piece of work by simply changing the grinding wheels. In the grinding of valves the head is set to the required angle and the valve stem is held in a draw-in collet chuck. It is stated that valves for standard cars are ground in less than one minute. Such an operation is illustrated in Fig. 5. Other operations readily accomplished on the machine are the grinding of wrist-pins, in which the work is held between centers and rotated by a key or pin inserted in the center of the work-head, provision being made for holding a wheel-truing tool on the tailstock; the grinding of tapers on valve cages;

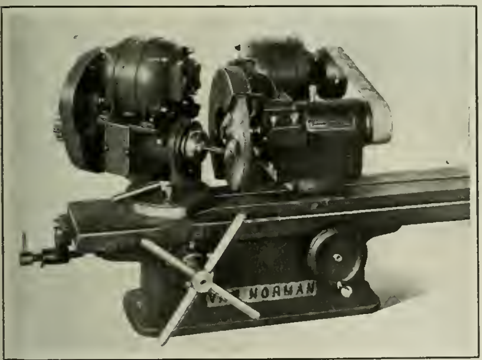

Fig. 5. Grinding an Automobile Engine Valve with Work-head set in an Angular Position

the grinding of valve reamers, in which a support finger is placed under the reamer teeth as they are being ground; and the repairing of armatures. In the last operation, the work is mounted between centers, and the worn parts may be finish-turned, scored or ground.

Some of the specifications of the machine are as follows: Size of grinding wheels, 8 by ½ inch and 1 by ¼ inch; swing of work-head, 8 inches; distance between centers, 12 inches; travel of table, 10½ inches; capacity of draw-in collet, ¾ inch; bench space required, 3 by 4 feet; size of wheel-head motor, ¼ horsepower; size of work-head motor, ⅛ horsepower. Low and high speeds of work-head spindle, 63 and 170 revolutions per minute, respectively; motor speeds, 1700 revolutions per minute; speed of wheel-spindle, 2800 revolutions per minute; and weight of machine, approximately 330 pounds.

ST. LOUIS POLISHING MACHINE

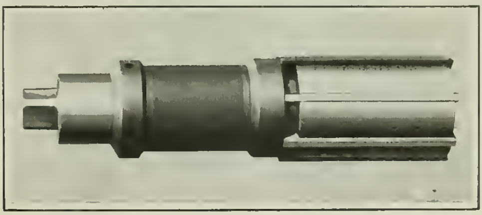
Another polishing machine known as the "Western" No. 10 has been added to the line of polishing and grinding equipment built by the St. Louis Machine Tool Co., 932 Loughborough Ave., St. Louis, Mo. The machine has a wide-face pulley and long bearings for the wheel-spindle, the bearings having large oil reservoirs and being amply provided for filling and draining. Circulation of lubricant is accomplished by means of chains. It will be seen that the lower half of the bearings is cast integral with the column. The arbor is made from 0.40 carbon steel, and has extra coarse-pitch

"Western" No. 10 Polishing Machine built by the St. Louis Machine Tool Co.

square threads. The machine may be furnished with taper-point arbors, either right or left, when desired. A few of the principal dimensions are as follows: Length of arbor, 48 inches; distance between wheels, 38 inches; and height from floor to center of arbor, 34 inches.

"RANSOME" PARALLEL-EXPANSION REAMER

An expansion reamer known as the "Ransome" has been developed especially for remachining automobile engine cylinders, by H. A. Hopkins & Co., Inc., 301 Laporte Ave., South Bend, Ind. It is made in five sizes to cover cylinders ranging from 2¾ to 4 inches in diameter. Each reamer is suitable for cylinders varying not more than ¼ inch in diameter, and has an extra expansion of 1/16 inch to allow for regrinding of the reamer blades. The tool consists only of a body, nut, and blades. The latter are anchored to the body by means of flanges that engage slots in the body. This construction eliminates chatter and always presents



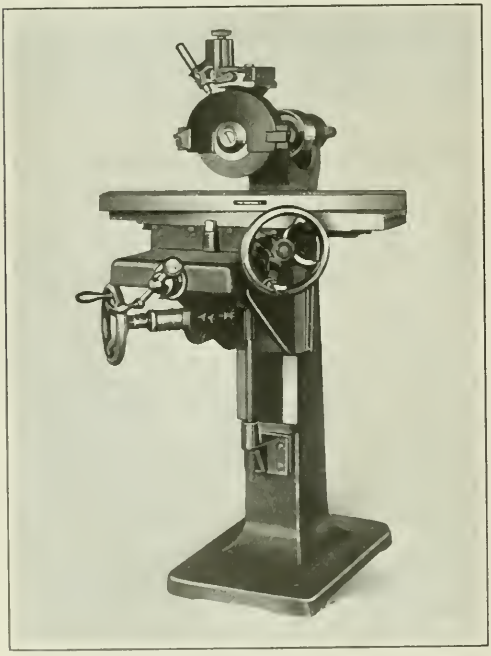
Parallel-expansion Cylinder Reamer made by H. A. Hopkins & Co., Inc.

an even cutting edge. The blades have a pilot end that permits them to be entered into the cylinder a short distance before any cutting is done, the reamer then being adjusted to the required size.

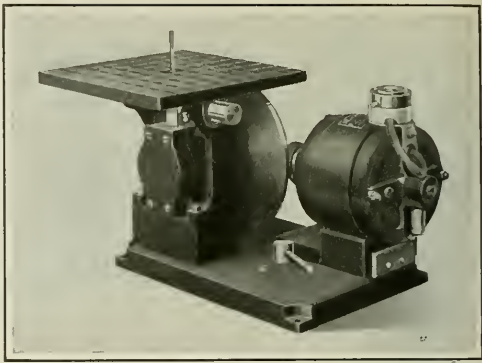
The actual cutting of the metal is done by a small corner of the blades, the reamer cutting from the end like a boring tool instead of scraping the cylinder surface. A micrometer dial facilitates accurate settings of the reamer blades. The reamer may be supported by a rope attached to the top of the shank, which is run over a pulley and provided with a counterweight at the opposite end. By such an arrangement the tool is permitted to feed at the desired rate and will enter the cylinder properly. A ratchet wrench is employed for revolving the reamer in a cylinder bore.

WILMARTH & MORMAN SURFACE GRINDING MACHINE

In November, 1909, MACHINERY was published a description of a No. 1 surface grinding machine developed at that time by the Wilmarth & Morman Co., 1180 Monroe Ave., N. W., Grand Rapids, Mich. This machine has since then been completely redesigned, and is now furnished with an adjustable swivel sub-table, as shown in the accompanying illustration, an improvement which provides a means of conveniently and accurately handling certain grinding operations. It particularly adapts the machine for grinding work of angular or irregular shape, as it is unnecessary to remove the work from the table and reset it in order to procure the proper angle. This is accomplished by swiveling the sub-table which has suitable graduations to enable close adjustments to be made. The sub-table is also provided with T-slots for attaching a headstock and a tailstock, or a dividing head, when grinding work held between centers. The wheel can also be trued without disturbing the work on the table, by means of a built-in truing device permanently located on the wheel hood. The machine is especially recommended for use in accurate gage or die work.



Wilmarth & Morman No. 1 Surface Grinder provided with a Swiveling Sub-table



Motor-driven Die-filing Equipment made by the R. G. Haskins Co.

HASKINS DIE-FILING MACHINE

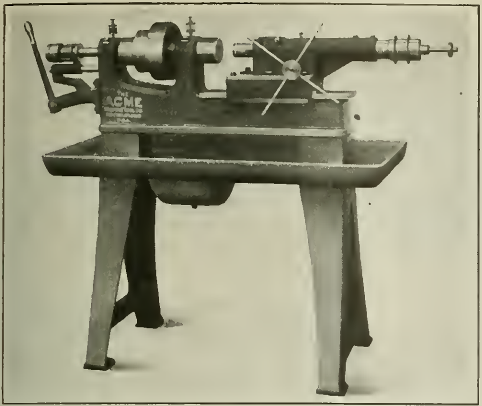
The accompanying illustration shows a motor-driven filing equipment built by the R. G. Haskins Co., 27 S. Desplaines St., Chicago, Ill., which is intended to eliminate the delay and expense of hand filing. The equipment is especially suitable for such work as machining templets, dies, tools, etc. The filing spindle is square in cross-section, and has provision for compensating for wear. Because of the construction it is possible to file sharp corners without play of the spindle. A reciprocating motion is imparted to the spindle by means of a hardened and ground tool-steel block and slide. This mechanism is entirely enclosed and adequately supplied with oil. The table is 9 inches square and may be locked in position for filing at an angle. A series of grooves in the top of the table prevents chips from accumulating on the surface and interfering with the rigid holding of work.

The motor is of 1/4-horsepower capacity, equipped with ball bearings, and is mounted on a dovetail slide. The drive from the motor to the spindle is through a friction wheel and plate. By pushing the motor either forward or backward on its base, the speed of the spindle may be varied from 300 to 700 revolutions per minute. A cam enables the machine to be stopped without stopping the motor. Standard machine files are furnished in sets of twelve, in various shapes and with 1/4-inch diameter shanks. The machine is light in weight, and so can be easily carried from bench to bench. All reciprocating parts are made of tool steel and ground.

ACME HORIZONTAL HIGH-SPEED DRILLING MACHINE

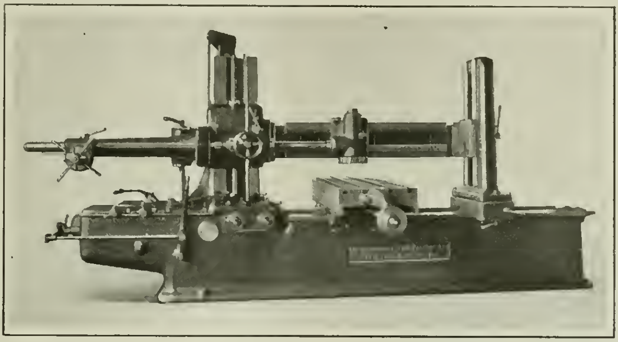
In the accompanying illustration is shown a horizontal high-speed drilling machine recently added to the line of machinery manufactured by the Acme Machine Tool Co., Cincinnati, Ohio. This machine is especially adapted for drilling small-diameter deep holes, such as grease-cup holes in king bolts, or similar work requiring quick operation. The design of the machine in general is similar to a hand screw machine, the spindle and chuck operation being the same as on that type of machine. The work is held in an automatic chuck that is opened and closed by operating a lever located at the head end of the bed.

On a turret-slide saddle is mounted a casting that carries the drill spindle. This arrangement permits the machine to be readily arranged for handling long or short pieces. The spindle is ordinarily run at approximately 3000 revolutions per minute, while the work-spindle is run at 500 revolutions per minute. The spindle is provided at the front end with a No. 1 Morse taper socket for holding drill chucks, and is driven from a flanged pulley on the rear end that is connected by means of a belt to a pulley on a countershaft. The spindle and its driving pulley are equipped with ball



Horizontal High-speed Drilling Machine developed by the Acme Machine Tool Co.

bearings, the bearings for the pulley being mounted on a separate stationary sleeve through which the drill spindle passes. This construction relieves the spindle from all belt pull, and permits it to be operated easily and quickly. The spindle is mounted in a sleeve which has rack teeth that mesh with the teeth of a gear on the turnstile shaft. Operation of the turnstile handle moves the spindle backward or forward, while a stop-collar on the rear end of the spindle may be set to stop the spindle movement when a drill has been fed to the desired depth.



Boring Machine built by the Blomquist-Eck Machine Co., equipped with a Vertical Milling Attachment

BLOMQUIST-ECK MILLING ATTACHMENT FOR BORING MACHINES

A vertical milling attachment, as shown in the accompanying illustration, has been provided for the horizontal boring machines built by the Blomquist-Eck Machine Co., 1146 E. 152nd St., Cleveland, Ohio. This attachment is supported by a cross-rail placed between the horizontal spindle saddle of the machine and the outboard bar support. The vertical spindle saddle of the attachment may be adjusted along the cross-rail by means of a rack and pinion, and is accurately located after placing in the approximate position, by binder screws. Motion is transmitted to the vertical spindle from the regular horizontal spindle by means of bevel gearing in the vertical spindle saddle. On all the boring machines made by the Blomquist-Eck Machine Co. the outboard bar support and the horizontal spindle saddle are machined so that this vertical milling attachment can be applied to any machine whenever desired.

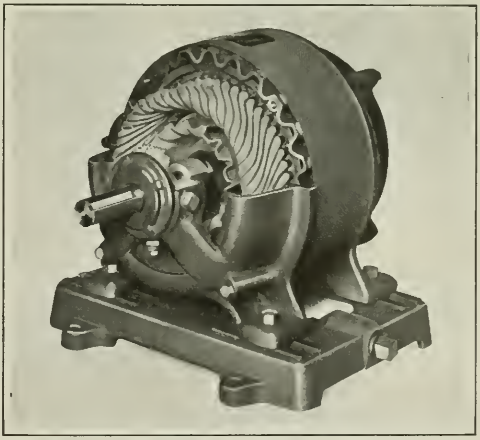
MYERS COMBINATION WORK-BENCH

In August MACHINERY appeared a description of a combination work-bench built by the Myers Machine Tool Corporation, Columbia, Pa., on which was mounted a geared automatic hacksaw provided with a vise, a 10-inch sensitive drilling machine equipped with a table and a 3/8-inch chuck, a grinder head supplied with emery and muslin polishing wheels, and a 4-inch machinist's vise having hardened steel jaws. The entire equipment was driven by a 1/2-horsepower motor running at 1750 revolutions per minute, which was mounted on a shelf supported by the table legs. A countershaft, mounted on the shelf with the motor, enabled individual or collective use of the different machines. Another work-bench similar to this, but equipped with a 10- by 45-inch engine lathe having a double friction countershaft, instead of the hacksaw, has now been placed on the market by the same concern. The new equipment is known as the No. 2 combination work-bench. The lathe is of standard design having a hollow spindle, power cross-feed, compound rest, thread-cutting mechanism, back-gearing, and three-step cone.

WOODS INDUCTION MOTORS

A line of general-purpose, polyphase, squirrel-cage, induction motors, one of which is here illustrated with one-half a head on one end, is now being introduced to the trade by the S. A. Woods Machine Co., Boston, Mass. These motors are enclosed in all sizes up to one horsepower inclusive, and semi-enclosed in larger sizes. They are ventilated by incoming air, which is screened as it enters the motor. The air then passes through gaps, is guided by a baffle plate over the windings, and exhausted through the bearing heads by the action of a fan. It is said that this system of ventilation insures that the motor will always be dry and free from oil-soaked windings.

The corrugated stator housing gives increased surface area for the radiation of internal heat. All motors have a temperature rise of 40 degrees C. when operated at full load, and the temperature rise does not exceed 50 degrees C. when an overload of 25 per cent is sustained continuously. Lubrication of the bearings is accomplished through the



New Type of Squirrel-cage Induction Motor built by the S. A. Woods Machine Co.

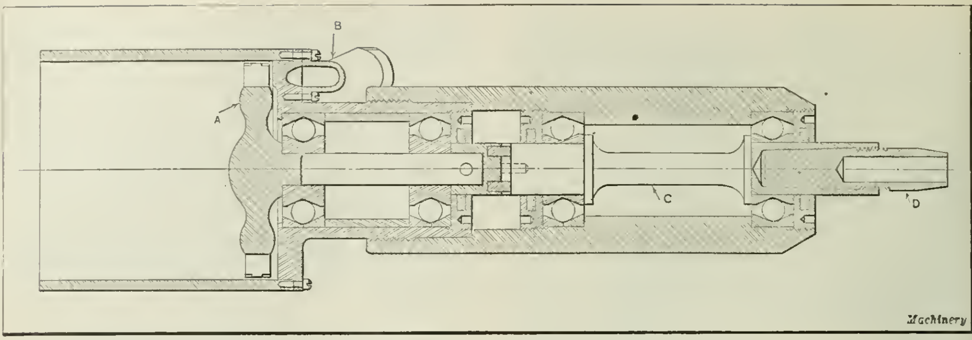


Fig. 1. Air-driven High-speed Grinding Spindle made by the Ex-Cell-O Tool & Mfg. Co.

use of wool waste. The stator windings consist of double cotton-covered enamel wire, while the rotor winding is of the cast unit type. Manufacturers who desire may simply purchase the stator and rotor, and supply their own shaft and bearing heads, enabling the motor to be built as an integral part of their product.

PARKER GRINDING SPINDLES

A high-speed grinding spindle adapted for use on various small-size internal and form grinding machines, and driven by an air motor which gives speeds up to 100,000 revolutions per minute, is shown in Fig. 1. This spindle is a product of the Ex-Cell-O Tool & Mfg. Co., 1214 Beaubien St., Detroit, Mich., sold under the trade name of Parker. It is said that the air drive affords a transmission free from vibration. The air is transmitted to a turbine rotor *A* through two nozzles *B* located diametrically opposite each other. The rotor is constructed of a steel of high tensile strength, and has thirty buckets on its periphery. It has a stem that is connected at the right-hand end to spindle *C*, to the outer end of which a quill *D* is attached. Thus as air is admitted against rotor *A*, it is caused to revolve due to the air being exhausted through its buckets. Air is usually supplied at pressures of from 40 to 60 pounds per square inch, the pressure depending upon the desired speed of rotation. Quill *D* is tapered at its inner end to fit snugly the taper socket in the end of the spindle.

It will be seen that the device is adequately provided with ball bearings. These bearings are of special construction, the outer races consisting of two rings, each of which has a different angle for the surface with which the balls make contact. The angularity of each of these surfaces corresponds with that of the face diagonally opposite on the inner races. In this design, the point of contact of a ball on one race is farther from the axis of rotation than on the other, and this condition causes the balls to revolve about their own axes as well as about the axis of the entire device. The result is a uniform wear of the balls and the elimination of lateral thrust. The angularity of the surfaces of the ball races is such that each ball revolves about its own axis approximately once to every 365 revolutions of the bearing. It is only necessary to oil the bearings every fifty hours of continuous rotation. The construction of the entire unit is such that it can be readily mounted on a machine.

Another grinding spindle intended for internal grinding operations, made by the Ex-Cell-O Tool & Mfg. Co., but which is driven by belt, is shown in Fig. 2. This spindle is equipped with the same type of ball bearings as the air spindle, and both equipments can be furnished to suit any make of grinding machine.

BARR PNEUMATIC DROP-HAMMER

Through a recent improvement in the valve control of the pneumatic high-speed hammer built by H. Edsil Barr, Erie, Pa., which has hitherto been mainly adapted for light forging and tool dressing operations requiring continuous rapid blows, the machine has been made suitable for drop-hammer work in which it is desired to form or straighten pieces completely at one blow. With this improved control, the hammer is always in the raised position when air is turned on. After a piece has been placed on the dies and the foot-lever is depressed, the hammer strikes a quick powerful blow without rebounding, and is returned instantly to the raised position. Rebounding of the hammer is eliminated by admitting air under the piston before a blow is struck. The hammer is also held in the raised position by air, and should the air be accidentally turned off, the ram will slide gently to the bottom position. The stroke of the hammer is 10 inches, and the potential blow, with air supplied at a pressure of 80 pounds per square inch, is about 442 pounds. With an air pressure of 100 pounds per square inch, the blow is about 540 pounds.

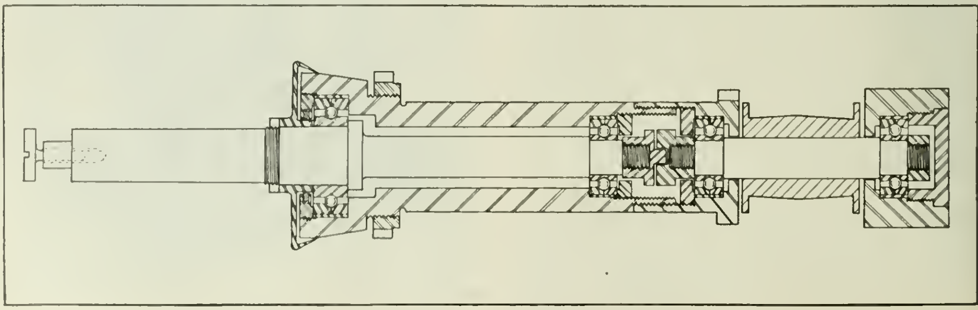

Fig. 2. A Belt-driven Grinding Spindle intended primarily for Internal Grinding

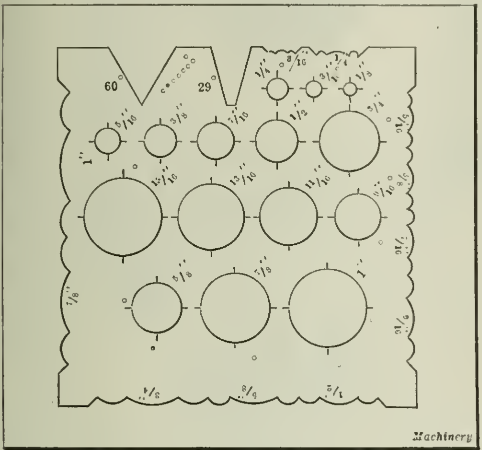
LOPEZ "DRAFTSQUARE"

An instrument intended to simplify the work of draftsmen by making more convenient the drawing of circles, arcs, fillets, nuts, and screw threads has been brought out by the Lopez Mfg. Co., 425 S. Wabash Ave., Chicago, Ill., under the trade name of "Draftsquare." This instrument is transparent, 0.055 inch thick, and 4¾ inches square. Its four edges have a series of arcs in sets of three, each set corresponding to the arcs used in drawing a three-sided view of a nut. The three arcs for any particular nut are identified by the nut size, which is marked on the square for each set. The



Engineers' "Draftsquare" placed on the Market by the Lopez Mfg. Co.

thickness of a nut is determined by marking the drawing through a small hole provided in each case, which is located the proper distance from the top of the arcs.

In drawing 60-degree V-threads, it is only necessary to draw lines representing the outside and root of the thread and then use the sides of a vee cut in one edge of the square for drawing the threads. A second vee facilitates the drawing of Acme threads. Holes ranging from ⅛ to 1 inch in diameter are provided for drawing circles and arcs. A series of holes 1/16 inch apart and a single hole 1/32 inch above these may be used for drawing guide lines for lettering. Angle lines for the same purpose may be quickly drawn by using the sides of the vees provided for drawing screw threads.

BLACK & DECKER PORTABLE DRILL

A new portable electric drill intended for drilling holes up to ¼ inch in diameter in steel has been added to the line of portable drills made by the Black & Decker Mfg. Co., Towson Heights, Baltimore, Md. The drill has an aluminum alloy housing and weighs only 5 pounds. It is of the same general design and construction as other drills made by the same concern, including the pistol grip and trigger switch. Through double reduction gearing the no-load speed is 1600 revolutions per minute. The gears have stub teeth, are made from chrome-nickel steel and heat-treated, and run in oil. All bearings are renewable. The switch mechanism is arranged in the grip in such a way that the tool is particularly adapted for close work, it being possible to drill within an inch of any obstruction.

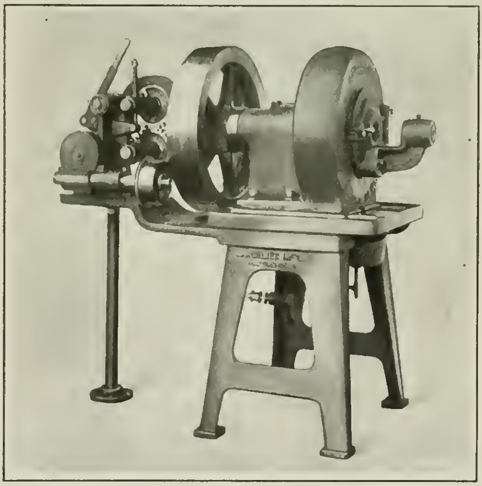
The brushes can be replaced from the outside of the case, and by removing four screws, the commutator, switch mechanism, field leads, and cord terminals may be exposed. The commutator end bearing of the motor armature is carried in a spider that is integral with the motor case. It is thus impossible for the armature to get out of alignment. The commutator may be inspected and cleaned while the drill is running. The drill may also be used for grinding operations, a base, clamp washers, and a grinding wheel being furnished for this purpose. The base can be mounted on a work-bench, and when the device is to be used as a bench grinder, it can be quickly attached to the base and an emery wheel secured to the spindle.

LANGELIER ROLLER-CAGE SWAGING MACHINE

A roller-cage type swaging machine, known as the No. 3½ AT4, is now being built by the Langelier Mfg. Co., Arlington, Cranston, R. I. This machine differs somewhat from the standard machines made by this concern in which the rolls are inserted directly in the head proper, the new type having a hardened steel ring driven into the head, which receives the revolving cage carrying the rolls. Other features of the mechanism are practically the same as on the fixed-roll machines.

The spindle head is slotted for the reception of the hammer blocks, which are bored at their upper ends to accommodate the hammer block rolls. The lower ends of the hammer blocks are slotted to receive the dies. The hammer blocks, rolls and dies are made of a special tool steel, and hardened. A spindle plate screwed to the front end of the spindle retains the different working parts, and limits the opening of the swaging dies during the operation of the machine.

When the machine is operating, as the spindle rotates, the centrifugal force tends to throw the hammer blocks out from their center, thus enabling the dies to open. The head rolls in the revolving cage project toward the center beyond the path of the hammer block rolls, and as they contact, they produce an intermittent rotation of the cage, retarding

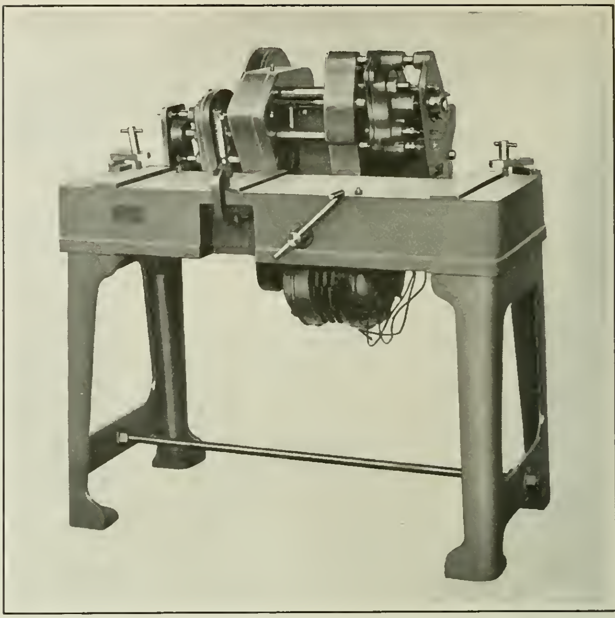


Swaging Machine of the Roller-cage Type which has been developed by the Langelier Mfg. Co.

the blow and resulting in a sliding or squeezing action. This action differs from that on the standard type of machine manufactured by this concern, in which the blow is direct and much more sharp. It is said that slow blows are better adapted to solid work, as more time is given for the stock to flow.

The machine has a roller attachment by means of which the stock is withdrawn after swaging, with a steady and smooth motion that insures a maintenance of the straightness of the work. This attachment is mainly used in light swaging or sizing work. It can be moved to and from the end of the spindle, over a distance of 5 inches, by means of an adjusting screw beneath the baseplate. The surface speed of the rolls may be changed from 30 to 45 inches per minute. These rolls, with their driving gears, are mounted on crank-arms fulcrumed on the upright casting of the attachment. The lower arm is held stationary by means of a set-screw. The upper roll is pressed against the lower roll by the manipulation of the lever, and tension is maintained by means of an adjustable spring. A bushing on the end of the machine spindle guides the stock into the center of the rolls and prevents it from catching on the gear teeth. The rolls can be opened instantly by means of the lever, and changed quickly by loosening a nut.

CRANKCASE DRILLING AND BORING MACHINE



Horizontal Machine for drilling and boring Automobile Crankcases, which has been brought out by the Manufacturers' Consulting Engineers

A machine that simultaneously drills three holes and bores another for a starter or generator, in each end of an automobile crankcase, is shown in the accompanying illustration. This machine is a recent development of the Manufacturers' Consulting Engineers, McCarthy Bldg., Syracuse, N. Y. It is designed to enable the completion in one operation of work usually accomplished in three operations. The machine consists of a bed supported on legs, on which are mounted a driving motor and two sliding heads. Each head carries three drills and a boring head, although the number can be altered to suit other operations. The heads are fed in opposite directions through the manipulation of a hand-lever, the arrangement being similar to that employed in effecting the feed on sensitive drilling machines.

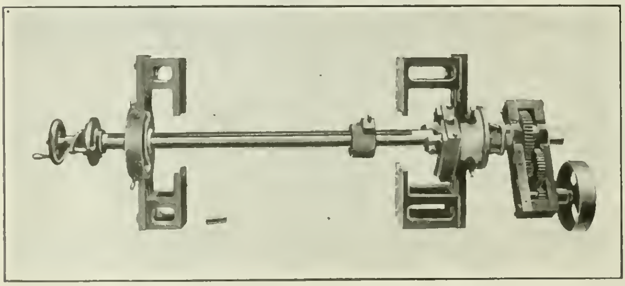
CLEVELAND "MEZZO" TWIST DRILLS

A new line of twist drills which are made from a special steel and given a special heat-treatment to adapt them to drilling conditions under which carbon or high-speed steels do not render satisfactory service, has been introduced on the market by the Cleveland Twist Drill Co., Cleveland, Ohio, under the trade name of "Mezzo." This term was selected to imply that the drills are intended for conditions midway between those under which carbon and high-speed drills are most satisfactory. Many shops, not being properly equipped to obtain maximum results from high-speed drills, are forced to reduce the speed at which they are used, and, if rigidity is lacking, also the rate of feed. These reductions, of course, affect production considerably.

For maximum efficiency, a high-speed drill must be run fast enough to keep it fairly hot, and if the equipment does not allow this, a reduced speed frequently results in breakage. Costly breakage forces many shops without proper equipment to use carbon tools with a subsequent reduced production. Thus it is evident that a saving in expense can be made as well as an increased production obtained in such cases by the use of a drill which will run at speeds and feeds above those of carbon drills and still stand up under the work. The "Mezzo" drills are designed to fulfill these requirements. They are intended for use at approximately double the speeds under which carbon drills work satisfactorily. In order to make them readily distinguishable, the new drills are given a blue-black rust-resisting finish.

PEDRICK PORTABLE TAPER BORING-BAR

A portable boring-bar designed primarily for taper-boring operations, but which may also be used for straight boring and facing, is a recent product of the Pedrick Tool & Machine Co., 3639 N. Lawrence St., Philadelphia, Pa. The special features of the bar are the possibility of taking it to the job and its adjustability to suit any degree of taper. The boring-bar is supported on the part being machined by means of cross-heads having four set-screws that enable the bar to be finally and accurately aligned after it has been roughly centered in the hole to be machined.



Portable Taper Boring-bar made by the Pedrick Tool & Machine Co.

A conical rotation of the bar is produced through a cross-slide and yoke to which the bar is attached. The degree of taper is controlled by the distance that the slide is moved from its central axis. The lower end of the bar, to which the feed-case is attached, describes an orbit and thus necessitates the provision of a spherical-shaped bearing in its cross-head. By preventing the handwheel of the feed-case from turning, the feed becomes constant and automatic. The gearing of this device may be driven by belt, electric motor, or air drill. When a facing arm is used with the boring-bar, the latter is held by spiders inserted in the bore of the work.

PARKER GRINDING, DRILLING AND TURNING MACHINE

Such operations as the grinding of valve reseating tools, valve cages, commutators, and gears, the sharpening of milling cutters, the drilling and regrooving of pistons, the milling of keyways, and other small machine operations can be readily accomplished by the use of a new bench grinding, drilling and turning machine, which has been brought out by the Ex-Cell-O Tool & Mfg. Co., 1214 Beaubien St., Detroit, Mich., under the trade name of Parker. From Fig. 1 it will be seen that the upper or grinding spindle is driven by belt from a $\frac{1}{4}$-horsepower motor, mounted on the same arm as that which supports the spindle on the column. The grinding spindle can be adjusted to various positions to suit angular operations, the motor swiveling with the head. The motor can be furnished to run from any lighting current. A small lever on the right of the grinding spindle head is employed for reciprocating the grinding wheel back and forth across the work.

The lower spindle, or work-spindle, is shown equipped with a 4-inch universal scroll chuck, but a 6-inch faceplate is also provided. The work-spindle may also be swiveled to any desired angle, as will be apparent by referring to Fig. 2, in which the upper spindle is in a vertical position and provided with a chuck and drill for drilling holes at an angle through the wall of an automobile piston. Both the swiveling members of the upper and lower spindle heads are graduated to enable accurate adjustments. In Fig. 2 it will also be seen that a large pulley has been mounted on the upper spindle instead of the small pulley seen in Fig. 1. A larger pulley is necessary in drilling and milling operations for reducing the speed of the spindle to suit these classes of operations. The lower spindle may also be revolved by a handwheel which is driven by a V-shaped belt, the handwheel being provided with a groove around its periphery for this purpose. This V-shaped belt is connected to the small pulley mounted on the shaft extending from the lower end of the motor, previously referred to in connection with Fig. 1. The proper tension is maintained on this driving belt by means of a double idler pulley fastened to a spring on an adjustable rod secured to the motor support. This arrangement is not illustrated.

The upper spindle is equipped with ball bearings, while the work-spindle has a straight bearing which extends its full length and also has a $\frac{1}{4}$-inch 45-degree angle thrust bearing. Both external and internal grinding operations can be performed on the machine, and an idea of its grinding range can be obtained from the fact that it is used for grinding the outside cylindrical surfaces of automobile pistons and for grinding holes as small as 5/16 inch in diameter. The regrooving of pistons and the turning of small armatures can be accomplished by mounting a tool in the lug at the left of the grinding spindle bearing. An overhanging center bracket can be furnished. The lower spindle head has a horizontal travel of 7 inches and a vertical movement of $8\frac{3}{4}$ inches. The machine has an over-all height of 24 inches, and weighs about 135 pounds.

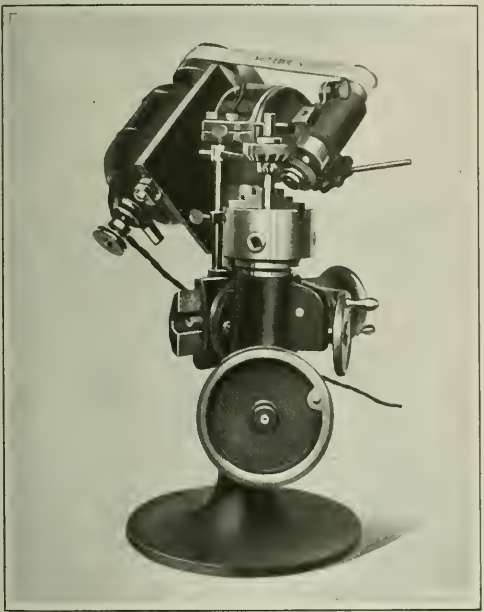


Fig. 1. Grinding, Drilling and Turning Machine placed on the Market by the Ex-Cell-O Tool & Mfg. Co.

Fig. 2. Machine set up for Drilling Operation, the Work-spindle being at an Angle and the Upper Spindle Vertical

---

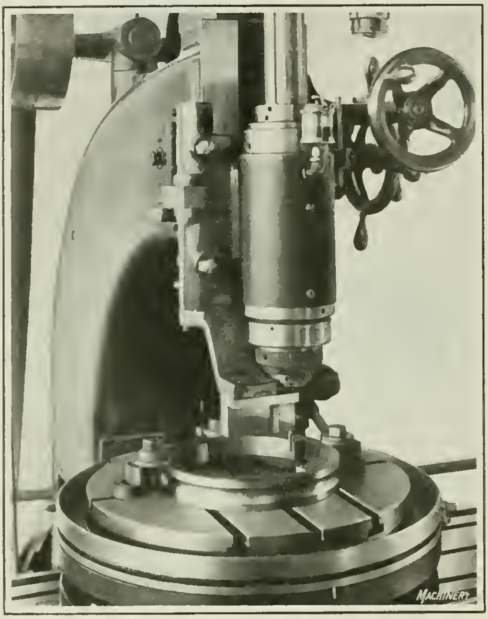
TURNER GASOLINE-KEROSENE BLOW-TORCH

The Turner Brass Works, Sycamore, Ill., have recently brought out a new style blow-torch using either gasoline or kerosene for fuel. On this torch the shut-off valve is located below the orifice. This construction prevents enlarging of the orifice through shutting off tightly when hot by forcing the point of the needle in, or through fuel corroding the needle point when the torch is cool. An adjusting needle in the orifice permits all gases to escape. It can be regulated so as to obtain any size flame without destroying the orifice. A cone-shaped tube on the burner siphons the correct amount of air regardless of the adjustment. The feed-tube is placed on the outside of the tank so as to prevent any possibility of heating the fuel in the tank to such a degree that it would create gas pressure and cause an explosion. The leather on the plunger of the air pump is loose in the cylinder, decreasing wear and allowing air to pass freely on the upward stroke. On the downward stroke the leather flares out and forces a large volume of air into the tank.

BECKER MILLING MACHINE ARRANGED FOR HIGH SPINDLE SPEEDS

Light milling operations must sometimes be performed on work so large as to require a large size machine having a large table space and throat clearance, when a much smaller machine would be preferable because of the higher spindle speeds obtainable with small cutters. To meet such requirements the Becker Milling Machine Co., 677 Cambridge St., Worcester, Mass., has arranged its No. 5-C vertical milling machine so that on special order, spindle speeds up to 1400 revolutions per minute may be obtained and cutters as small as 7/32 inch in diameter successfully used. The normal range of speeds for this machine is from 13 to 500 revolutions per minute. The high speeds do not interfere with the regular speeds, so that the machine may be used for all usual jobs and also be promptly available for high-speed work.

A special three-speed countershaft, with one shipper for obtaining the regular speeds and another for the high speeds, is employed. In the job shown in the illustration a groove 7/32 inch wide and 1/4 inch deep is milled tangent to the circular wall previously milled and about 1 inch below the top face of the work. Because of the necessary extension from the spindle face of the frail cutter employed for the operation, a special bracket is bolted to the spindle head, to which is attached a bushing which supports the cutter close to the surface being milled. This particular job does not require a large throat clearance, the machine set-up being primarily intended for other sizes of work which necessitate the use of a large machine.



Operation performed on the No. 5-C Vertical Milling Machine built by the Becker Milling Machine Co.

CONSOLIDATED SCREWDRIVER SET

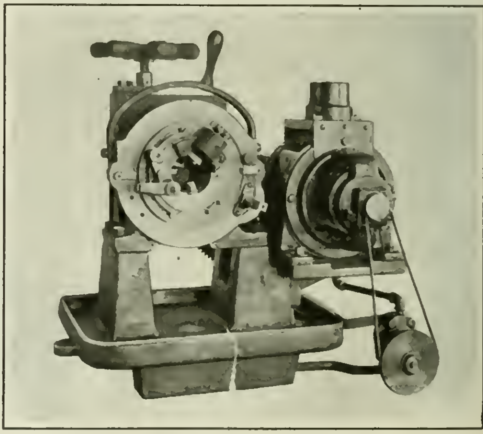
A screwdriver set consisting of one handle and four blades, any of which may be inserted in the handle to suit the slot in the head of the particular screw that it may be desired to drive into place or remove, is now being placed on the market by the Consolidated Tool Works, Inc., 296 Broadway, New York City. Two blades of the set fit into one end of the handle, and the other two into the opposite end. The blades are made of tool steel, ground and tempered, while the handle is turned from cold-rolled steel and knurled. The ends of the blades are 1/8, 3/16, 1/4, and 5/16 inch wide, respectively, and the length is 3 1/8 inches. When a blade is inserted into a handle, the over-all length of the screwdriver is about 6 1/2 inches. The blades are held in a positive manner in the handle and may be quickly interchanged.

Four-blade Screwdriver Set placed on the Market by the Consolidated Tool Works, Inc.

CURTIS MOTOR-DRIVEN PIPE-THREADING MACHINE

A No. 430 motor-driven pipe-threading machine has been designed by the Curtis & Curtis Co., 324 Garden St., Bridgeport, Conn., to meet the requirements for a portable outfit equally adaptable for use in the shop or in the field. The pipe is held stationary in a vise which forms part of the machine, and the dies, which are contained in a die-head, are screwed on the pipe, power being supplied by the motor through rawhide, steel, and cast-iron reduction gears.

The die-head is equipped with an automatic release which opens the dies at the completion of a threading operation while the machine is still running, so that the pipe may be removed without backing off the thread or stopping the machine. By turning a small lever, the dies are reset and the machine made ready for the next cut, which is identical with the preceding one, both as regards the length and diam-



No. 430 Pipe-threading Machine built by the Curtis & Curtis Co.

eter of the thread. The die release is adjustable to enable either long or short threads to be cut. The machine is equipped with a cutting-off attachment that cuts the pipe square without leaving a burr. High-speed steel tools and an oiling system with a pump are furnished with each outfit. The rating of the motor is 1 horsepower, and it may be run on ordinary lighting current. The machine, complete, weighs approximately 350 pounds.

DAVIS-BOURNONVILLE WELDING OUTFIT

A welding outfit contained in a substantial fiber case to facilitate transporting it to a job, which is said to be suitable for any welding operation, is shown in the accompanying illustration. This outfit has recently been brought out by the Davis-Bournonville Co., Jersey City, N. J., and includes a torch, three extension tubes, five welding tips, decarbonizing tube, oxygen regulator, acetylene regulator, 12 feet of oxygen hose and connections, 12 feet of acetylene hose and connections, spark lighter, pair of colored glasses, and torch and regulator wrenches.

The gas tubes are silver-soldered into both the head and rear ends of the torch. The needle valves are quick-opening,

Welding Outfit placed on the Market by the Davis-Bournonville Co.

and are also silver-soldered in place. The mixing chamber in the head end of the torch is so constructed that the gases are correctly mixed before entering the tips. Some sizes of the tips are made of copper and others of brass. The tip nut is made with a fine thread on the inside to fit the brass sleeve, and threaded on the outside to fit the head of the torch. Thus the tip can be made gas-tight in the head by hand pressure alone. Numbers are stamped on the handle of the torch showing the pressures of acetylene for use with the various sizes of tips in order to give a strong welding flame. The copper extension tubes can be furnished in any length desired. The tubes are flexible so that it is possible to weld in places otherwise inaccessible.

COATS-LEONARD RENEWABLE PLUG GAGES

Plug gages on which the gaging ends are renewable to make replacements possible at a minimum cost are now being placed on the market by the Coats Machine Tool Co., Inc., 110-112 W. 40th St., New York City. The gages are made of hardened steel and are ground within an accuracy of 0.0001 inch. They are put up in two sets in wooden cases. The No. 1 set comprises fourteen sizes from 1/4 to 1 1/4 inches in diameter, the sizes increasing by increments of 1/16 inch

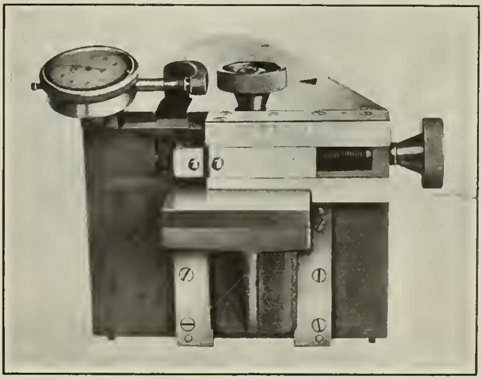
Case of Renewable Plug Gages placed on the Market by the Coats Machine Tool Co., Inc.

up to 1 inch, and by 1/8 inch increments from 1 to 1 1/4 inches. Any special combination of sizes can be supplied to order. The four smaller sizes are made solid with the handle. The No. 2 set comprises sizes from 1 3/8 to 2 1/4 inches in diameter, increasing by increments of 1/8 inch. Renewable limit plug gages are also supplied by the same concern to meet the demand for limit gages which can be furnished from stock. Each gage consists essentially of three parts, a "Go" end, a "Not Go" end, and a handle. The handles are interchangeable, and one size will fit a range of plug sizes. Stocks of hardened ends in both English and metric measurements are always carried on hand.

TOLEDO THREAD-LEAD GAGE

Imperfect lead of threads is largely responsible for the loose fit of screws in machines, because if the lead is inaccurate only two or three threads of the screw may bear against the threads of the tapped hole which the screw engages, with the result that when the members held together are stressed, the screw stretches a sufficient amount to produce a loose fit. In order to check closely the lead of all taps and accurately machined studs, the Toledo Tap & Die Co., Clinton St., Toledo, Ohio, designed the lead gage here illustrated, and has now placed it on the market. By means of this device on which patents are pending, the lead of threads can be quickly checked.

This gage has an arm 8 inches long that is pivoted on adjustable angle bearings and carries at its outer end a hardened and ground conical point. The arm also has a hardened button which comes in contact with the plunger of

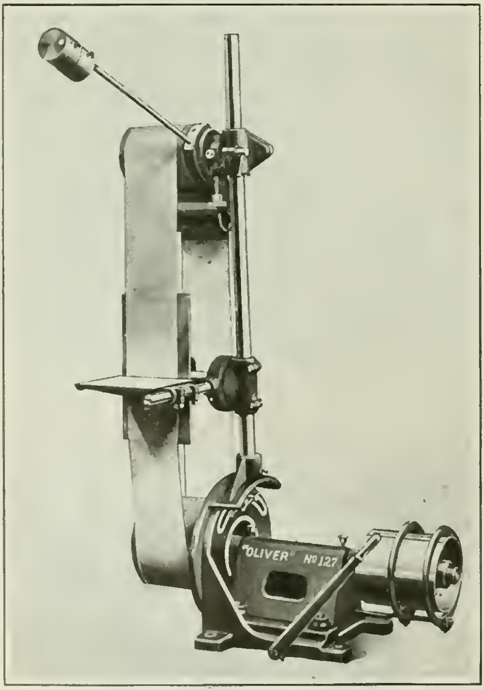


Gage for checking Lead of Threads, which has been developed by the Toledo Tap & Die Co.

the dial gage and registers, positively, any variations between a master thread gage and the work being inspected. There is a second hardened and ground conical point mounted on a slide which may be operated horizontally, so as to vary the distance between this point and that on the pivoted arm. The distance between the two points may be varied from ½ to 2 inches. In employing the device, a master gage is first laid on the table after the latter has been elevated until the center line of the gage coincides with the conical points. Then the latter are made to engage with two threads of the gage the desired distance apart, and the slide is adjusted until the dial indicator registers zero. The threads of work to be tested are then pressed firmly against the conical points and any difference in lead from the master setting will be indicated accurately on the dial. The dial may be furnished to show variations of either 0.001 or 0.0001 inch. The arm and pivot points are fully enclosed so that they cannot be tampered with.

OLIVER NO. 127 BELT SANDER

The No. 127 variety belt sander here illustrated is now being built by the Oliver Machinery Co., Grand Rapids, Mich., for pattern shop use. It is suitable for sanding concave and convex surfaces and the various irregular shapes met with in the manufacture of patterns, performing work usually done on disk and drum sanders. The table may be tilted to suit angular surfaces or draft on work. The machine is driven from a pulley mounted on a countershaft located on the base. On this base is mounted a frame that swings about the center of the countershaft and carries a supporting arm. On the latter are mounted two brackets,



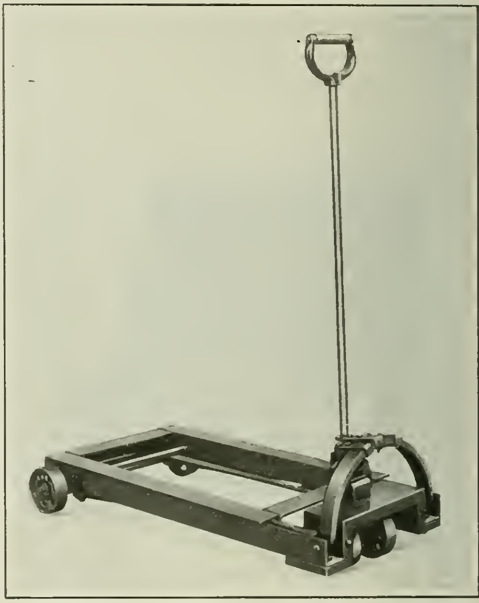
No. 127 Variety Belt Sander built by the Oliver Machinery Co.

one of which supports the main idler pulley and tension idler, while the other supports the table and backing plate, forms, or flexible pads.

The machine will take belts up to 10 inches wide and 14 feet long. The backing plate is 10 inches wide and can be adjusted in and out to produce a suitable tension on the belt. It has holes drilled in it for attaching flexible pads. The main idler is leather-faced and adjustable up and down the entire length of the idler arm to suit different lengths of belts. The tension idler is also faced with leather; it fulcrums on the center of the main idler, and is balanced by weights to give the correct tension to the belt. A fork idler may be mounted on the machine in place of the table, for doing oval sanding. This machine may also be motor-driven, in which case a motor of two-horsepower capacity is provided.

WESTERN LIFT TRUCK

The "Champion" lift truck here illustrated is a product of the Western Tool & Mfg. Co., Springfield, Ohio. This truck is constructed entirely of iron and steel parts, many of which are hand-forged. The front wheels swivel on thrust

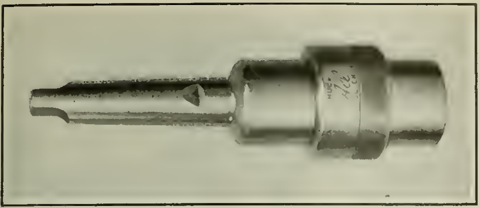


Steel Lift Truck made by the Western Tool & Mfg. Co.

ball bearings, and all wheels are provided with cage roller bearings. Weights up to 2000 pounds can be raised easily by one man. The truck turns in its own length. The over-all length is 46 inches and the over-all width 26 inches. The platform dimensions are regularly 23 by 38 inches, but platforms may also be supplied in any other lengths desired. The truck will raise a load through a distance of 1½ inches.

"SAVE-ALL" QUICK-CHANGE DRILL CHUCK

A positive safety quick-change chuck for drills or other tools with taper shanks is now being placed on the market by the Save-All Tool Co., 59 River St., Waltham, Mass. The drill or other tool is held in a collet which may be slipped into the chuck when the sleeve on the latter is raised. By lowering this sleeve, jaws are made to engage the taper end of the collet and hold it in place. This chuck has a device which prevents the breaking and burning of tools by shearing a pin that drives the collet whenever the cutting tool is overloaded. This pin is held in place by a pointed screw which seats in a groove in the pin, and, after a pin has been sheared, it can readily be removed by loosening the screw.

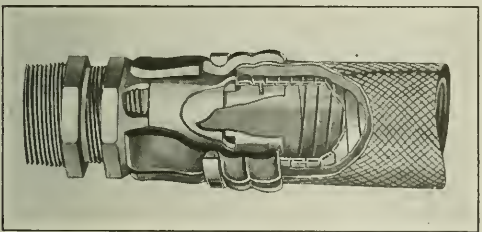


Safety Quick-change Drill Chuck made by the Save-All Tool Co.

The construction of the collet and chuck body is such that the members do not stick when tools are changed. A compensating collet lock automatically takes up wear and eliminates end motion, while a "Bristo" hollow set-screw prevents the tool from pulling out. Tools can be changed while the machine is in motion. The release of a tool from the collet is effected by striking a light blow on an ejector in the small end of the collet. The chuck illustrated accommodates drills having Nos. 1, 2, 3, and 4 Morse taper shanks. All parts are hardened, except the shearing pin.

"KNORR" DETACHABLE COUPLING

The "Knorr" metal coupling, which is readily detachable, leak-proof, and suitable for hose used with pneumatic tools, is placed on the market by the Barlow Mfg. Co., 108-114 Park Place, New York City. This coupling is also suitable for hose employed in conveying gasoline, etc., and is capable of withstanding pressures of over 450 pounds per square inch. Three or more arms of stamped steel closely embrace the end of the hose of any given outside diameter, these

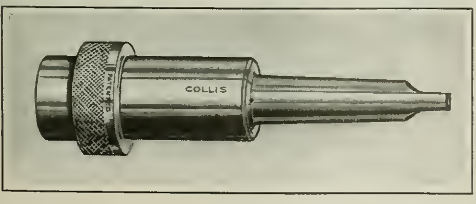


Coupling for Metal-lined Hose which is placed on the Market by the Barlow Mfg. Co.

arms being held in place by a steel ring. The arms are made to grip the hose through a wedge or spreader-nut threaded on the shank of the coupling, which forces out the arms at the other end. This lever combination enables the user to exert an easily adjusted pressure upon the hose and to remove the latter quickly by revolving the spreader-nut several times. Slight variations in the thickness of hose do not interfere with the attachment of the coupling. The shank or body is thin at the hose end and threaded, so that it can be screwed into the interior lining of the hose.

COLLIS QUICK-CHANGE DRILL CHUCK

The "Wonder" quick-change drill chuck here illustrated has been designed by the Collis Co., Clinton, Iowa, for use in the spindle of lathes, drilling machines, screw machines,



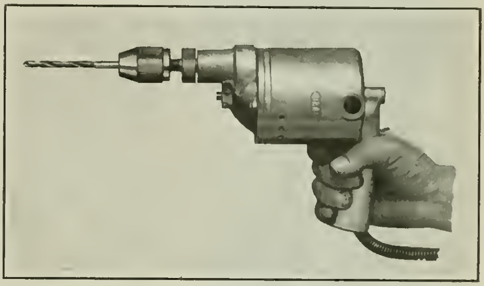
"Wonder" Quick-change Drill Chuck manufactured by the Collis Co.

and other machines having rapidly rotating spindles. The chuck can be operated by one hand, and collets inserted or released while it is revolving at speeds up to 1500 revolutions per minute. The ease with which a tool can be replaced adapts the chuck for use in the performance of several operations without removing the work.

The collets have taper shanks and may be used either in a horizontal or a vertical position. By the use of different collets either taper or straight shank drills and hand taps can be accommodated. A special style of collet known as the "Use-Em-Up" enables drills with twisted or broken shanks to be used, it being only necessary to grind a flat on the remaining portion of the shank. The chuck is made in six sizes.

"CYCLONE" ELECTRIC DRILL

A small portable electric drill having a capacity for drilling holes up to 5/16 inch in diameter in metal, has been brought out by the United States Electrical Tool Co., 6th Ave. and Mt. Hope St., Cincinnati, Ohio. This drill has an aluminum alloy housing, weighs about 5½ pounds, and has an over-all length of 9 inches. The gears are made of chrome-nickel steel, and are hardened and run in grease. The electric switch is located in the handle so as to be con-

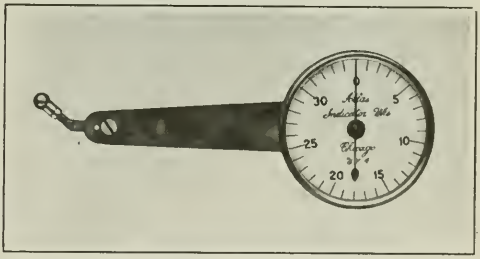


Portable Electric Drill manufactured by the United States Electricel Tool Co.

veniently controlled by the thumb at all times. The motor is of the universal type, air-cooled, and wound for operation by 110- or 220-volt current. It operates on from 25- to 60-cycle, single-phase, alternating current or direct current, and may be attached to any lamp socket. This drill is especially suitable for corner drilling, as it may be used within ¾ inch of walls.

ATLAS DIAL INDICATOR

A small indicator reading over a range of 0.055 inch, known as the "Junior," is being sold by the Atlas Indicator Works, 160 N. Wells St., Chicago, Ill. The indicator dial



"Junior" Indicator made by the Atlas Indicator Works

is carried on a swivel mounting that offers a convenient means of attaching the instrument to suit the various jobs on which it may be employed. After adjusting the contact point on the work, the dial may be revolved so as to bring the zero mark in line with the indicator hand. The reading of the indicator may be magnified or diminished by adjusting its contact point, this feature being of value when the instrument is employed by inspectors to detect the presence of errors on work, but not to measure their magnitude. The contact point may be locked in any desired position by means of a threaded collar on which patents are pending.

BLACK & DECKER CLEANING MACHINE

An equipment designed for cleaning small parts such as ball and roller bearings, gears, motor and generator parts, drills, milling cutters, and other tools has been produced by the Black & Decker Mfg. Co., Towson Heights, Baltimore, Md. The device consists of a cast-iron pedestal at the top of which a bowl is mounted. This bowl is 13 inches in diameter, 12 inches deep, and has a fine-mesh brass screen supported at about 5 inches from the bottom. The housing of a plunger pump is cast integral with the bowl. The latter has a safety cover so arranged that it cannot be left open. The cover is lifted by means of a convenient handle that operates the pump each time the cover is raised. A gallon of gasoline, kerosene, or other desirable liquid cleanser is poured into the bowl of the machine and the operation of the pump forces a stream of this fluid toward the center of the bowl from one side. The part to be cleaned is held under the stream of cleansing fluid so that dirt and chips are washed from the part and deposited on the screen below, the fluid passing through the screen and returning to the sump to be used again.

Apparatus for cleaning Small Work, made by the Black & Decker Mfg. Co.

SHEPARD ELECTRIC HOIST

A new electric hoist known as the "Liftabout," which is manufactured by the Shepard Electric Crane & Hoist Co., Montour Falls, N. Y., is shown in the accompanying illustration. The motor furnished with this equipment is of the fully enclosed type, with interchangeable frames for direct and alternating current. The motor is especially designed for hoist service and carefully insulated and impregnated to protect it from moisture. A standard series-wound interpole motor is furnished for direct current, and when the motor is running without load, its speed is approximately twice its full-load speed. The hoisting speed with an empty hook is, therefore, about twice that of the full-load speed. The induction motor furnished for alternating current may be of either the squirrel-cage or slip-ring type, the squirrel-cage motor being used with a single-speed control and the slip-ring type with a variable-speed control.

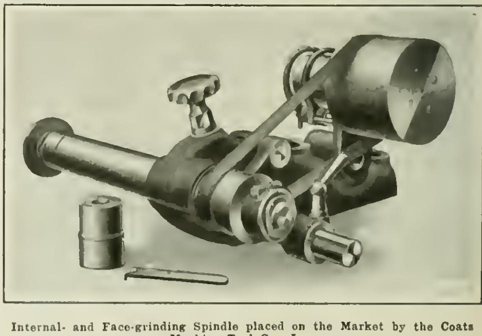
Either variable- or single-speed controllers are furnished, depending on the service in which the hoist is to be employed The variable-speed control for direct current offers eleven or thirteen running speeds, the number of speeds depending upon the size of the motor. Eight running speeds are possible with alternating current. The operating parts of the controller are fully enclosed from dust and moisture, but are readily accessible. The entire mechanism including the resistance may be removed from its case without disconnecting a single wire, and, likewise, the contacts and brushes may be removed without disturbing other parts of the controller. A single-speed control is afforded through a switch, the only function of which is to start, stop, and reverse the hoist mechanism. The hoist gearing consists of a double train of spur gears having either two or three speed reductions.

New Electric Hoist manufactured by the Shepard Electric Crane & Hoist Co.

A mechanical brake of the multiple disk type automatically holds the load when the motor is at rest, and prevents excessive speed in lowering, while an electric brake, also of the multiple disk type, brings the motor promptly to rest when the current is cut off or accidentally interrupted. An automatic limit switch prevents over-running of the load hook.

"FORTUNA" GRINDING SPINDLES

A line of spindles known as "Fortuna" designed especially for use in shops in which no grinding machine is installed has been placed on the market by the Coats Machine Tool Co., Inc., 110-112 W. 40th St., New York City. This line consists of a spindle intended for internal grinding, a second spindle for both face and internal grinding, and a third for vertical internal and face grinding. The spindles may be driven from a pulley similar to that illustrated, or by means

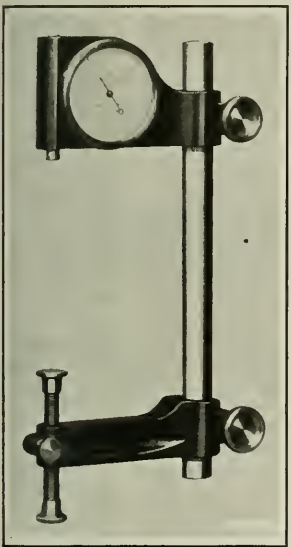


Internal- and Face-grinding Spindle placed on the Market by the Coats Machine Tool Co., Inc.

of a motor mounted on the clamping block. This block may be attached on the slide of a machine for feeding the grinding wheel across the work, it being especially suitable for use in connection with a lathe. The spindles are equipped with "Norma" ball bearings, and all attachments are readily interchangeable. The clamping block permits a quick reversing of the countershaft or the motor so as to enable work to be revolved to the left as readily as to the right. The construction of the attachment permits grinding wheels to be run at their maximum speeds.

HORSTMANN INDICATING CALIPER

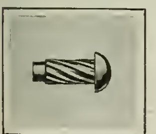
The extension-beam indicating caliper shown herewith is a modification of the indicating caliper placed on the market several years ago by the F. W. Horstmann Co., 196-210 Coit St., Irvington, N. J. The rear surfaces on the arms of the new instrument are machined flat, so that it may be used while lying on a flat surface. The device is employed for ascertaining the exact amount that work varies from a desired size. It is set by placing a piece of the desired length between the plunger of the indicator and the adjusting screw, and advancing the screw until the pointer of the indicator registers zero. Variation in the length of pieces can then be observed by noting the amount that the indicator pointer moves from the zero mark when pieces are placed between the screw head and the plunger. The distance between internal surfaces may be measured by reversing the arms on the beam. The beam is 6 inches long and ½ inch in diameter, but any necessary length can be substituted. Two of the classes of work for which the instrument is especially valuable are gaging across the face of large-diameter work in a lathe, or across wide pieces being machined on a planer.



Indicating Caliper made by the F. W. Horstmann Co.

PARKER NAMEPLATE "DRIVE-SCREW"

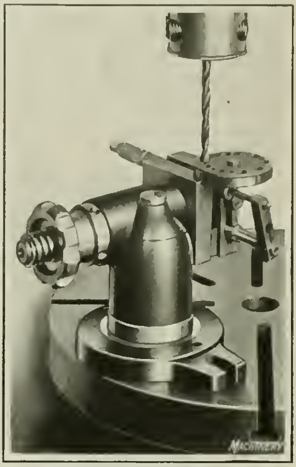
The "drive-screw" shown in the accompanying illustration was designed to present an easy and inexpensive method of permanently attaching nameplates, trademark plates, etc., to machine tools. The screw has a round head which is not slotted, threads of a very coarse lead, and a cylindrical pilot. In attaching a plate, holes slightly larger in diameter than the screw pilot are drilled into the part to which the plate is to be attached, and the screws are driven into place with a hammer. Owing to the fact that the screws are hardened and heat-treated, the threads readily cut their way into iron castings, and as the heads are not slotted, the screws cannot be easily removed in order to substitute another nameplate. This nameplate "drive-screw" is made by the Parker Supply Co., Inc., 793 E. 135th St., New York City.



Parker Nameplate Drive-screw

W. B. U. COMBINATION VISE, DRILL JIG AND MILLING FIXTURE

The W. B. U. Tool Co., 104 Harding St., Worcester, Mass., has recently brought out the combination vise, drill jig, and milling fixture here illustrated, which has been designed to hold work with accuracy. The vise is adapted for holding work on which two or more cuts are to be taken at different angles, and such operations can be accomplished without resetting the work. Both the jaw and swivel base are graduated through 360 degrees to facilitate angular settings. The equipment is especially suitable for use on machines where work can be tested with a square, directly from the work-table.

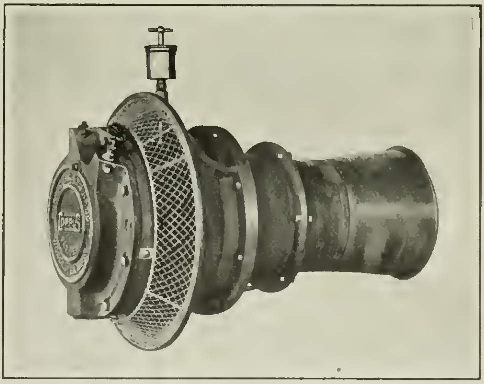


Combination Vise, Drill Jig, and Milling Fixture made by the W.B.U. Tool Co.

Part of the equipment is a solid drill bushing plate having eighteen holes ranging from 7/64 to ⅜ inch in diameter. The vise may be set for the drilling of round stock from 5/16 to 1 inch in diameter, which is held in a vee. By reversing the bushing plate, flat or square stock can also be drilled. The device is quickly adjusted by turning the screw. In filing work held in the vise, it is unnecessary for a toolmaker to remove the work frequently in order to ascertain whether it is being filed square.

COPPUS SCREW-BLADE PROPELLER BLOWER

A screw-blade propeller blower suitable for a variety of applications is being sold under the trade name of "Vano" by the Coppus Engineering & Equipment Co., Worcester, Mass. In the accompanying illustration this blower is shown arranged with a turbine drive, although an electric motor drive may also be supplied. Air is delivered from this blower in the same direction as that in which it enters. The principal feature is a stationary guide vane beyond the

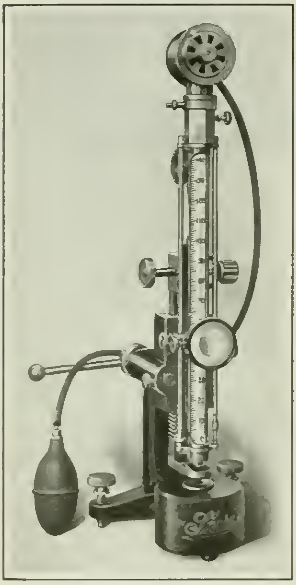


Screw-blade Propeller Blower brought out by the Coppus Engineering & Equipment Co.

propeller, which has individual blades that radially subdivide, without shock, the air current leaving the propeller. These blades, which have a curvature that increases in the direction of the propeller rotation, concentrate the air current and give it a further acceleration inside the stationary guide vane, so that a considerable portion of the pressure is produced in the latter. A large part of the end thrust is thus taken up by the stationary guide vane casing. The air streams into which the flow of air is subdivided by the blades rotate slightly as they leave the guide vane casing, and converge toward the axis so that the smallest section of the air flow is beyond the casing.

SHORE IMPROVED SCLEROSCOPE

A number of improvements have been made to the Model C scleroscope which has been manufactured by the Shore Instrument & Mfg. Co., Van Wyck Ave. and Carll St., Jamaica, N. Y., and the improved instrument is now known as "Model C-1." Among the new features is the provision of a special fine screen at the top which prevents dust from getting into the operating mechanism. A tungsten steel piston has been substituted for the leather piston previously supplied, the metal piston being unaffected by temperature and moisture and thus insuring a more uniform operation. The former rigid adjustments for the hammer hook mechanism have also been replaced by a flexible adjustment which greatly prolongs the life of the glass tube. The hammer hooks have also been provided with shock shoulders to eliminate breakage or misalignment of the parts. The improvements largely eliminate the disintegrating effects on the various members due to repeated shocks in testing and reduce the wear of parts.

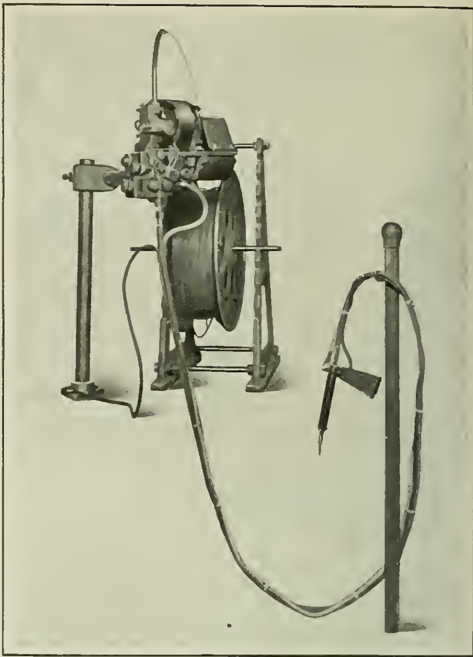


Improved Model C-1 Scleroscope made by the Shore Instrument & Mfg. Co.

GENERAL ELECTRIC SEMI-AUTOMATIC ARC-WELDING TOOL

A semi-automatic arc-welding tool has just been developed by the General Electric Co., Schenectady, N. Y., for use in conjunction with its automatic arc-welding head which was described in March, 1920, MACHINERY. This new device enables the operator to direct the arc as required by the conditions of the work. It is held by the operator, and acts as a guide for the electrode wire. The handle of the tool resembles that of an automatic pistol, and contains a switch for operating the control on the panel of the automatic welder, to start and stop the electrode wire movements.

Attached to the tool is a 10-foot length of flexible steel tubing, having an adapter on the other end for attachment to the automatic welding head. The electrode wire passes from the feed-rolls into the flexible tubing, and thence to the arc through a guide nozzle in the welding tool. With this new device, the automatic welder functions as usual, tending to hold the arc length constant, but the operator directs the arc as required by the particular job in hand.

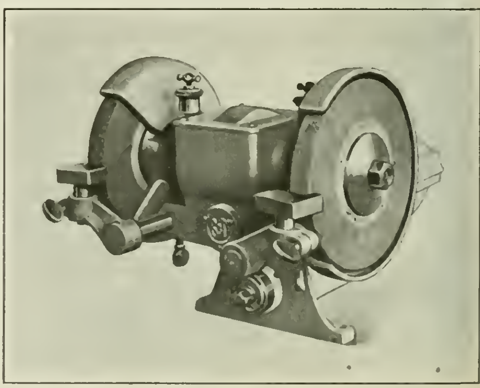


General Electric Arc-welding Equipment with Semi-automatic Lead

The field of application for this tool is work in which the seams to be welded are of irregular contour, or large work where the travel mechanism and clamping necessary for the full-automatic welder would be complicated. In many cases the edges of seams are not accurately prepared, so that there are gaps in some places and tight fits in others. The automatic welder cannot compensate for these conditions by varying the speed or by manipulation of the electrode, but with the semi-automatic arrangement this is taken care of.

BLACK & DECKER BENCH GRINDER

The 8-inch electric bench grinder shown in the accompanying illustration, which is a recent product of the Black & Decker Mfg. Co., Towson Heights, Baltimore, Md., is driven



Black & Decker Eight-inch Electric Bench Grinder by a ¾-horsepower motor of the universal type, similar to that supplied in portable electric drills manufactured by this company. The motor operates on either alternating or direct current. The grinding wheels are set well away from the motor casing and arranged to overhang the bench. This construction makes it possible to grind long pieces and odd shapes, and also enables the grinding wheels to be worn down to the clamping washers. The motor is air-cooled, the intake for the air being located 12 inches from the grinding wheels, a sufficient distance to eliminate the danger of grit being drawn into the machine. Grease is used as a lubricant throughout. This machine is supplied with one coarse and one fine grinding wheel, 8 inches in diameter and ¾ inch in width. Wheel guards, adjustable tool-rests, and an electric cable are also furnished as regular equipment.

NEW MACHINERY AND TOOLS NOTES

Nut Chamfering Machine: William H. Haskell Mfg. Co., Pawtucket, R. I. A machine made in two sizes for chamfering cold-punched square and hexagonal nuts, from ¾ to 2 inches. The nuts are placed in a chute at the front of the machine from which a feed-finger takes them, one at a time, and places them on a hardened steel die. Here they are chamfered and ejected into a truck or other receptacle.

Balancing Machine: Precision Balancing Machine Co., 3020 E. Franklin Ave., Minneapolis, Minn. A balancing machine adapted for a wide variety of work, including automotive crankshafts, flywheels, and parts readily mounted on arbors. It will receive bodies up to 24 inches in swing and 32 inches in length between bearings. The machine will give dynamic and static balance by two single corrections, individually measured and located near the ends of the body.

Portable Electric Grinding Machine: Arva Stroud, 327 Broadway, New York City. A portable electric grinding machine intended for use on any type of machine tool or in a vise for the accurate grinding of hardened parts. The machine is furnished in two models which are driven by ½- and 1-horsepower motors, respectively. The motors are of the universal commutator type operating on alternating or direct current. Grinding wheels 5 inches in diameter are supplied. The net weight of the machine is 22 pounds.

Cylinder Refinishing Machine: Bridgeport Cutter Works, Inc., 50 Remer St., Bridgeport, Conn. A portable electrically driven machine for reboring and refinishing automotive cylinders, which consists essentially of a sliding head supported on a guiding way carried on the top of the cylinder block by means of brackets. The guiding way may be adjusted in line with the center of the cylinder by means of an indicator. The sliding head carries a cutter-bar which is centered over each cylinder by the aid of an indicator.

* * *

RAILROAD RATES AND WAGES COMPARED

Data prepared by the Bureau of Railway Economics show that since 1915 the average increase in freight rates has been 78 per cent, while the total increase in wages of all classes of railroad employes has been 119 per cent. The figure given for the increase in freight rates is an average of all the schedules increased. It does not mean that the receipts for moving a given amount of freight actually increased by 78 per cent. On the contrary, the average receipts of the railroads per ton-mile increased from 0.722 cent in 1915 to 1.052 cents in 1920, or only 46 per cent, this being due to the fact that the rates were raised proportionately less on the classes of freight that are handled in the largest bulk by the railroads. The wage increase, on the other hand, was actually 119 per cent—the average annual compensation per employe having been increased from $830 to $1820 per year between 1915 and 1920. Hence the comparison should actually be based on a 46 per cent increase in ton-mile receipts by the railroads and a 119 per cent increase in wages.

INDUSTRIAL NOTES AND COMMENT

There have been considerable fluctuations in the iron and steel business during the past weeks, one week indicating a slightly increased output, partly due to an expectation of a reduction in freight rates, and another showing a slight falling off; but sufficient orders are on hand to keep the mills going at the present rate of production. There has been a much better demand from the railroads, orders for rails and cars demanding an increased output of the mills. The tinplate and sheet mills are particularly active. The ingot production during October was more than double that of July, according to reports from thirty companies to the American Iron and Steel Institute. Some of the independent companies in the Mahoning Valley are operating at 65 per cent capacity, the U. S. Steel Corporation averages 50 per cent, and the industry as a whole may safely be said to operate at from 40 to 45 per cent capacity. Several blast furnaces are preparing to resume operation in the Pittsburg district, and the export demand for steel, though still small, is better than at any previous time during the year.

The rumor of a merger of independent companies is becoming more persistent, and it is said that preparatory conferences have been held. The foreign trade in iron and steel and its products is mainly with non-European countries, Japan buying railway materials, sheets, and tinplate, while Argentina has placed large orders here for locomotives and other railway rolling stock and equipment.

Activity in the Automobile Industry

A very keen competition is expected in the automobile field next year, as the productive capacity is above the probable demand. The Department of Commerce reports improved outlook for exports of automobiles. A canvass made of the automobile industry indicates that it is now operating at from 30 to 50 per cent of normal capacity in the Detroit district, with the exception of the Ford plant, which is reported as operating at 80 per cent of its highest peak production. Reports indicate that farmers are buying more freely, both in the grain producing states and in the South.

During the first nine months of 1921, fifty-two passenger cars were reduced, on an average, nearly 20 per cent in price. The greatest reductions averaged 39 per cent for cars below $1000. For cars over $4000, the average reduction was 17 per cent. The average peak price of the fifty-two cars was $2344, and the average present price is $1890.

Railroad Traffic Indicating Increased Business

As is generally well known, the net earnings of the railroads have been quite satisfactory during recent months, due partly to the fact that the roads have spent less for maintenance than during the corresponding period of 1920. It is stated that nearly 200,000 freight cars are in need of repairs. On the whole, railway freight traffic has been quite satisfactory, and during one week in October, for the first time in 1921, the loadings of merchandise and miscellaneous freight (the group which includes manufactured goods) were heavier than in the corresponding week of 1920. The volume of traffic as a whole is now only about 10 per cent less than during corresponding periods in 1920.

Labor Conditions

A report of the Department of Labor and Industries in Massachusetts indicates better industrial conditions in New England, with unemployment from all causes reduced during three months from 25 to 20 per cent, and the amount of unemployment directly traceable to lack of work from 20 to 14.6 per cent. All the unemployment is not due to the industrial depression. The United States Department of Labor estimates that strikes and lockouts in the first half of the present year cost, in wages alone, $1,179,000,000. On the other hand, it is estimated that the direct wage loss due to unemployment because of lack of work amounts to about $4,000,000,000 a year.

STANDARDIZATION WORK OF THE GEAR MANUFACTURERS

In November MACHINERY in referring to the fall convention of the American Gear Manufacturers' Association, the comprehensive standardization program of the association was outlined. In addition to the standardization details there given, the association has formulated a program for the standardization of gearing materials and their treatment, electric railway and mine gearing, transmission gearing, and differential gearing. In order that the cooperation of engineers everywhere may be obtained, the details of this standardization program are given below. It is essential for any real standardization work in the gearing industry that the cooperation of the entire mechanical engineering field is obtained. Those who may desire to communicate with the association in connection with the standardization program should address B. F. Waterman, chairman of the general standardization committee, American Gear Manufacturers' Association, Brown & Sharpe Mfg. Co., Providence, R. I.

Standardization of Gearing Materials and their Treatment

(1) Carbon and alloy steel specifications—chemical and physical; (2) non-ferrous alloy specifications for the following purposes: bronze for spur and bevel gears, bronze for worm-gears, bronze for bushings, and brass for flanges of composition gears; (3) steel casting specifications—chemical and physical—in several carbon ranges for steels for use in casehardened, heat-treated, or untreated state; (4) gray-iron casting specifications—for gears only; (5) specifications of hardness limits which will be acceptable when purchasing bars, forgings, or castings of various chemical specifications; (6) consideration of burnt or badly overheated forgings; (7) recommended practice as to the hardening of hubs and bores to take ball and roller bearings; (8) recommended practice as to the combining of two gears or a gear and a clutch, in one piece; (9) recommended practice on under-cuts and reliefs to clear grinding wheels, and on the use of fillets and elimination of sharp corners; on the prevention of hardening trouble arising from keyways and oil-holes; and on obtaining clean threaded holes in hardened work; (10) recommended practice as to the hardening of bores and fork grooves of gears which slide on splined shafts; (11) recommended practice as to the prevention or control of shrinkage and warping in hardening; (12) report on methods of preventing scale, especially hard and adherent scale; (13) report on the economic factors governing the choice of bar stock, open-hammer forgings, drop-forgings, or upsetter forgings; (14) recommended practice for the inspection of forgings and castings—consideration of defects that call for rejection and those that call for a rebate; (15) recommended practice as to recording of heat numbers and the stamping of these numbers on gears to give the maximum of information without excessive complexity—proposal of standard A. G. M. A. system; (16) report on the design, construction, and operation of furnaces for the heat-treatment of gears; (17) report on pyrometry as applied to the gear industry, with recommendations; (18) report on microscopic examination of metals, as applied to the gear industry, with recommendations; (19) report on the testing of hardness; (20) recommended practice on the selection, test, and use of carburizing materials, and the design and use of carburizing pots; (21) recommended practice on "local" hardening as applied to gear work: (a) local carburizing, (b) local heating, (c) local quenching; (22) report on quenching mediums and quenching apparatus; (23) recommended practice as to depth of casehardening for different classes of gear work, giving consideration to the kind of steel, the tooth dimensions and the hardness; (24) report on researches on the relation of durability and wear of gears to hardness and other factors; (25) a standard nomenclature.

Standardization of Transmission Gearing

(1) Investigate the effects of Hotchkiss drive on transmission with and without slip joints on propeller shafts. Cooperate with Differential Committee on this work; (2) cooperate with other interested organizations to reduce to a minimum the number of bell housing sizes for unit power transmissions. In connection with this, the committee should work with the motor builders and the S. A. E. to establish reasonable manufacturing limits of parallelism and concentricity between flywheel, motor housing and transmission unit, power flange or clutch housing; (3) recommend proper center distances, width of face, pitch and pressure angles of gear teeth for a range of motor torques. Also cooperate with the Spur Gear Committee and the Metallurgical Committee in recommendation of steels; (4) investigate with all concerns who build transmissions, either for themselves or for the trade, any troublesome features in connection with either past or present construction, and report findings for the benefit of the A. G. M. A. in order to eliminate poor designs, either from trouble in the field or from manufacturing difficulties; (5) study and make recommendation for proper lubricants and proper methods of lubrication; (6) recommend proper shapes of gear blanks to reduce to a minimum manufacturing difficulties and heat-treating distortions; (7) recommend case wall thickness for the various types of transmissions and kinds of material; (8) work with the Tooth Form Committee in experimenting with and testing of any tooth form under consideration; (9) inspection.

Standardization of Differential Gearing

(1) Investigate effects of the Hotchkiss drive on differentials with and without slip joint on propeller shafts. Cooperate with Transmission Committee in this work; (2) investigate with all concerns who build differentials, either for themselves or for the trade, any troublesome features in connection with either past or present constructions and report findings for the benefit of the A. G. M. A. in order to eliminate poor designs either from trouble in the field or from manufacturing difficulties; (3) study and make recommendations for proper lubricants and proper methods of lubrication; (4) recommend proper shapes of gears to reduce to a minimum manufacturing difficulties and heat-treating distortions; (5) study the merits of close fitting differential inside gears and pinions, to reduce backlash to a minimum, tending to aid in reducing noise in rear axles, and establish limits based on a good manufacturing basis, in conjunction with the Spur and Bevel Gear Committees; (6) recommend properly designed mountings for differentials to insure load-carrying capacity to keep drive pinion and gear in proper mesh and correct alignment; (7) study effect of thrust on bevel drive pinion and also on bevel ring gear and recommend remedies to overcome any of the objectionable features, in conjunction with Bevel Gear Committee; (8) work with the Tooth Form Committee in experimenting with and testing of any tooth form under consideration; (9) possibility of the use of this committee in consulting way for the members of the A. G. M. A. who may require aid in solving some of their differential problems; (10) inspection in conjunction with the Inspection Committee; (11) cooperate with other interested organizations to reduce to a minimum the various types of differentials for automotive trucks, tractors, passenger cars, etc., to make for less models and greater production on those standardized.

Standardization of Electric Railway and Mine Gearing

(1) Nomenclature, symbols and formulas; (2) design of railway and mine gears in conjunction with other interested organizations; (3) tooth form in conjunction with Tooth Form Committee; (4) materials and treatments in conjunction with the Metallurgical Committee; (5) design of mountings; (6) lubrication.

PERSONALS

Walter E. Heibel, who for the last two years has been eastern district manager of the Wilmarth & Morman Co., Grand Rapids, Mich., has become connected with the New York office of the B. F. Sturtevant Co. at 52 Vanderbilt Ave.

Clyde E. Dickey, 233 Broadway, Woolworth Bldg., New York City, has been appointed sales representative for the Metropolitan District of New York City for the Peerless Drawn Steel Co., of Massillon, Ohio, manufacturer of cold-drawn screw stock, shafting and alloy steels.

C. H. Hobbs has been appointed assistant general manager of sales of the Detroit Seamless Steel Tubes Co., Detroit, Mich. Mr. Hobbs was connected with the Lackawanna Steel Co. for more than fourteen years, and for the last five years has been district representative in charge of the Detroit office.

Arthur G. Hertzler, who has been sales manager of the Bearings Co. of America, Lancaster, Pa., and connected with that firm in various capacities over a period of eighteen years, has left Lancaster, and will make his home in Salt Lake City, Utah. He has not yet announced his plans for the future.

F. T. Coup has been appointed district manager of the Cincinnati office at 20 E. 9th St., of the Wagner Electric Mfg. Co., St. Louis, Mo. Mr. Coup is well acquainted with the Wagner line of products, as he has been connected with the company for many years and was until recently in charge of its Milwaukee office.

Frank W. Trabold, for twenty years associated with J. H. Williams & Co., Brooklyn, N. Y., has terminated his connection with that company. Since 1909 Mr. Trabold has been successively sales manager, works manager, general manager, and vice-president. He is at present located at 30 Church St., New York City, but has not yet made definite plans for the future.

Henry R. Towne, chairman of the board of directors of the Yale & Towne Mfg. Co., and honorary member and former president of the American Society of Mechanical Engineers, has been elected honorary president of the Taylor Society. Mr. Towne is said to be the first engineer-executive to appreciate the genius of Frederick W. Taylor, the creator of scientific management.

J. H. Wilhelm, Lloyd E. Larson and John Cetrule, consulting engineers, 18 E. 41st St., New York City, have been elected president, vice-president, and secretary-treasurer, respectively, of the Triplex Machine Tool Corporation of New York, manufacturer of the Triplex line of combination machines. The new connection will not interfere in any way with their consulting engineering practice.

Fred E. Holtz has been appointed Milwaukee district representative of the W. A. Jones Foundry & Machine Co., Chicago, Ill., manufacturer of power transmitting machinery. Mr. Holtz assumes his duties immediately, making his headquarters in the First National Bank Building of Milwaukee. He has been associated with the company for the last two years, having been calling on Jones' customers in all lines of business throughout the United States.

Ernest Reich, formerly vice-president of the Hill Pump Valve Co., Chicago, Ill., and general manager of plant of the Chicago Pressed Steel Co., has recently returned from a seven months' survey of industrial conditions in Europe, and is now engaged in marketing domestic and foreign patents. Mr. Reich has also established connections for exporting novel manufacturing equipment, and would like to receive catalogues and quotations for such equipment, at his office 11 S. La Salle St., Chicago.

Leonard W. Kearns, for many years associated with the leather belting industry, has become affiliated with the sales organization of the Chicago Belting Co., Chicago, Ill. Mr. Kearns has been active in the leather belting business for twenty-two years, eighteen of which he was in the service of one company. He has been branch manager at Atlanta, Ga., Charlotte, N. C., and Chicago, Ill., and has sold belting throughout the United States and Cuba. He has a knowledge of the practical side of the industry, being a belting engineer, and has specialized in the belting requirements of saw mills, steel mills, woodworking plants, flour mills, and machine shops.

Stanley P. Rockwell, 65 Highland St., Hartford, Conn., has engaged in business for himself as a consulting metallurgist. Mr. Rockwell is a graduate of the Yale Scientific School and has had wide experience in the work which he is now undertaking, having been general foreman of heat-treatment and metallurgist of the New Departure Mfg. Co., Bristol, Conn., metallurgist with the E. F. Houghton Co., Philadelphia, Pa., district metallurgist and Captain of Ordnance of the United States Army, vice-president and general manager of the Weekes-Hoffman Co. of Syracuse, N. Y., and metallurgist of the Whitney Mfg. Co., Hartford, Conn. He will continue his association with the last-named company in an advisory capacity. Mr. Rockwell hopes to be able to serve the small concerns whose limited production does not warrant the continual attendance of a metallurgist. He is the inventor of the Rockwell hardness tester, and is also the author of a series of articles published in Machinery in 1920, under the title of "Carburizing and Casehardening," as well as other articles relating to heat-treatment.

OBITUARY

CHESTER L. LUCAS

Chester L. Lucas, advertising manager of Machinery for the Central West, died in Syracuse, N. Y., on November 3, following an operation for appendicitis, in the forty-first year of his age. Mr. Lucas became a member of Machinery's editorial staff in 1911, changing into the advertising department in 1918; and in both of these fields, differing widely, he achieved a marked success, due not only to his winning personality and sterling qualities of heart and mind, but to his unceasing efforts to serve his advertisers in practical ways. From all parts of the country have come to us letters showing the high regard in which he was held by his business friends.

Mr. Lucas was born in 1881 in Middleboro, Mass., educated in the public schools there and in Providence, and in 1899 moved to Bridgeport and entered the employ of the Schwerdtle Stamp Co. to learn the trade of engraving and die-sinking. After finishing his apprenticeship he went to work for the John Robbins Mfg. Co. of Boston, and afterward for the General Electric Co. in Lynn. While working at the General Electric plant he contributed a number of articles to Machinery on the subject of engraving and die-sinking. He was married in 1903 to Miss Ella M. Barnesa. His father and brother constitute the firm of J. L. Lucas & Son, Inc., of Bridgeport, in which firm he was financially interested. He was a 32nd degree Mason.

Mr. Lucas leaves a widow and three children, the eldest of whom is in the Exeter Preparatory School. To those with whom he was closely associated in Machinery's organization, who knew him so well and valued him so highly, his loss is a personal bereavement.

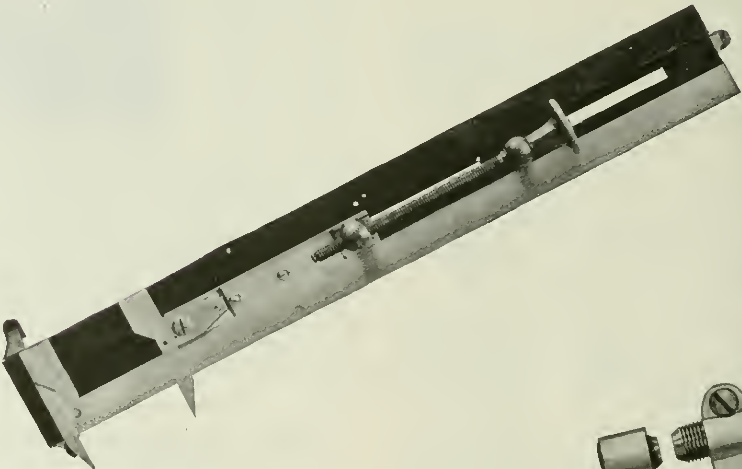
CIVIL SERVICE EXAMINATIONS FOR ENGINEERS, PHYSICISTS AND TECHNOLOGISTS

The United States Civil Service Commission announces open competitive examinations to fill vacancies in the Bureau of Standards. These include examinations for engineers, physicists, and technologists with salaries of from $2800 to $4000 a year; for associates with salaries of from $2000 to $2800 a year; and for assistants with salaries of from $1500 to $1800 a year. Applicants may qualify in electrical engineering, mechanical engineering, civil engineering, chemical engineering, ceramic engineering, radio engineering, engineering of materials, and any other specialized line of engineering. Those desiring to take the examination should apply for Form 2118, stating the title of the examination desired, to the Civil Service Commission, Washington, D. C. Examinations are also announced for junior engineers and junior technologists on January 11, March 8, and May 17. The salary for these positions is from $1200 to $1500 a year, and applicants should apply for Form 1312 to the Civil Service Commission, Washington, D. C.

THE FIRST PRECISION TOOLS IN AMERICA—1851

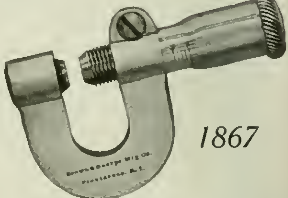
WHEN Joseph R. Brown of the Brown & Sharpe Mfg. Co. gave the world the invention of the Vernier Caliper, he established, 70 years ago, a World-wide Standard of Accuracy. In 1867, Mr. Brown and Lucian Sharpe introduced, in America, the first Micrometer Caliper.

The steadfast and satisfactory performance of these fine tools is a tradition maintained and protected by the conscientious efforts of skilled workmen.



1851

The first and original Vernier Caliper, so far as is known, invented by Mr. J. R. Brown in 1851—over 70 years ago.



1867

"The Pocket Sheet Metal Gauge." The first Micrometer Caliper in America—over 50 years ago—a Brown & Sharpe Product.

BROWN & SHARPE MACHINISTS' TOOLS

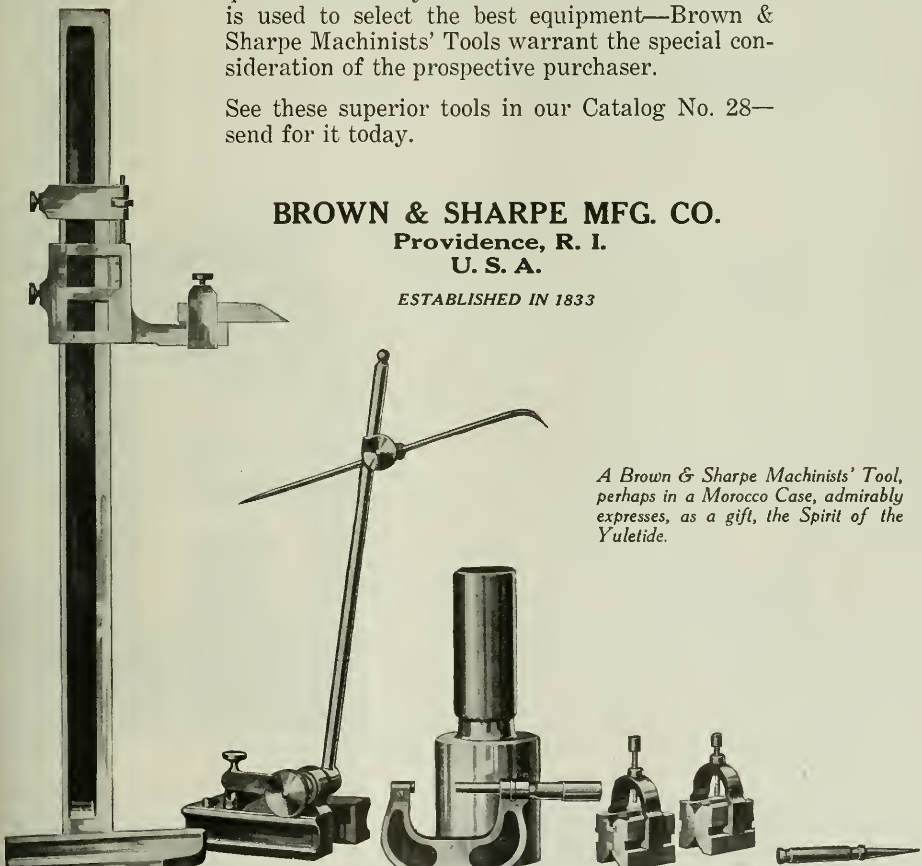
represent the accuracy and fine workmanship which only pride in product and experienced master craftsmen can accomplish.

When productive and efficient accuracy are as requisite to industry as now—when extreme caution is used to select the best equipment—Brown & Sharpe Machinists' Tools warrant the special consideration of the prospective purchaser.

See these superior tools in our Catalog No. 28—send for it today.

BROWN & SHARPE MFG. CO.
Providence, R. I.
U. S. A.

ESTABLISHED IN 1833



A Brown & Sharpe Machinists' Tool, perhaps in a Morocco Case, admirably expresses, as a gift, the Spirit of the Yuletide.

NEW BOOK ON BEARINGS

Bearings and Bearing Metals. 120 pages, 6 by 9 inches; 44 illustrations. Published by The Industrial Press, 140-148 Lafayette St., New York City. Price, $1.

Few subjects related to the design or construction of machinery are of greater importance than the subject of bearings. All classes of mechanisms have bearings of some kind, and bearings that are properly designed and constructed are a necessity. As every experienced mechanic knows, a poor bearing may tie up a machine or even cause an entire plant to shut down temporarily. Owing to the importance of this subject, designers and mechanics in general should understand the fundamental principles governing bearing design and should know what approved types are in common use on different classes of machinery.

This treatise deals exclusively with plain bearings, ball and roller bearings being covered in another book of this series. The types of plain bearings illustrated were selected to show how designs are modified to suit different conditions, and also practical methods of arranging bearings to insure adequate lubrication and thorough protection against the entrance of foreign material liable to injure the bearing surfaces. The designs illustrated were taken from actual practice and have proved satisfactory when properly constructed and applied. This treatise contains, in addition to the features mentioned, condensed information on compositions of various bearing metals, their properties, the classes of service to which different bearing alloys are adapted, and the general methods of procedure in designing plain bearings to meet different service conditions.

The book is divided into four separate chapters, the first one covering bearings of different types used in machine construction. The second deals with bearing metals, explaining the characteristics of different alloys and giving the composition of those most commonly used. The third chapter takes up the methods of lubricating bearings, and the last chapter deals specifically with the design of plain bearings.

STATEMENT OF THE OWNERSHIP, MANAGEMENT, ETC., REQUIRED BY THE ACT OF CONGRESS OF AUGUST 24, 1912

of Machinery, published monthly at New York, N. Y., for October 1, 1921.

State of New York }
County of New York } ss.

Before me, a Notary Public in and for the state and county aforesaid, personally appeared Matthew J. O'Neill, who, having been duly sworn according to law, deposes and says that he is the treasurer and general manager of The Industrial Press, Publishers of Machinery, and that the following is, to the best of his knowledge and belief, a true statement of the ownership, management, etc., of the aforesaid publication for the date shown in the above caption, required by the Act of August 24, 1912, embodied in section 443, Postal Laws and Regulations, printed on the reverse of this form, to wit:

1. That the names and addresses of the publisher, editor, managing editor, and business managers are: Publisher, The Industrial Press, 140-148 Lafayette St., New York; Editor, Erik Oberg, 140-148 Lafayette St., New York; Managing Editor, None; Business Managers, Alexander Luchars, President, 140-148 Lafayette St., New York, and Matthew J. O'Neill, Treasurer and General Manager, 140-148 Lafayette St., New York.

2. That the owners of 1 per cent or more of the total amount of stock are: The Industrial Press; Alexander Luchars; Alexander Luchars, Trustee for Helen L. Ketchum, Elizabeth Y. Urban, and Robert B. Luchars; Matthew J. O'Neill; Louis Pelletier; and Erik Oberg. The address of all the foregoing is 140-148 Lafayette St., New York.

3. That there are no bondholders, mortgagees, or other security holders.

4. That the two paragraphs next above, giving the names of the owners, stockholders, and security holders, if any, contain not only the list of stockholders and security holders as they appear upon the books of the company but also, in cases where the stockholder or security holder appears upon the books of the company as trustee or in any other fiduciary relation, the name of the person or corporation for whom such trustee is acting, is given; also that the said two paragraphs contain statements embracing affiant's full knowledge and belief as to the circumstances and conditions under which stockholders and security holders who do not appear upon the books of the company as trustees, hold stock and securities in a capacity other than that of a bona fide owner; and this affiant has no reason to believe that any other person, association, or corporation has any interest direct or indirect in the said stock, bonds, or other securities than as so stated by him.

MATTHEW J. O'NEILL, Business Manager

Sworn to and subscribed before me this 27th day of September, 1921.

(SEAL) WILLIAM E. BACON,
Notary Public, Kings County No. 444
Kings Register No. 3109
New York County No. 79
New York Register No. 3047
(My commission expires March 30, 1923.)

COMING EVENTS

December 1-3—Annual meeting of the Taylor Society in the Engineering Societies' Bldg., 29 W. 39th St., New York City. Secretary, Harlow S. Pearson, 29 W. 39th St., New York City.

December 6-9—Annual convention of the American Society of Mechanical Engineers in the Engineering Societies' Bldg., 29 W. 39th St., New York City.

January 11-14—Annual meeting of the Society of Automotive Engineers in New York City. Secretary, Coker F. Clarkson, 29 W. 39th St., New York City.

April 19-20—Annual meeting of the National Metal Trades Association in New York City; headquarters, Hotel Astor. Secretary, Homer D. Sayre, Peoples' Gas Bldg., Chicago, Ill.

April 24-29—Annual convention and exhibit of the American Foundrymen's Association in Cleveland, Ohio; headquarters, Cleveland Public Hall, Lakeside Ave. and E. 9th St. Secretary, C. E. Hoyt, 140 S. Dearborn St., Chicago, Ill.

May 8-11—Spring meeting of the American Society of Mechanical Engineers in Atlanta, Ga. Assistant Secretary (Meetings), C. E. Davies, 29 W. 39th St., New York City.

NEW BOOKS AND PAMPHLETS

Time Study and Job Analysis. By William O. Lichtner. 397 pages, 6 by 9 inches. Published by the Ronald Press Co., 20 Vesey St., New York City. Price, $6.

This work, dealing with time study and job analysis, is a timely one, in view of the present general interest in the question of reducing costs and increasing production. The aim of the book is to explain the practical application of time study and job analysis in simple non-technical terms. Special emphasis is placed upon the relation of standardization work to problems of management. The author shows how job standardization will increase productive ability, decrease labor turnover and enable manufacturing plants to earn greater returns. He shows how the work of standardization can be handled by training the clerical force already employed, and explains how to make the preliminary study, how to take the time study data, how to determine the rates on operations, and how to apply standardization. He also discusses job standardization in relation to industrial problems. There are six appendixes to the book, in which are given concrete examples of job analyses.

Drawing-room Practice. By Frank A. Stanley. 253 pages, 6 by 9 inches. Published by the McGraw-Hill Book Co., New York City. Price, $2.50.

The making of drawings, from the simplest constructions to complete assembly and working drawings of various classes, is dealt with in this book. Because of the difficulty often experienced by students in visualizing the parts to be drawn, use has been made of photographic views of different classes of machine parts, together with actual working drawings. Besides material for the beginner, chapters are included for experienced draftsmen regularly engaged in the production of working drawings, as, for example, the chapters dealing specifically with tool drawings and limit dimensions on working drawings. The thirteen chapters in the book treat of the subject under the following headings: Drawing Instruments and their Uses; Projection; Practical Applications of the Principles of Projection; Development of Surfaces—Intersections; the Helix and its Applications; Screw Threads in their Conventional Forms; Showing Detail Parts—Sections; Parts and Sections in Assembly Drawings; Working Drawings; Working Drawings of Small and Medium Sized Parts; Tool Drawings; Limit Dimensions on Drawings; and Isometric and Oblique Drawings—Shop Sketches.

Machine Drawing. By Carl L. Svensen. 214 pages, 6 by 9 inches; 388 illustrations. Published by the D. Van Nostrand Co., 8 Warren St., New York City. Price, $2.25.

This book has been prepared as a text book for technical students and draftsmen who have had previous instruction in mechanical drawing but who desire to take up advanced work. It is intended to serve as a guide for the development of an understanding of the relation of machine drawing to engineering. The text is made as brief as a clear presentation of the subject matter permits. A chapter on elementary principles is given as an introduction to the course and for review purposes. Working drawings, drafting-room practice, and idiomatic expressions of the engineering language are discussed, following which there is a chapter on the principles and practice of dimensioning. A study of the common machine details, empirical machine design, jigs and fixtures, etc., is included. About two hundred problems are presented to be worked out by the student, and these are conveniently grouped in the last chapter. The necessary instructions and references to the text are given to enable the student to work out any of the problems. The problems are presented by lay-outs or other specifications so that the instructor is relieved of the preliminary details which ordinarily arise in assigning machine drawing studies.

Waste in Industry. 409 pages, 6 by 9 inches. Published by the Federated American Engineering Societies, Washington, D. C. Sole Selling Agent, McGraw-Hill Book Co., Inc., New York City. Price, $4.

This book comprises a report of the Committee on Elimination of Waste in Industry appointed by the Federated American Engineering Societies to investigate causes of waste in industry. The report is the result of five months of intensive study. It covers an analysis of waste in six typical branches of industry, as follows: Building industry, men's clothing manufacturing, shoe manufacturing, printing, metal trades, and textile manufacturing. The report on the metal trades industry, which is of particular interest to the machine tool field, was written by Fred J. Miller, assisted by William B. Ferguson, and covers present unemployment, extent of the industry, and major causes of waste. It was found that the principal causes of waste are instability of labor employment; inefficient management; restrictive labor organization rules or customs; waste of materials through the lack of a well organized inspection system or lack of training of workers; and lack of thorough research work. In compiling the material covering the metal trades' industry, thirty-two plants were visited and field reports were made out for seventeen plants. In addition to the field reports made in the six industries mentioned, general reports are included on unemployment, strikes and lockouts, legal machinery for settling disputes, industrial accidents, health of industrial workers, eye conservation, and purchasing and sales policies. These general summaries were made from available information compiled by statisticians, economists, and others.

NEW CATALOGUES AND CIRCULARS

New Departure Mfg. Co., Bristol, Conn. Sheet 140 FE for loose-leaf binder, showing application of New Departure ball bearings in can seamers.

R. G. Haskins Co., 27 S. Desplaines St., Chicago, Ill. Circular outlining the constructional features of the Haskins die-filing machine, which is designed to eliminate the delay and expense of filing dies, templets, tools, etc., by hand.

Truscon Laboratories, Detroit, Mich., are issuing a monthly publication known as "The Maintenance Engineer," treating of such maintenance problems as rustproofing steel, protecting concrete against moisture, waterproofing processes, etc.

Sebastian Lathe Co., Cincinnati, Ohio. Catalogue 26, illustrating and describing the Sebastian line of engine lathes which includes two types, the Type S lathe being made in sizes of 13, 15, and 18 inches, and the Type M in 13- and 15-inch sizes.

Benjamin E. Jarvis, Inc., Newark, N. J. Pamphlet entitled "Right to the Line," illustrating the Jarvis portable motor-driven bench band saw for use in automobile body factories, pattern-making shops, manual training schools, and other places requiring a wood-cutting saw.

E. Horton & Son Co., Windsor Locks, Conn., is publishing a series of drill chuck circulars containing descriptive material covering the Horton-Morrow hand-operated ball bearing drill chuck, Horton geared drill chucks with hardened bodies, and Horton two-jaw drill chucks.

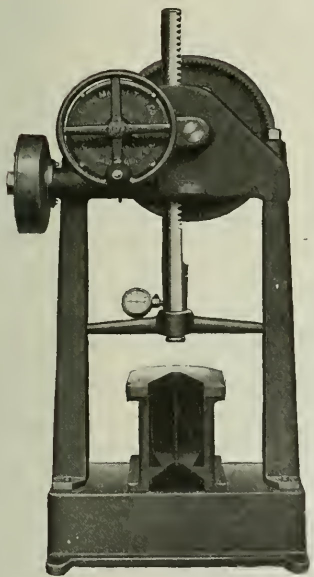
Take Us Into Your Confidence!

We frequently run across some peculiar job that can be done on the

LUCAS
Power Forcing Press

better than on any other machine.

If you have any jobs requiring pressure let us look them over, maybe we can help.



Illustrated Circular
Tells the Whole Story

WE ALSO MAKE THE
"PRECISION"

BORING, DRILLING AND MILLING MACHINE

LUCAS MACHINE TOOL CO. NOW AND ALWAYS OF **CLEVELAND, OHIO, U.S.A.**

FOREIGN AGENTS: Alfred Herbert, Ltd., Coventry. Societe Anonyme Belge, Alfred Herbert, Brussels. Aux Forges de Vulcain, Paris. Allied Machinery Co., Turin, Barcelona, Zurich. Benson Bros., Sydney, Melbourne. V. Lowener, Copenhegen, Christiania, Stockholm. R. S. Stokvis & Zonen, Rotterdam. Andrews & George Co., Tokyo.

Ilg Electric Ventilating Co., 2850 N. Crawford Ave., Chicago, Ill. Circular entitled "Correct Ventilation—That's What Our Men Needed," showing the application of Ilg electrically driven blowers and fans for the ventilation of factories, offices, laboratories, etc.

Smalley-General Co., Inc., Bay City, Mich. Circular containing a number of time studies showing the time required for producing six different parts on the Smalley-General No. 23 thread milling machine. A time study is also given of the threading of a rotary tool joint on the Smalley-General No. 1 thread miller.

Ingersoll Milling Machine Co., Rockford, Ill. Circular illustrating and describing a special heavy Ingersoll adjustable-housing milling machine designed for large and heavy work, the main bed of the machine being 27 feet long, the width over all 31 feet 10 inches, the over-all height 15 feet 4 inches, and the weight 150,000 pounds.

Pawling & Harnischfeger Co., 38th and National Aves., Milwaukee, Wis. Bulletin descriptive of the P & H No. 6 radial wall drill, which has been designed to meet the demand for a simple machine for drilling, reaming, and countersinking large unwieldy pieces, such as structural shapes, boiler plates, long beams and similar bulky objects.

Oilgear Co., 60 Twenty-seventh St., Milwaukee, Wis. Catalogue treating of variable-speed hydraulic power transmissions and illustrating installations of these drives on different types of machines. The Oilgear feed control system comprises a variable delivery oil-pump driven from any available source of power and an oil-motor driven by pressure from the pump.

Whiting Corporation, Harvey, Ill. Catalogue 158 (superseding No. 151) illustrating and describing Whiting standard crane designs, including electric traveling cranes, bucket-handling cranes, gantry cranes, jib cranes, pillar and bracket cranes, and lifting attachments. Tables of clearances for electric traveling cranes and for hand-power cranes are included.

Westinghouse Electric & Mfg. Co., East Pittsburg, Pa. Leaflet 3665, containing data on motors for elevator service, including formulas for selecting motors for this class of service. Leaflet 1732, illustrating and describing enclosed floating switches used on motor-operated pumps for automatically maintaining a water level in open tanks. Leaflet 1950, discussing the advantages of electric drive for power pumps.

Davis-Bournonville Co., Jersey City, N. J. Circular illustrating and describing the Davis-Bournonville new garage and small machine shop welding torch and carrying case outfit. This equipment affords the small shop a convenient means for repairing broken steel, cast-iron, aluminum, copper, brass, and other metal parts. Instructions for setting up and adjusting the apparatus for welding are included.

Stanley P. Rockwell, 65 Highland St., Hartford, Conn., consulting metallurgist and specialist in the heat-treatment of steel, has published a circular containing questions and answers intended to give prospective clients an idea of the work in which he is engaged, and his previous experience. The circular also reproduces a number of letters of recommendations from firms in the metal-working and allied industries.

Chicago Pneumatic Tool Co., 6 E. 44th St., New York City. Bulletin 710, describing the details of construction of the Chicago pneumatic dry vacuum pumps which are made in steam-, belt-, and motor-driven styles. Tables of capacities, speeds, and general dimensions are given for the different classes of machines produced. Special publication No. 674, giving complete specifications for pneumatic hammers, drills, grinders, rammers, and air hoists.

Vanadium-Alloys Steel Co., Latrobe, Pa., is distributing to the trade a reference card containing suggestions for the tool hardener. The card is 8½ by 11 inches in size, made of heavy cardboard and is provided with a cord so that it can be hung on the wall of the hardening room or the tool-room. On the front of the card are given thirty-seven "tips" for the tool hardener, and on the back are listed the various grades of tool steel made by the company.

Gardner Machine Co., Beloit, Wis., manufacturer of disk grinding and polishing machinery and accessories, has published a new sixteen-page booklet containing complete instructions for the proper setting up and use of the Gardner improved abrasive disk. This pamphlet will undoubtedly prove of use to all who are using this improved disk. Two-color circular entitled "The Gardner Improved Abrasive Disk," treating of a heavy abrasive disk manufactured by this company.

Smith & Mills Co., Cincinnati, Ohio. Catalogue 2, containing specifications of the different sizes of pillar type shapers made by this company. The plain crank shapers are made in three sizes of 12, 14, and 16 inches; the back-geared cone drive crank shapers in 16-, 20-, and 25-inch sizes; and the back-geared single-pulley drive shapers in sizes of 28 and 32 inches. The pamphlet also contains a detailed description of the various parts of the machines, and the attachments supplied.

Precision & Thread Grinder Mfg. Co., 1 S. 21st St., Philadelphia, Pa. Circular describing in detail the method of setting and operating the precision thread lead variator, which is used on lathes in conjunction with the multi-graduated precision grinder of this company's manufacture for producing threads with precision leads. By the use of the variator, leads can also be elongated sufficiently to compensate for shrinkage in hardening, and metric threads or threads of unusual lead can be cut.

Vacuum Oil Co., 61 Broadway, New York City. Booklet containing information compiled by the technical department of the company, covering the principle, construction, operation, and lubrication of the surface-ignition type of oil engines. Booklet containing technical data on the mechanical principles, construction, operation, and lubrication of stationary steam engines, as well as information on boiler plant and steam production. Copies of these books will be sent to those interested upon request.

National Acme Co., Cleveland, Ohio. Calendar for November 1921-November 1922 containing on each page, calendar for the current month and the preceding and following months as well as a view of the machines and tools made by this company, including Acme multiple-spindle automatic screw machines, "Namco" self-opening die-heads, Gridley single-spindle automatic turret lathes, "Namco" plain and castellated milled nuts, screw products, "Namco" collapsing taps, and Gridley piston and piston-ring machines.

Collis Co., Clinton, Iowa. Bulletin A, illustrating and describing the "Wonder" quick-change chuck for drilling and tapping machines. Price lists of the chucks, collets, and bushings are included. Bulletin E, containing price lists and capacities of Collis drill chuck arbors which are made to fit any size drill chuck requiring an arbor, and which are furnished with standard taper shanks, Brown & Sharpe, straight, or special tapers. Catalogue 10, containing dimensions and price lists of "Use-em-up" drill sleeves and sockets, drill drifts, lathe centers, lathe bushings, and arbors.

Garrison Machine Works, Dayton, Ohio. Catalogue illustrating and describing the construction and workmanship of the Garrison precision pitch-line control gear chucks, by means of which spur, helical, internal, sprocket, and bevel gears are automatically chucked true with the pitch diameter, thus insuring concentricity of the gear, regardless of errors in turning or mounting on the arbor of hobbing or generating machines. Specifications are given for the different styles of chucks. Circular of Garrison gear chucks, showing how the use of these chucks enables production to be increased and reduces the size of the scrap pile because of the precision control.

Simmons Method-Hob Co., Second St. and Duncannon Ave., Philadelphia, Pa. Catalogue containing tables of sizes and prices for Simmons method-hobs, which are provided with generated teeth of different forms for hobbing gears of various types. The tables give data for hobs used on Adams-Farwell machines, Barber-Coleman No. 12 machines, Lees-Bradner main cutter-arbors, Lees-Bradner fast cutter-head machines, Gould & Eberhardt machines, and Schuchardt & Schutte machines. Tables are also given of dimensions for B & S standard 14½-degree gear tooth parts, gear shaper 14½-degree system, gear shaper stub tooth system, and gear tooth and hob tooth parts for the Simmons standard involute system.

National Tube Co., Pittsburg, Pa. Bulletin 13, treating of National hammer-weld pipe. This circular contains a detailed description of the manufacture of lap-weld pipe 24 to 96 inches in diameter by hammer-welding illustrated with views showing the various steps in the process. Following the article on manufacture is an outline of the characteristics of hammer-weld pipes, including physical properties, bursting and collapsing strength, carrying capacity, and comparative discharge rates. The bulletin also discusses installation advantages, protective coatings, joints, and uses of hammer-weld pipe. Complete specifications of the different sizes are given, as well as tabular material and formulas relative to the flow of water in pipes.

Garrison Gear Grinder Co., Dayton, Ohio. Circular describing the features of construction of the Garrison gear grinder, which is designed for generating and grinding the teeth of hardened gears. By the use of this machine, tooth contours of any pressure angle can be generated, the correct contour and size being automatically produced after the diamonds are set and the wheel dressed to grind teeth of the desired size and pressure angle. The advantages claimed for this machine are use of only one wheel; elimination of precision adjustments; economy and strength of wheel; generation of teeth of correct contour and size; elimination of heat; accurate indexing of work; simplicity of operation; durability; and elimination of finishing cuts ordinarily taken on gear-cutting machines.

Eastern Machine Screw Corporation, 23-43 Barclay St., New Haven, Conn. Catalogue descriptive of the H & G self-opening die-heads, containing 96 pages of material, completely indexed, and approximately 51 illustrations. The book is wider in scope than a regular catalogue, containing also data which should be useful to the man working out threading problems. It describes in detail the features of construction of the H & G die-heads, and gives sizes and capacities of the four types, which comprise the Style A rotating die-head, the Style B "Ford Special," the Style C non-rotating type, and the new Style D die-head for use on Brown & Sharpe automatics. The single-spindle and double-spindle H & G threading machines are also described. A special section is devoted to the chasers for H & G die-heads, and information on ordering the heads and chasers is included. Operating instructions are given, as well as complete instructions for grinding chasers, the latter being a new feature of this edition of the catalogue. Another of the products illustrated and described is the H & G chaser grinder. The last section of the book entitled "Useful Information" contains data pertaining to standard threads, decimal equivalent tables, and tables giving weights of cold-drawn steel screw stock, and cutting speeds.

TRADE NOTES

Seneca Falls Foundry Co. has recently rented the foundry of the Seneca Falls Mfg. Co., Inc., Seneca Falls, N. Y., manufacturer of "Star" engine lathes and "Short-cut" lathes.

Peerless Machine Co., 1611 Racine St., Racine, Wis., announces that a substantial reduction has been made in the price of Peerless high-speed saws, effective October 20. Revised price lists have been issued.

William S. Walker Co., Park Bldg., Pittsburg, Pa., advertising agent, has opened an office at 340 Leader-News Bldg., Cleveland, Ohio, which will operate for the present as a sales office and by the first of the year will be used as a service office.

Cincinnati Hy-Speed Machine Co., Cincinnati, Ohio, has made an exclusive selling arrangement with the Niles-Bement-Pond Co., 111 Broadway, New York City, covering the full line of "Hy-speed" products. Circulars of "Hy-speed" drilling and automatic tapping machines are now ready for distribution.

Joseph T. Ryerson & Son, Jersey City, N. J., have moved their general offices from 30 Church St., New York City, to their plant office building, West Side Ave., Jersey City, and request that all correspondence be sent to that address. The company will continue to maintain its sales and export offices at 30 Church St.

Loy & Nawrath Co., 21 Runyon St., Newark, N. J., manufacturer of power brakes, squaring shears, miter presses, and forming and miter dies, has opened a New York office in the Hudson Terminal Bldg., 30 Church St., Room 1922. The telephone number is Cortland 6297. All correspondence should be addressed to the New York office.

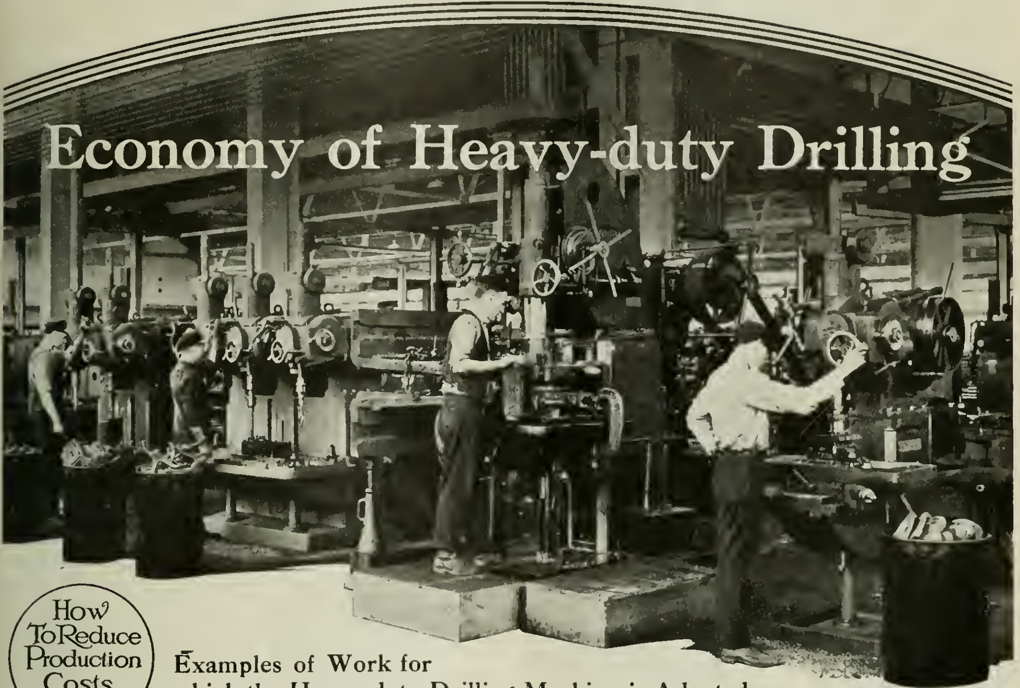
Coats Machine Tool Co., Inc., World's Tower Bldg., 110 W. 40th St., New York City, has obtained the exclusive agency in the United States for the original Hirth minimeter and "Fortuna" internal and face grinding spindles. The supply of Hirth minimeters in this country was discontinued at the outbreak of the war in 1914, and users will be glad to know that they can now obtain these instruments in the United States.

Timken Roller Bearing Co., Canton, Ohio, was one of the exhibitors at the National Exposition of Mines and Mining Equipment, held in conjunction with the recent convention of the American Mining Congress in Chicago. The Timken exhibit showed the application of tapered roller bearings in the mining industry. Mine car axles equipped with Timken tapered roller bearings were features of the exhibit, and samples of bearings were also shown.

Arrow Machinery Co., 234 N. Third St., Philadelphia, Pa., has been organized to deal in machine tools, shop equipment, and small tools, and would like to receive catalogues, price lists and dealers' discount sheets from manufacturers. W. A. Heilprin, head of the company, has been a manufacturer of sheet-metal specialties for many years, and was maker of the "Columbian Safety" air gun. He was also manager of the Metalform Tool & Stamping Co., manufacturer of jigs, fixtures, tools, and dies.

Rockford Tool Co., 2400 Eleventh St., Rockford, Ill., has appointed the Crane Machinery Co., 501 Morgan Bldg., Buffalo, N. Y., exclusive distributor of the Sundstrand 9-inch manufacturing lathe in the Buffalo territory. The Crane Machinery Co. will also represent the Rockford Milling Machine Co. in Buffalo. The Aumen Machinery Co., 107 E. Lombard St., Baltimore, Md., has been appointed exclusive distributor for the products of the Rockford Milling Machine Co and the Rockford Tool Co. in the Baltimore territory.

Wetmore Mechanical Laboratory Co., 129 Michigan St., Milwaukee, Wis., which was organized in 1915 by Charles P. Wetmore and P. B. Rogers is again actively engaged in engineering and manufacturing work. This company designed and manufactured the Wetmore inserted-blade expanding reamer which was used in the production of shells during the war, and later developed commercial reamers of this type. The company will now devote its efforts to developing mechanical devices and to perfecting manufacturing methods, including jigs, fixtures, and tool work; it is also handling contract manufacturing work, as well as die and screw machine work. The president of the company is Charles P. Wetmore, and the secretary and treasurer, P. B. Rogers. Mr. Wetmore will be in charge of the mechanical work.



Economy of Heavy-duty Drilling

How To Reduce Production Costs ?

Examples of Work for which the Heavy-duty Drilling Machine is Adapted

By FRED R. DANIELS

THE heavy-duty manufacturing type of drilling machine is especially useful as a production machine when accuracy is one of the main considerations. In this type of machine the work is located on a substantial foundation so that it will withstand the thrust produced by the powerful drive. The present article deals with the use of The Colburn Machine Tool Co.'s heavy-duty drilling machine for work where heavy cuts are required. This machine is built either in single units or in gangs, and the examples here given include both types.

The two-spindle machine is particularly suited to machining work such as motor-truck axles, on account of the possibility of adjusting one spindle unit so that the center distance will agree with the spacing of the holes in opposite ends of the work, thus eliminating the necessity of reversing the work. One operator can handle the work alone. Fig. 1 illustrates the application of a two-spindle Colburn heavy-duty drilling machine for machining truck axles in the plant of the Timken Detroit Axle Co., Detroit, Mich. The operations consist of drilling and reaming the 1⅛-inch diameter holes at each end and counterboring a large hole in the lower arm of the steering-knuckle yoke. These axles are produced at the rate of four per hour. The arrangement for adjusting the center distance in these machines, when handling work of this class, is illustrated in Fig. 3. The dotted outline at the base shows the position when the minimum center distance of 44 inches is obtained. This may be increased to a maximum of 63 inches by simply turning the handwheel that actuates the right-hand unit through the medium of worm-gearing.

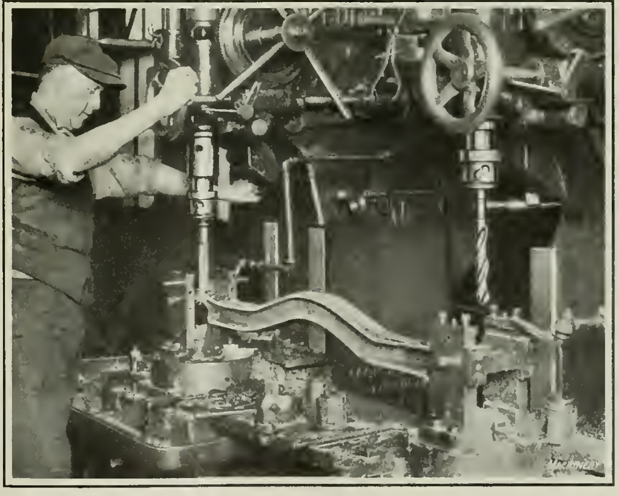


Fig. 1. Two-spindle Drilling Machine machining Motor-truck Axles

The three-spindle No. 2 Colburn manufacturing drilling machine illustrated in Fig. 5 is employed by the Tokheim Oil Tank & Pump Co., Fort Wayne, Ind., for machining cast-iron pump cylinders. The operations consist of boring, reaming to 3¾ inches

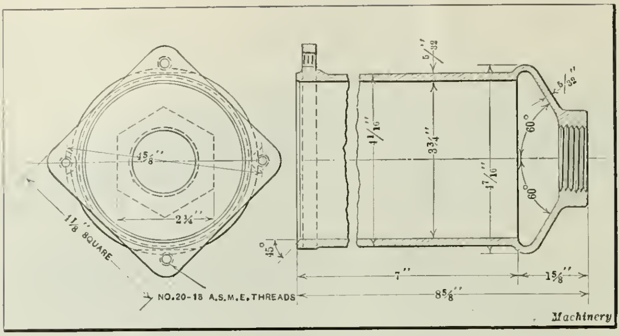

Fig. 2. Pump Cylinder machined with Set-up illustrated in Fig. 5

diameter, and facing the open end of the cylinder. A detail view of this cylinder is shown in Fig. 2, from which the nature of the work performed may be better understood. From Fig. 5 it will be seen that the cylinders are chucked in special sliding fixtures so that after the hole has been bored under the first spindle, the fixture may be slid forward to an auxiliary table, which carries it to the right, and it is then slid back under the second spindle for reaming. This arrangement enables the operator to keep the three spindles constantly at work and to so time the feed of each spindle that as soon as the work has been faced under the third spindle it can be removed and replaced with a rough casting, which is transferred to the first spindle to undergo the same series of operations. The track on which the fixture carriages ride extends at the end of the machine a sufficient distance to permit the end carriage to clear the end spindle entirely when unloading, so that the fixture carrying the reamed casting may be advanced for facing.

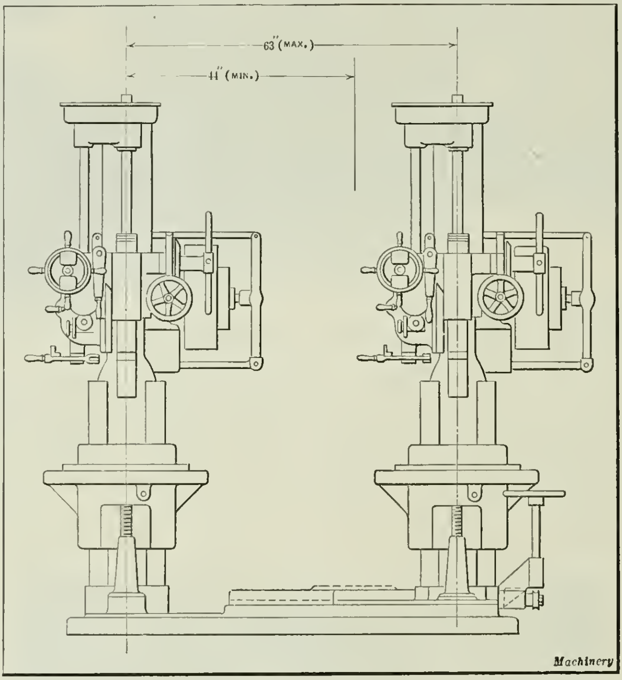

Fig. 3. Diagram showing Provision for adjusting Center Distance of Spindles

For driving large boring-bars, reamers, and other tools where a powerful drive is employed and the tools are run at their maximum recommended speed, the noses of the spindles are slotted to accommodate a driving lug on the shank of the tools. The spindle speed employed for the operation described in the foregoing is 80 revolutions per minute, and the feed 0.012 inch per spindle revolution. This special equipment enables a production of eight castings per hour to be attained. This job is not primarily a drilling machine operation; therefore, the increase of the output per operator by the use of this special drilling machine arrangement, lends considerable interest to the job from the aspect of reducing manufacturing costs through greater production.

Cutting Acme Threads

The elevating screw nut used in the construction of the Colburn boring mill has a left-hand Acme thread, four threads per inch, which was formerly produced by chasing on a lathe. The work is now being performed on a drilling machine, using an angle-plate fixture to which the work is strapped, as shown in Fig. 6. These nuts are made of cast iron, and they are first drilled and reamed to 1.3125 inches in diameter, after which three taps (two roughing and one finishing) are run through the reamed hole to produce the Acme thread. The outside diameter of this thread is 1 9/16 inches. For drilling, a speed of 240 revolutions per minute is used, with a feed of 0.016 inch per revolution. For reaming, the speed is 45 revolutions per minute, and the feed 0.035 inch per revolution. The production time by this method of machining is six pieces per hour; whereas when the work was done on a lathe only seven castings were produced in a nine-hour day.

Machining Lever Brackets

For machining cast-iron lever brackets, such as those shown on the table of the machine in Fig. 7, a box-type jig is used which is designed to accommodate both right- and left-hand castings and also to permit the use of a box-tool for turning the end of one bearing on this casting. A plan view of this fixture showing the position of the casting, as well as the provision for handling opposite-hand castings is shown in Fig. 4. The work is located against one of the studs *A*, and is fastened to the side of the fixture by two hook-bolts *B* which reach over the foot of the casting and secure it in position after the set-screw at the end of

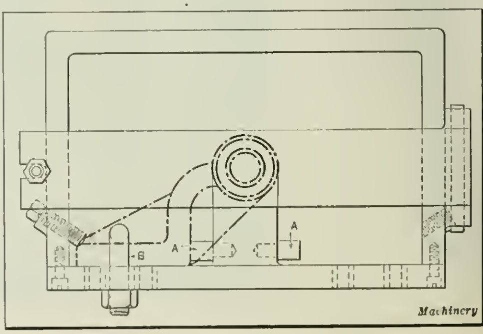

Fig. 4. Box Jig used in Operation illustrated in Fig. 7

the jig has been tightened against the end of the casting, locating it firmly against stud *A*.

With the work thus located and the cover fastened down, a hole 1⅛ inches in diameter is drilled and reamed through both bearings of this bracket, after which the cover is thrown back and a box-tool is employed to rough- and finish-turn the outside diameter at one end of the casting. This is the operation illustrated in process in Fig. 7. The diameter of this turned end is 2¼ inches, and the length 1¼ inches. The next operation is that of spot-facing the inside of each bearing, using a double facing tool which is fastened to the cutter-bar after it has been run down through the two reamed holes, so that the cutter is located between the two surfaces to be finished. The cutter is first fed up and then down, and its use assures parallelism of these two faces.

With the work still in position, the jig is turned on its side and four 17/32-inch holes are drilled and spot-faced in the foot of the casting. The jig is open at the back, so that as it is turned over, the chips fall out, thus overcoming the objection commonly raised to the use of box fixtures. For the 1⅛-inch hole, the drill speed is 300 revolutions per minute and the feed 0.018 inch per spindle revolution; for reaming, the speed is 45 revolutions per minute and the feed 0.035 inch. For turning the 2¼-inch diameter, a spindle speed of 160 revolutions per minute is employed with a feed of 0.018 inch per revolution. For the 17/32-inch holes in the foot, the drilling speed is 430 revolutions per minute, and the feed 0.15 inch. The production time is five brackets per hour.

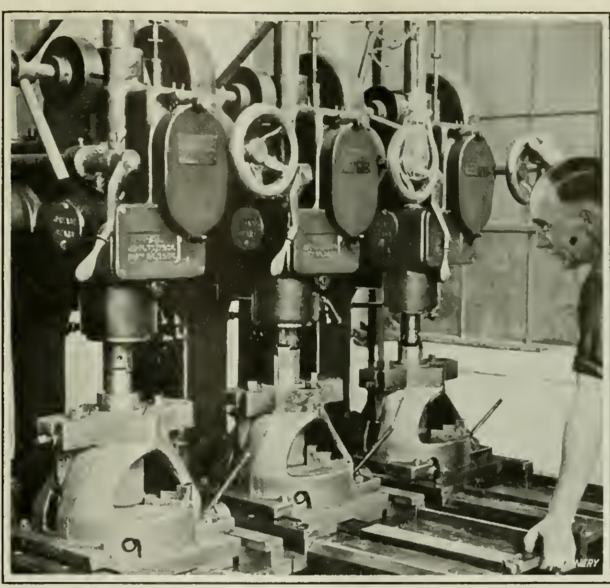

Fig. 5. Three-spindle Heavy-duty Drilling Machine with Track for moving the Jigs from Spindle to Spindle

Special Tooling for Multiple-spindle Drilling Machines

The three-spindle heavy-duty Colburn drilling machine illustrated in Fig. 8 is equipped with a special auxiliary table, which is fastened to the regular table and carries a parallel against which the jigs are guided as they are traversed from station to station. The jigs are provided with rollers for advancing them to the various spindle positions,

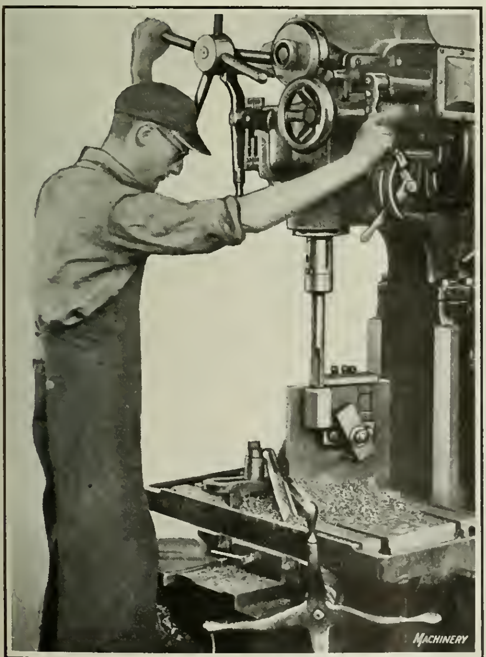

Fig. 6. Tapping Acme Threads by the Use of Three Taps

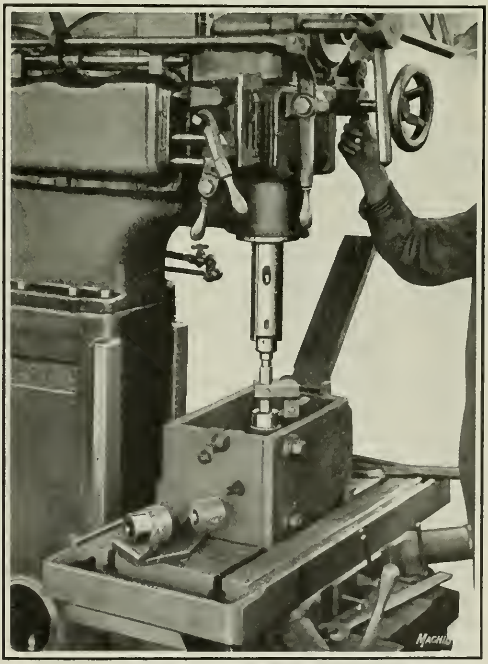

Fig. 7. Turning Hub of Cast-iron Bracket with Box-tool

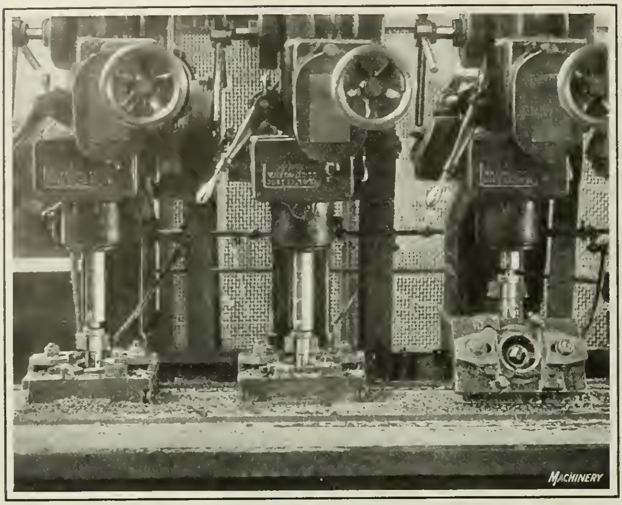

Fig. 8. Three-spindle Drilling Machine with Auxiliary Table and Tracks for sliding the Jigs from One Spindle to Another

as well as with rollers set at right angles to these, so that at the completion of the longitudinal travel of the jig it may be rolled forward on tracks running to the front of the table and at right angles to it, for convenience in loading. These tracks are not shown in the illustration. This method of moving the jig from one end of the table to the loading position at the opposite end makes it unnecessary for the operator to exert any manual effort, and also saves time.

The construction of the jigs will be understood by reference to Fig. 9, which is a plan view showing, by heavy broken outline, how the work is located in pairs, so as to form a complete circle. The work is located by V-blocks, and is clamped in this position by set-screws, being held down by large clamps *A*. The operations performed on this multiple-spindle drilling machine are rough- and finish-boring a 2.44-inch hole formed by two castings, as shown in Fig. 9, to limits of plus or minus 0.003 inch, and counterboring with a 2⅞-inch diameter tool to a depth of 1/16 inch. These steel castings are first disk-ground on the back surface to enable them to be properly seated in the boring jig. Four jigs are used for this work, the extra one being loaded while the operations are being performed on the first pieces. The spindle speed is 80 revolutions per minute and the rate of feed 0.006 inch per revolution. The production time is forty pairs or eighty machined castings per hour.

Drilling Spindle Sleeves

The spindle sleeves used in the construction of the Colburn heavy-duty drilling machine are drilled with the equipment illustrated in Fig. 10, which consists of a four-spindle No. 2 manufacturing type machine, on the table of which four jigs are mounted. The design of these jigs is shown in Fig. 11. The body *A* is mounted on trunnions which are carried in supports bolted to the face of the jig. The body is made of cast iron, and there are two serrated steel strips *B*, 120 degrees apart on the inside, which act as a cradle for holding the sleeves to be drilled; the work is secured in place by two set-screws, one at each end of the body.

There is a locating member *C*, which is assembled midway between the ends of the body, and on this member a flat milled on the side of the spindle sleeve rests, which takes the thrust during the drilling operation and also locates it centrally in the body of the jig. For loading and unloading, the body is swung into a horizontal plane, in which position latch *D* drops down and engages a slot in the end of one trunnion, as indicated by the dotted outline. The index-pin which locates the body in a vertical position during the drilling operation is operated by a small lever, which withdraws the pin against spring pressure and permits the body to be revolved. In Fig. 10 the operator is shown loading the first jig, from which the advantage gained by designing the jig to swing to a horizontal position is apparent. The drill bushings are knurled and slabbed, and are prevented from turning by a pin in each end of the body.

These spindles are made of 0.35 per cent carbon steel, and are 17¼ inches long with a 1 7/16-inch hole extending through them. In drilling this hole, the drills are fed half way through the sleeves, and the jig is then indexed through 180 degrees so that a hole may be drilled in the opposite end of the piece to meet the first one. It has been mentioned that a flat milled on the side of the sleeves is used to locate them in the jig. This flat is afterward milled off in finishing the outside of the sleeve, and rack teeth are cut on the exterior. When the space between the end of the bushing and the adjacent end of the work becomes filled with chips the bushing is lifted to allow the chips to escape, but there is no liability of inaccuracies resulting from this, because the body is held firmly and the drill is free from vibration. The production on this operation is one sleeve every 2½ minutes, that is, 24 per hour, floor to floor. This rate depends on the spindles being kept in continuous operation, and no time being lost in loading and unloading the jigs.

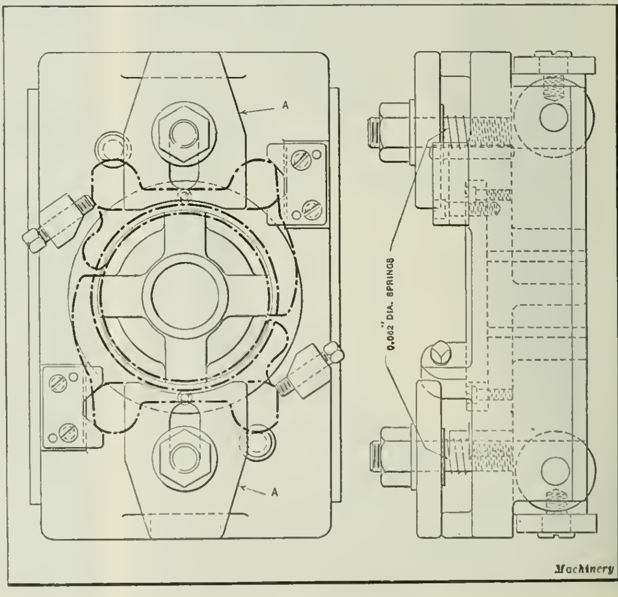

Fig. 9. Detail View of Jigs used in Operation Illustrated in Fig. 8, showing how the Work is located

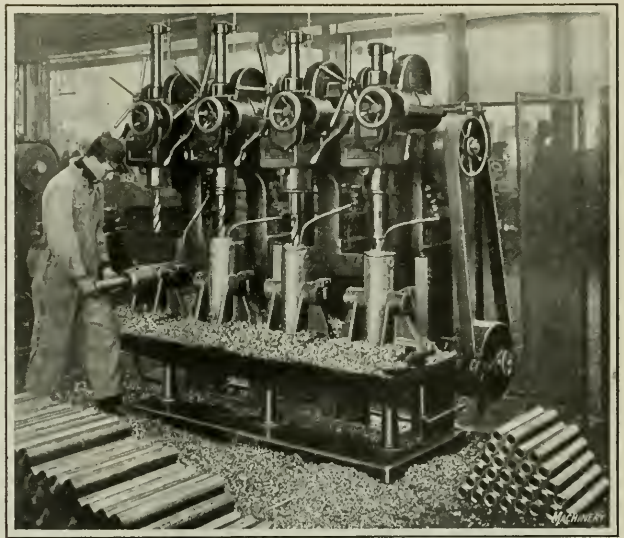

Fig. 10. Drilling Spindle Sleeve Holes 17¼ Inches Long by 1 7/16 Inches in Diameter

Drilling Bottle-filling Machine Gage Bodies

A cast-iron gage body for bottle-filling machines is illustrated in Fig. 12, in position on the Colburn heavy-duty drilling machine used in boring and reaming this piece. The jig used to hold the casting while machining the eight holes in each end is shown attached to the special base of the machine, which, in this case, is used as a table. This construction is employed when there is an unusual distance between the spindle nose and the locating surface. The jig is bolted to this special base, and is supported at the top by a bracket attached to the vertical ways on which the regular machine table is usually mounted. A combination boring and reaming bar is used in this operation, carrying two boring heads and two reamers and an extending pilot which enters the base of the jig.

The jig is of the indexing type, and two boring-bars are provided, one of which is in use while the other is placed in the next hole to be machined, so that as the work is revolved this boring-bar is brought into alignment with the spindle and connected with the quick-change collet chuck. The work is so long that if this were not done it would be necessary to rotate it to remove the boring-bar, then turn it again in order to permit the same bar to be passed through the holes, and finally turn it backward to bring it into alignment with the spindle of the machine. When indexing, a circular clamp at the top of the jig is loosened, a strap at the bottom is released, and the index-pin withdrawn by means of a cam-lever shown at the front of the jig.

The work seats on a cast-iron shoulder of the jig and is clamped down by a slotted washer at the top. A plug on the shoulder of the jig locates the gage centrally. The sixteen holes are 4⅝ inches in diameter and 5 inches deep, and the production time is thirty minutes per casting, as compared with 3 hours and 20 minutes by another method.

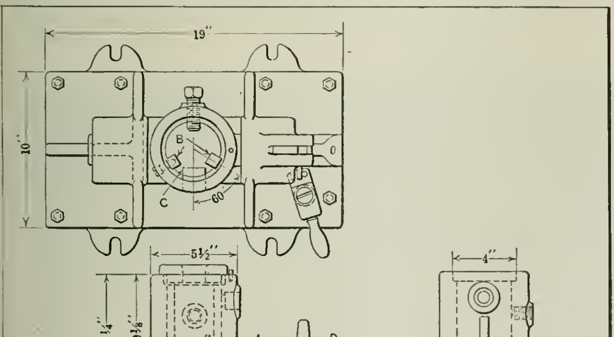

Fig. 11. Revolving Fixture in which the Spindle Sleeves are located while drilling

Boring Hole in Dredge Saddle

The boring of a saddle for a dredge is illustrated in Fig. 15. This is a steel casting the design of which is shown in Fig. 13. The machine used is a D-8 Colburn heavy-duty drilling machine, and the operation consists of rough- and finish-boring a 12-inch cored hole to 13 inches finished diameter. This hole is 10 inches long, and three cuts are required to complete the operation. For each of these cuts it takes fifteen minutes to feed the boring-bar through the work, so that the entire operation consumes 45 minutes. The rotative speed of the spindle is 23 revolutions per minute, and the feed is 0.030 inch per spindle revolution. While this is not a production job, it illustrates very well the capability of this type machine for handling work where heavy cuts in tough material are required.

Handling Large-diameter Work

It often happens that work of large diameter, which would be exceedingly awkward to handle unless some special provision were made, may be machined by employing some such arrangement as is illustrated in Fig. 16. Here a No. 14 Colburn drilling head is mounted on a boring mill table in which a post is located around which the work may rotate during the drilling and reaming of the various holes in this casting. The work to be machined is a cast-iron can tester wheel which is used in testing cans by means of compressed air. A partial plan view and section of this wheel are shown in Fig. 14. There are forty-two 1¼-inch holes drilled and reamed on a circle of 31 inches radius, and the same number of 1-inch holes on a circle of 35 inches radius. All these holes are drilled and reamed with the set-up illustrated in Fig. 16.

The stationary post on the table, previously referred to, carries a slotted index-wheel at the top by means of which the work is indexed for drilling each hole. A radial arm is also carried on this vertical post under the index-wheel in which there are two bushings, one for the inner circle of holes and one for

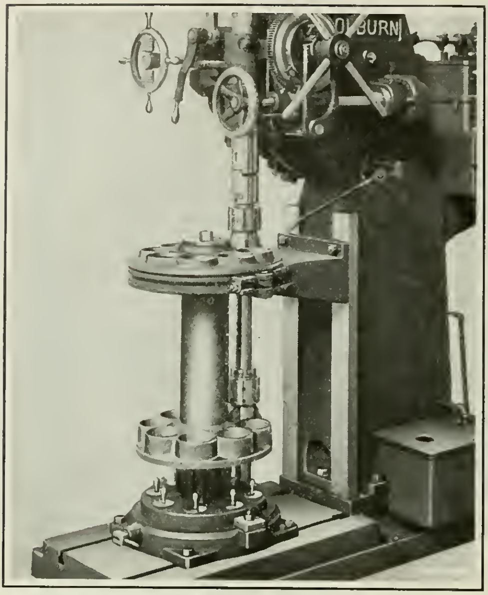

Fig. 12. Use of Extended Base and Indexing Jig for boring and reaming Long Work

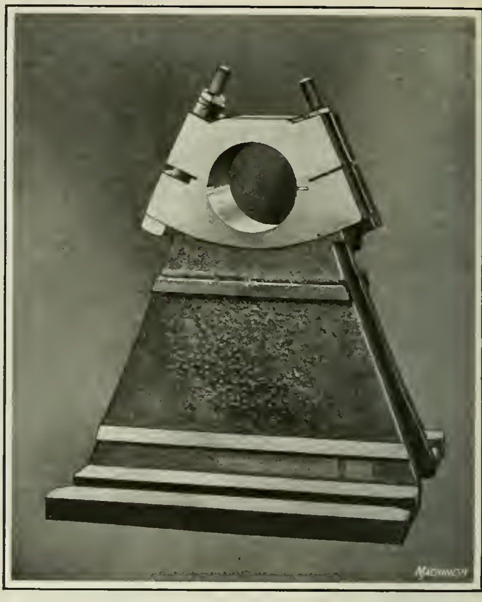

Fig. 13. Saddle for Dredge, showing Hole bored on Machine illustrated in Fig. 15

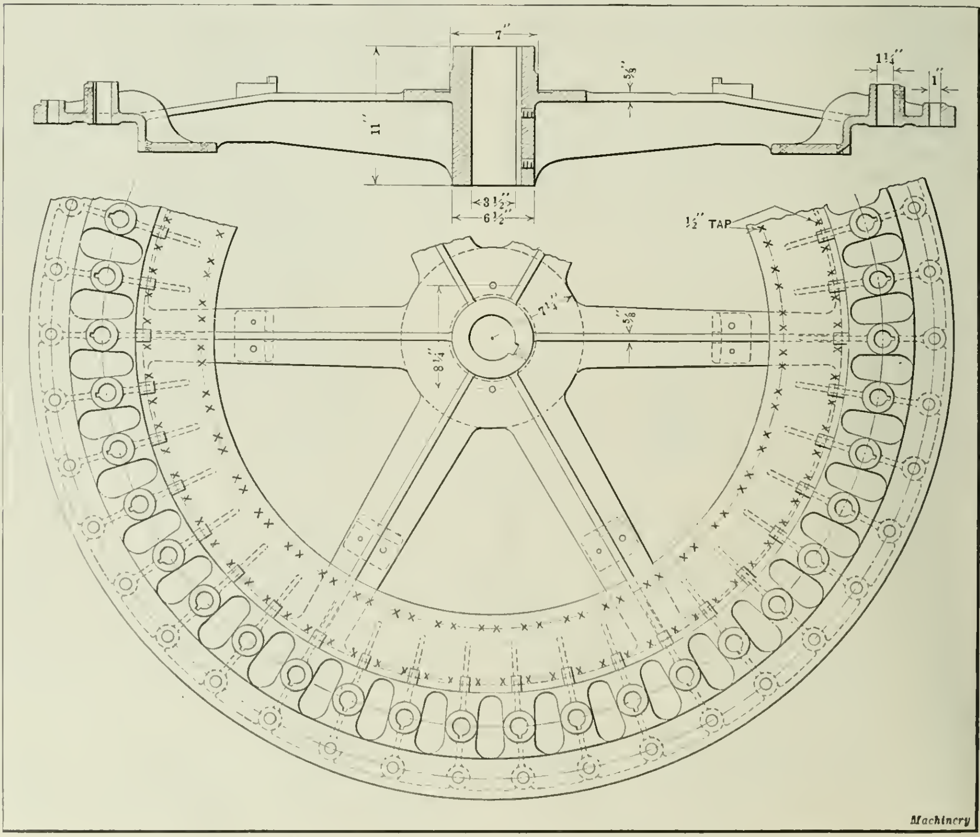

Fig. 14. Can Tester Wheel in which Eighty-four Holes are drilled with the Equipment illustrated in Fig. 16

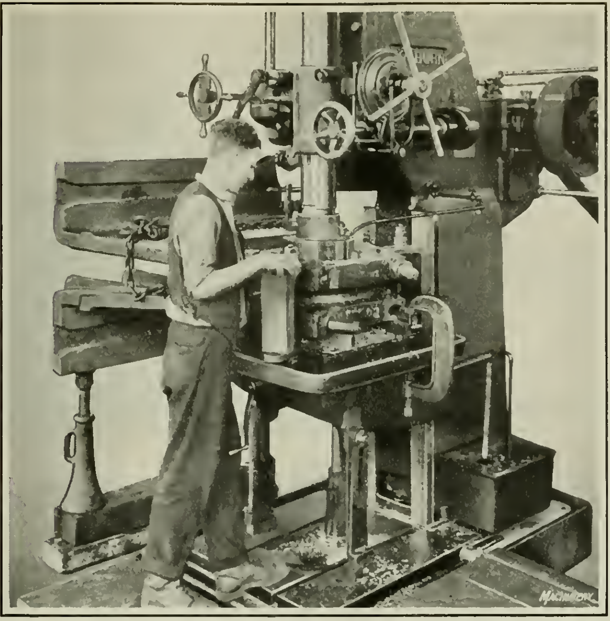

Fig. 15. Boring a 13-inch Hole in a Saddle for a Dredge

the outer circle of holes. After the larger holes are drilled and reamed and the work has made two complete revolutions, the post is moved outward in the T-slot of the table in which it is clamped to obtain the correct radial distance for drilling the outer circle of holes. Then a plug is used in the larger bushing hole in the radial arm, and is passed down through one of the 1¼-inch holes so that the smaller holes are kept in radial alignment with these. A limit of 0.001 inch is allowed on the location.

The 1¼-inch holes are drilled and reamed through 3¼ inches of metal, using a drill speed of 160 revolutions per minute and a reamer speed of 45 revolutions per minute. The drill feed is 0.015 inch and the reamer feed 0.038 inch per spindle revolution. The 1-inch holes are drilled and reamed through 1¾ inches of metal, the drill speed being 300 revolutions per minute and the reamer speed 45 revolutions per minute. The feed used is 0.018 inch per spindle revolution for both drilling and reaming. The production is two wheels per eight-hour day.

ANNUAL MEETING OF THE TAYLOR SOCIETY

At the annual meeting of the Taylor Society, held in the Engineering Societies Bldg., New York City, December 1 to 3, the program covered many problems of management. Some of the papers read are given in the following: "The Technique of the Appraisal of the Efficiency of an Industry" comprised a critical examination of the evaluation sheet devised and used by the engineers of the Committee on the Elimination of Waste in Industry. The discussion on this paper was opened by C. E. Knoeppel, C. E. Knoeppel & Co., New York City. A report of the Committee on Sales Engineering was made by Willard E. Freeland, Winchester Repeating Arms Co., New Haven, Conn. A paper on "Reflections of a Production Manager" was presented by Charles F. O'Connor, Universal Winding Co., Providence, R. I., and a paper on "The Necessity of the Quota for Proper Sales Cost Accounting" was presented by Charles P. Staubach, Burroughs Adding Machine Co., of Newark, N. J. Another paper "The Application of the Principles of Scientific Management to the Office" was read by William H. Leffingwell, Leffingwell-Ream Co., Chicago and New York, and a paper on "The General Control of a Business" was presented by John H. Williams, Day & Zimmermann, Philadelphia, Pa. The subject "Combination Routing" was brought up by D. J. Walsh, Jr., and a paper on "The Formula for an Efficient Workman" was presented by Boyd Fisher, Lockwood, Greene & Co., Boston, Mass.

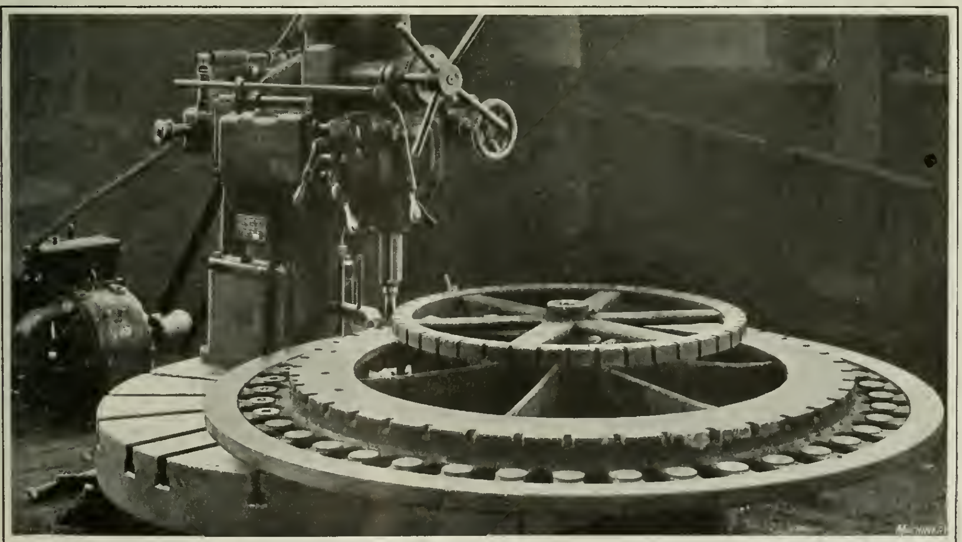

Fig. 16. Drilling Head mounted on a Boring Mill Table for handling Work of Large Diameter

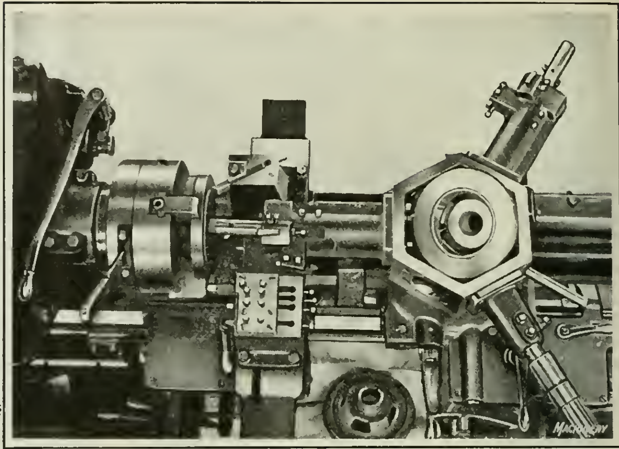
Turret Lathe Tooling

Equipment for Machining Differential Gear Housings on Foster Turret Lathes

By I. F. YEOMAN



THE illustrations accompanying this article show the tooling lay-out for machining a differential gear-case on a turret lathe. Before describing the various operations and equipment employed a brief review will be given of the way in which production problems for the Foster turret lathes are handled at the Foster Machine Co.'s plant in Elkhart, Ind.

When the blueprints are received from the customer, the head tooling engineer makes a study of them, and after ascertaining the surfaces to be machined and the limits required on these surfaces, notes on the blueprints the cutting speeds and the number of cuts required, together with the various feeds to be used in performing the machining operations. He also indicates the preferable method of holding the work in the chuck. The next step consists of making a rough sketch of the work to be machined, on which certain methods of finishing are indicated. For example, in Fig. 1 the details of both members of a differential housing are shown. It will be noted that the finished dimensions for the various surfaces to be machined are given; and also that the method of machining certain of these surfaces is indicated.

How To Reduce Production Costs

Sketches are then made showing the recommended type and location of the tools required in performing the operations for each chucking of the work, as well as the best method of chucking the part to be machined. If, as in the present case, two chuckings are required in finishing the work, one of these tooling lay-out sketches will be made for each operation. Figs. 2 and 3 show the general tooling arrangement provided for machining the differential gear housing, in the first and second chucking, respectively. After the preliminary sketches of the proposed tooling lay-out are completed, these and the engineer's suggestions regarding the machine to be used are submitted to the assistant tool designer who computes the floor-to-floor time estimate for each series of operations.

After the time study has been made, a copy of this and the lay-out made by the engineering department are sent to the prospective customer, who is given a complete explanation of the proposed method of machining the parts and is also advised regarding certain other details which have been observed in studying the job and in making the time study. As soon as an order has been received on the strength of the preliminary investigation, the design of the tools and all calculations pertaining to the machining of the work are carefully rechecked before the finished tool drawing is made. Blueprints of these drawings, accompanied by any necessary explanation, are then sent to the foreman of the special tool department, where the tools and designs are made.

Tooling for First Chucking on Differential Housing

All equipment used in machining the differential housing shown in Fig. 1, including chucks, expanding reamers, and special tool-holders are manufactured by the Foster Machine Co. and applied to a 2-B universal turret lathe of this company's manufacture. In the first chucking, it is considered advisable not to use the turret of the machine, a special arrangement being employed in its place, with the result that a substantial reduction is made in the cost and time required to machine the part. This arrangement consists of a multiple tool-holder, shown in Fig. 2, which is mounted on the cross-slide of the lathe in the position shown in Fig. 4, so that the tools may be brought successively into engagement with the various surfaces to be machined, by simply operating the cross-slide screw and feeding the carriage along the bed until it comes in contact with a positive stop.

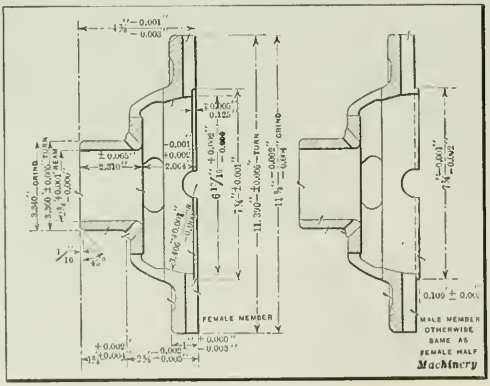


Fig. 1. Sketch giving Dimensions of Differential Gear Housings

In the first chucking, the housing is chucked on the inside, using a special 16-inch, three-jaw Barker wrenchless chuck, having corrugated and hardened steel jaws, carried in a heavy steel body. The first operation is that of rough-turning the outside diameters of the hub and flange. With the aid of the dial index of the cross-slide screw, the multiple tool-holder is traversed transversely to bring tools *B* and *C* into the proper position for turning the hub, which results in similarly positioning tool *E*, used in rough-turning the outside diameter of the flange. The cut required to machine the hub is divided between the two tools *B* and *C*, so that the operation will be completed in the same time that the flange is rough-turned. Tool *C* also turns the fillet at the base of the hub and rough-faces the adjacent surface *C'*. All surfaces finished are indicated by the same reference letters used in designating the tools employed in machining. For example, tools *C*, *D*, and *E* are used in machining surfaces *C'*, *D'*, and *E'*.

Fig. 4 shows the tools near the completion of the rough-turning operation. The traverse of the carriage is automatically terminated by means of a positive stop as soon as the rough-turning cuts are completed. This brings the tools *A*, *C*, and *D*, Fig. 2, into the proper position for rough-facing the three surfaces similarly designated, during which operation the carriage is fed radially outward, as the feed diagram in the lower right-hand corner of the illustration indicates.

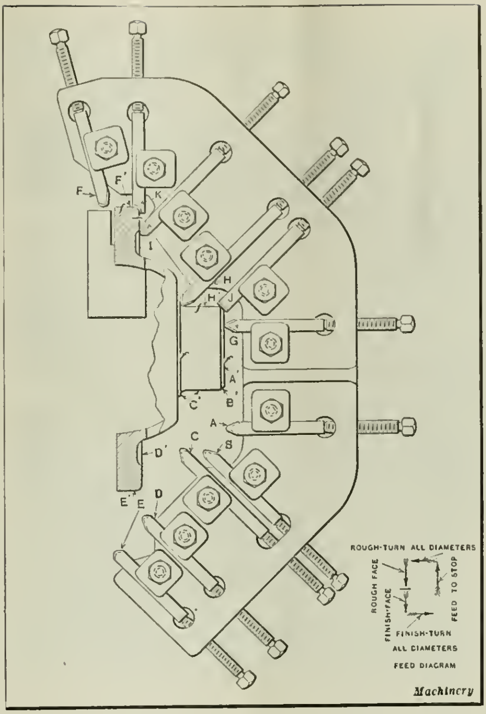

Fig. 2. Multiple Tool-holder which carries all the Tools used in the First Chucking

This completes the roughing operation, and the finish-facing cuts are immediately taken by continuing the cross-feed, which results in finish-facing the end of the hub with tool *G*, finish-facing the flange with tool *I*, finish-facing and forming the fillet at the base of the hub with tool *H*, as well as chamfering the end of the hub with tool *J* and forming a radius on the flange with tool *K*. This brings tools *F* and *H* to the proper position for finish-turning the outside diameter of the flange and the hub, respectively, and this is the position which the tool occupies in Fig. 2. In finish-turning these two surfaces, the carriage is simply fed longitudinally back to the starting position. This completes the operations performed in the first chucking, and the casting is then removed from the machine preparatory to performing the second series of operations. During the test made at the Foster plant, the floor-to-floor time for completing the first chucking on these malleable iron castings, was from 4½ to 5½ minutes.

Tooling for Second Chucking

In the second chucking, a combination of cutting tools is used in which both the turret and the cross-slide are employed. The casting is located in the three-jaw Barker wrenchless chuck, with the previously faced surface of the flange seating on three pins *A*, Fig. 3. The chuck, which holds the work by the periphery of the flange, is provided with special soft jaws, the gripping surfaces of which are corrugated as shown at *K*.

The surface *B'* surrounding the inner end of the hub and the corresponding outer surface of the casting are first rough-faced, the two facing operations being performed simultaneously. Tools *B*, *C*, *D*, and *E* are carried in a tool-block on the cross-slide so that after the tools have been properly adjusted by first positioning tool *B* for finishing the inner surface of the hub, the other tools will be in position for starting the facing cut on the flange.

The two tools *D* and *E* divide the cut, and so enable the flange to be rough-faced at the same time that surface *B'* is machined. The illustration shows the tools in the position that they occupy at the completion of this operation, at which time tool *C* produces the circular recess in the female member of the differential housing. (See Fig. 1). In machining the male member, it will of course be understood that the position of this tool will be such as to rough-face the annular projection corresponding to this recess. In these facing operations, the proper depth of cut is obtained by the use of a positive stop for the carriage, after which the surfaces are faced by feeding the cross-slide forward to a stop.

The hole in the hub is next rough-bored and the radius connecting the hole with the inner face of the hub formed, the tools being carried in the boring-bar mounted in the first side of the turret. This boring-bar also carries two radius-forming tools *F* for rough-forming the inner concave surface, and a tool *L* for taking a second cut in the female recess. The cutters *F* are located 180 degrees apart and are designed with chip clearance grooves as shown. When the male member is machined, tool *L* used in machining the female member is not, of course, required. The boring-bar mounted in the second side of the turret carries tools for finish-boring the hub, finish-facing surface *B'*, and for finish-forming the female recess and establishing the relation between the depth of this cut and the finished surface *B'*.

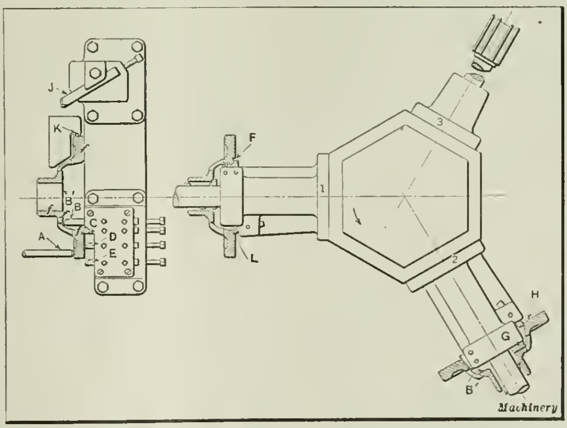

Fig. 3. Tooling Lay-out for the Second Chucking

When machining the male member, the recessing cutter is set at the proper angle for finish-turning the outside diameter of the annular projection. It will be observed that cutter *G*, used in finish-facing the inner end of the hub, is different in design from tools used in other facing operations, owing to the fact that it must take a sweeping cut. During the finish-boring operation, tool *J*, carried in a tool-block at the rear of the cross-slide, is fed across the flange of the housing to finish-face that surface. In the heading illustration, this operation is shown near its completion, the tool *J*, Fig. 3, having not quite completed its cut. The final operation in machining the casting is that of reaming the hole in the hub, using an expanding reamer carried in the third side of the turret.

It will be noticed that in both tooling set-ups the tools are designed with provision for adjusting the cutters by the use of adjusting screws. The radius-turning cutters *F* are also designed so that they may be adjusted in various directions. The time required to complete the second chucking operations, during the test of tools conducted in the Foster shop, was 7¼ minutes per casting.

It may be of interest to add, in connection with the description of the engineering service described in the opening paragraphs, that fifteen days after the receipt of the order for the tools described and illustrated in the foregoing, the equipment was thoroughly tested and delivered to the shipping department, ready for the customer's use. As the entire equipment was made in the plant of the Foster Machine Co., duplicate parts or tools can be supplied to the customer from the original drawings without delay.

TENSION IN BELTS

By N. G. NEAR

Some means of determining the tension in a belt while it is on pulleys is often desirable. The tension can, of course, be determined by means of a dynamometer, but as this method is a rather cumbersome one and takes considerable time, it is seldom used. When the belt drive is horizontal or nearly so, the writer has found it possible to determine the tension quite accurately by basing his calculations on the amount of sag in the belt. In employing this method, use is made of the following formula:

$$S = \frac{WL^2}{8T}$$

in which

S = sag, in feet;
W = weight of belt, in pounds per cubic inch;
L = span of belt, in feet;
T = tension in cross-section of belt, in pounds per square inch.

Applying this formula to leather belts, the writer computed the values given in the accompanying table, which will be found convenient for quickly determining belt tensions. To use the table, it is simply necessary to measure the span of the belt in feet, the distance between shaft centers, and the sag in inches, and then locate the columns in the table corresponding to these measurements. The tension can then be read directly in pounds per square inch. For example, if the span is 30 feet and the sag 5 inches, the tension will be 112 pounds per square inch. In some cases, it is possible to measure the sag, both on the tight and slack sides, while the belt is in motion. This cannot be done satisfactorily, however, unless the belt runs smoothly.

HOOVER CONFERS WITH TRADE JOURNAL EDITORS

The monthly conferences between Mr. Hoover and the editors of engineering and trade journals inaugurated shortly after Mr. Hoover became Secretary of the Department of Commerce are being continued, and the cooperation between the Department and the industries through the medium of the engineering and trade press is thereby facilitated to a marked degree. The problems of the industries may be transmitted to Mr. Hoover in this manner, and he, in turn, has a channel to which he can easily turn for information on any subject relating to the whole industrial field. The close cooperation with the industries that Mr. Hoover is endeavoring to establish is probably the greatest step ever taken in making the Department of Commerce of real value to commerce, trade, and manufacturing interests. The greatest help the industries can render is to make definite suggestions as to the assistance the Department can give.

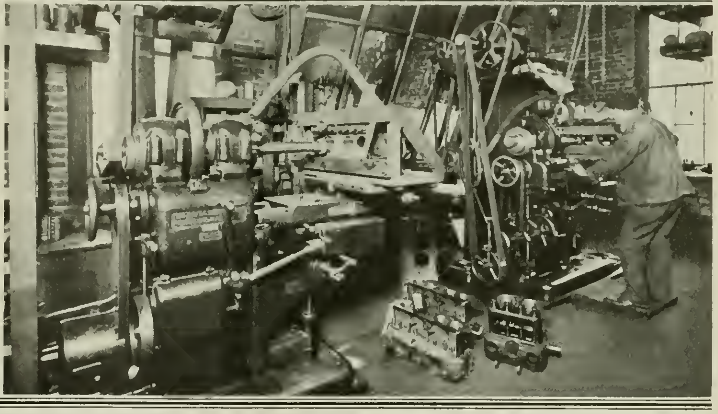
Machinery

Automobile Repair Shop Practice

First of Three Articles Describing Methods and Equipment Commonly Employed in Automobile Repair Shop Practice



THE greater part of automobile engine overhauling is confined to cylinder work; this includes, besides the resizing of the bores, refitting of pistons, rings, and wrist-pins, and aligning connecting-rods. When the pistons are loose, an automobile engine wastes power, due to the pumping of oil and the reduced compression. These troubles can be eliminated quickly and without much expense by regrinding and refitting, and this fact, coupled with the growing need for repair work of this general type, has led to the establishment throughout the country of repair shops for handling engine work exclusively.

Some shops do not have the equipment for handling parts other than cylinders, pistons, and rings, while others are fully equipped for repairing crankshaft bearings by welding or by grinding down the crankpin and main bearings; reseating cylinder valves; straightening, rebushing, and fitting connecting-rods.

The methods followed in different repair shops vary somewhat, although the results obtained are essentially the same. It may be that the practice in one locality would not be practical in another place due to the local demands, which of course would also affect the equipment used. In this series of articles the procedure followed in a number of repair shops for performing work of like nature is described.

Common Engine Troubles

When an engine is dismantled, it is often found that there is an excessive clearance between the piston and the cylinder. The piston-rings often have large black spots on their outer periphery indicating that the rings have not been bearing on the cylinder wall, and through the space thus left the expanding gas has been escaping, resulting in a loss of compression and efficiency of the engine. It is sometimes found that the cylinders and pistons are rough or scored, due to insufficient lubrication, so that it is impossible for the rings to prevent the escape of gas.

It may be that a wrist-pin is discovered to have worked loose and to have cut a groove in the cylinder wall, a condition which will also allow gas to escape. Even though the cylinder wall is perfectly smooth, it may he found upon investigation, that the part of the cylinder in which the rings travel has been worn larger, permitting the rings to expand and the gas to escape at the joint. If the cylinders are worn to this extent, the gas also usually escapes around the circumference of the ring even more than at the joint. The cylinder bore may be worn oval-shaped and be from 0.005 to 0.010 inch greater across one axis than the other and, of course, no ring can be made that will conform to such a condition. The wear in the region of the ring travel, which is only about half the length of the cylinder, is commonly encountered, but this can be readily remedied by regrinding.

Another phase of general automobile engine repairs has to do with the crankshaft. When the crankshaft has sprung out of alignment and when its journals are worn out of round, the result is excessive vibration, noise, and an unbalanced and uneven running engine. In overhauling an automobile engine, special attention should always be given to the crankshaft. If the crankshaft bearings need regrinding, this should not be neglected, as the cost of doing this work at the time when the engine is being overhauled is small. If this is not done and an attempt is made later to fit a set of bearings to a shaft which is not perfectly true, much more time will be consumed and a far less satisfactory result obtained. The practice of filing, lapping, and polishing a crankshaft is practically obsolete, as it is not only slow but almost impossible to obtain accurate results.

Cylinder Regrinding

If an engine has been dismantled and it is found that the cylinder bores are in need of resizing, a series of operations is necessary in order to put the piston back into proper running condition. First, each cylinder bore in the block must be accurately reground to the same diameter until all marks are removed, which sometimes necessitates the enlarging of the bores an average of 0.015 inch on the diameter. If the bores are deeply scored, it is often better practice to weld the worst places and then grind to size. New pistons must then be fitted to these ground cylinders, and for this purpose it is necessary either to keep a supply of rough or partly machined over-size pistons on hand or, if the establishment is large enough and the practice of finishing replacements from rough castings followed, a full line of patterns is required.

Over-size pistons may be procured commercially to meet almost any condition. They must then be machined to fit the cylinder bore; the outside diameter is usually finished by grinding, although in some cases the pistons are finish-turned. The pistons must be fitted with over-size rings, and these may be bought in sizes varying by certain increments, such as 0.005 inch on the diameter. The variation in diameter of the piston-rings has an effect upon the practice followed in regrinding the cylinder bores; for example, if the

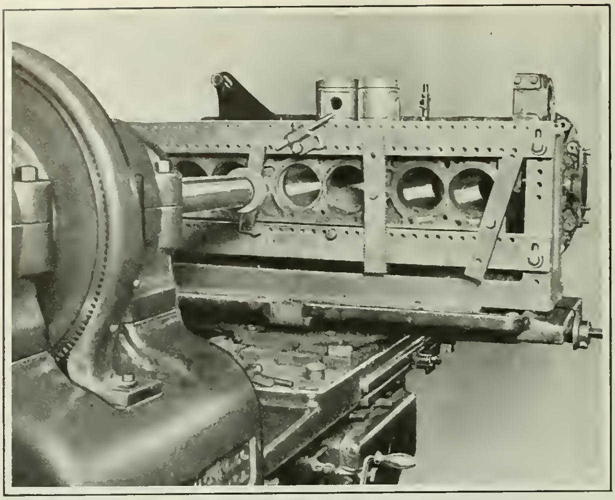


Fig. 1. Cylinder Grinder set up for regrinding the Bores of a Six-cylinder Marmon Sleeve-valve Engine

diameters are increased by increments of 0.005 inch (even although more metal may be removed than is absolutely necessary to clean up), the finished pistons may be fitted without any additional machining.

If it has been found, in disassembling the connecting-rod, that the wrist-pin is badly worn, it is, of course, necessary to furnish a new set of wrist-pins and in some cases, perhaps, provide new bushings in the connecting-rods. Wrist-pins may also be purchased to meet almost any desired condition. After the connecting-rod and piston have been properly fitted, the assembly should be tested for alignment and straightened so that the cylindrical surface of the piston will be at right angles to the crankpin bearing of the connecting-rod. An auxiliary repairing operation is regrinding the seats on the exhaust and intake valves, and this should not be neglected. This can be done with a special bench type of equipment to which reference will be made later.

Regrinding the Bore of a Sleeve-valve Engine

At the plant of Frostholm Bros., Syracuse, N. Y., all classes of automobile engine repair work are done. Fig. 1 shows a No. 55 Heald cylinder grinding machine on the table of which a Marmon sleeve-valve aluminum cylinder block is mounted. The cylinder regrinding work on a sleeve-type aluminum engine is the same as on a cast-iron block except that the factor of overheating must be taken into consideration. The block is attached to a regular angle-plate type of cylinder fixture similar to that furnished by the manufacturers of this grinder. This is a six-cylinder block, having a bore 3¾ inches in diameter, and it is ground with a No. 303S carborundum wheel. It is generally practicable in cylinder regrinding to take at least two cuts. For roughing, about 0.005 inch of metal is removed per table travel, and for finishing about 0.0015 inch, both these figures varying according to the judgment of the operator. This block is to be fitted with "Kant-Skore" aluminum alloy pistons, two of which are shown on top of the fixture.

In this fixture two steel parallels are bolted to the vertical side of the angle-plate, in which a number of holes are drilled. This enables the block to be bolted in place readily and also permits cylinders of any size or type to be mounted on the same fixture. It is recommended that the wheel be trued up before starting the finishing operation, and for convenience in doing this a diamond wheel-dresser is attached to the upper parallel of the fixture. The dust is removed from the cylinder by an exhaust fan to which a flexible tube is attached, with the open end resting in the outer end of the cylinder bore.

Regrinding an Overland Cylinder

The operation illustrated in Fig. 2 is that of regrinding an Overland four-en-bloc cast-iron cylinder, having a 4⅛-inch bore. This work is also done on a No. 55 Heald type machine equipped with a cast-iron angle fixture of similar design to that previously referred to. This machine is in use at the plant of the Nixon Tool & Broach Co., Syracuse, N. Y. This illustration shows the method of mounting the cylinder more clearly than Fig. 1. Four universal plates are provided for clamping the work to the fixture, two of which are carried at opposite ends of each parallel. These may be assembled in any of the holes in the parallel and may be tipped at any angle to suit the holes in the cylinder block. In this case, the lower left-hand plate was tipped so the bolt at this corner would reach through the hole in the plate.

The lower parallel has a T-slot in which the bracket which carries the wheel-dresser slides. In mounting the cylinder in the fixture, it is necessary to use an indicator at each corner in order to make the block perfectly horizontal. In setting up the job, the operator locates each bore centrally, relative to the grinding wheel, by setting the spindle eccentric, successively, at 90-degree positions by hand, until the trial spark produced at each quarter appears to be about the same. The experienced grinder can detect very accurately any variations in central position by either watching the spark or by the sound, although watching the spark is the more reliable way. While this work is being done the eccentric is not revolved, except as it is turned by hand, and the spindle is driven by power in the regular way.

Method of Setting and Adjusting Wheel Positions

The cylinder which appears to be the most deeply scored is first cleaned up and the other bores ground to this diam-

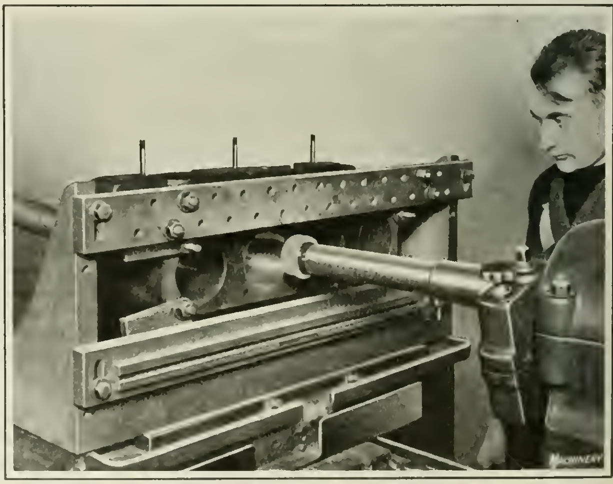

Fig. 2. Regrinding an Overland Four-en-bloc Cast-iron Cylinder

eter. For average work it is necessary to increase the cylinder bores about 0.020 inch, according to the experience of the Nixon Tool & Broach Co., and it has been noticed that rarely is it required to remove more than 1/32 inch from the diameter. A No. 36-H Norton wheel is used and about 0.005 inch of metal is removed in the first operation. If it is found that this does not clean up the bore, another 0.005 inch of metal is removed in the second travel of the table, and so on by increments of 0.005 until the cylinder is free from any score marks. This method is necessary in this plant on account of the practice of using over-size piston-rings varying by 0.005 inch.

After the first hole has been ground to the required size, the graduated dial for the radial feed of the wheel is set at zero, and the eccentric turned back so as to move the wheel in from the ground surface. This will enable the wheel to enter the second cylinder bore before starting this operation; in setting up, the same procedure of hand adjustment and observation of the spark, previously described, is followed. A 24-inch diameter exhaust fan is used to remove the cast-iron dust from the cylinder bore. The time required to grind a four-en-bloc cylinder of this size bore averages about 3½ hours.

Regrinding Large-bore Stationary Engine Cylinder

The cylinder regrinding operation illustrated in Fig. 3 is performed in the plant of Frostholm Bros. and consists of resizing a stationary engine cylinder, 8 inches in diameter, having a 20-inch stroke, on a Brown & Sharpe No. 23 cylinder grinder. This machine has a special tapered spindle, which is designed to eliminate wheel chatter. The general practice of this company is to use a No. 303S carborundum wheel for soft cast iron, and a 36-J Norton wheel on hard cast iron or semi-steel. On the job illustrated a No. 303S carborundum wheel is used. For the roughing cuts, from 0.002 to 0.003 inch of stock is removed on the diameter, but for finishing, the depth of cut is not over 0.0005 inch.

This regrinding job is an example of large work, which is very near the maximum limit. A 6-inch diameter wheel is used, running at 500 revolutions per minute, and it requires about fifty travels of the table to regrind the bore to the proper condition and with the degree of accuracy required. In the course of these fifty travels of the table, the diameter of the cylinder is increased about 1/32 inch. The diameter is tested by means of a special block with beveled edges, on which an Ames indicator is attached, and this test-block is slipped into the bore; the bearings of the two beveled edges of the block and the indicator point furnish a ready means for inspecting the parallelism and uniformity of diameter of the hole.

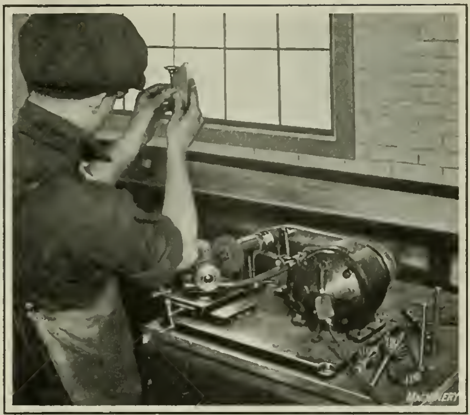

Fig. 4. Grinding Valve Heads to reseat in Exhaust and Intake Ports

Variations in Regrinding Practice on Cylinder Work

In the repair shop of Saucke Bros., Rochester, N. Y., Heald No. 60 cylinder grinding machines and the regular equipment are used, two of which are shown in the heading illustration. The block shown mounted on the first machine is a four-cylinder block taken from a Republic truck, the bore being 4⅛ inches in diameter and 10½ inches long. On the table of the other machine is mounted a six-cylinder Hudson block, 9½ inches long, with 3½-inch bore. In this shop it is the practice to first measure the blocks and determine which of the cylinders is scored the deepest. The bore that is scored deepest is ground first and all others are then ground to the same diameter. The most severely scored cylinder encountered in this shop required the removal of 1/16 inch on the diameter. Both the 303S and 30R carborundum wheels are regularly used for cylinder regrinding work in this shop, and the practice in the actual operation of the machine is to remove about 0.001 inch per traverse of the table until within about 0.002 inch of the finished diameter size. The wheel is then squared up and 0.0005 inch removed per cut until the finished diameter is obtained.

For the roughing operation the highest table feed is used, and for finishing, the lowest table feed. The work-head feed usually employed is the second feed provided on the machine. The recommended wheel speed is from 6100 to 6700 revolutions per minute for a 3-inch diameter wheel, which is equivalent to a surface speed of from 4825 to 5050 feet per minute. The approximate adjustment of the table crosswise when locating the work for successive cylinder bores is obtained by adjustable dogs, and the finer adjustments by the micrometer dial on the cross-feed screw. In actual practice, however, it has been observed that the operator depends more upon his observation of the spark than upon any mechanical means for obtaining the table location when aligning the cylinder bore with the machine spindle.

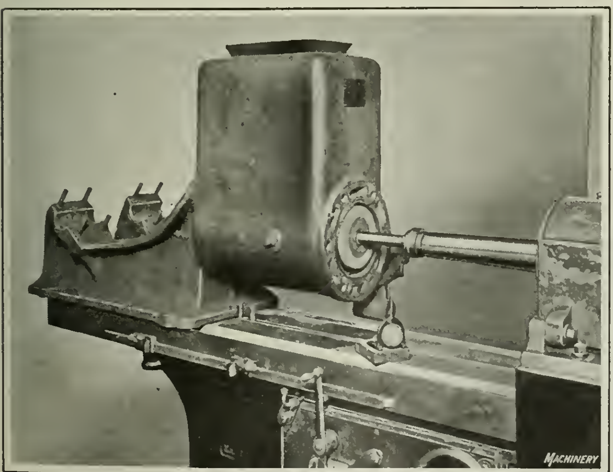

Fig. 3. Stationary Engine Cylinder set up for regrinding the Bore

Grinding Valve Stems

In grinding valve stems in the Frostholm Bros. plant, a Franklin Machine & Tool Co.'s grinding equipment is employed. This equipment is illustrated in Fig. 4 in which the operator is shown using the gage for testing the angularity of the seat relative to the stem. The gage has a semicircular groove in which the valve stem fits while the angularity is being gaged. A 46K Norton wheel is used with this motor-driven bench grinder, and the stem is chucked in a special draw-in collet chuck. The cutters shown on the bench are also ground with this equipment; they are mounted on an arbor and held in the draw-in collet chuck similarly to the valve stem. These tools are used for remachining the seats for these valves in the cylinder blocks.

Coming installments in this series of articles will deal with the practice of machining pistons and crankshaft repair work.

INDUSTRIAL STANDARDIZATION IN GERMANY

Standardization is playing an important part in Germany's industrial reconstruction. The German industries are carry ing out a far-reaching program of standardization as a necessary step in building up the industrial structure necessary to reduce production costs in order to gain extensive foreign trade. In no other country, except in Great Britain, is standardization work carried on upon a larger scale than in Germany. American industrial leaders must sooner or later take note of this standardization work, because our ability to compete in foreign markets with German goods will depend largely upon the manner in which we are able to produce standardized goods cheaply.

Scope of Standardization Work

Prior to 1917, a great deal of standardization work was done in Germany by individual companies, engineering societies, and industrial associations; but the work was not unified along national lines. Noting, however, the success of Great Britain, which organized its national standardization body in 1901, Germany formed a central standardization bureau in 1917, the membership of which consists of engineering societies, industrial organizations, government departments, and 700 leading industrial firms. In the four years since its formation, 144 approved data sheets of standards have been issued, and over 500 additional standard sheets of data have been so far developed that they have been published in tentative form. These standards are issued under the general designation of "German Industrial Standards." The data sheets are published in loose-leaf form, and generally so arranged as to make each sheet independent of the remainder. These sheets are bought by interested firms in any required quantity, and issued directly to their designers, draftsmen, and foremen. This plan is now also followed by the Austrian, Dutch, Swedish, and Swiss standardization bodies. The sale of the German data sheets of standards is said to amount to over 1,000,000 a year.

The standardization bureau has an extensive information service on standardization work in Germany and other countries which is available to the industries. A similar information service has been started by the American Engineering Standards Committee. In this connection it should be noted that the German and Japanese industries appear to study foreign developments much more closely than do the industrial leaders and engineers of other countries.

Methods of Standardization

The standardization work done on the continent of Europe in engineering, looked at broadly, indicates that these countries are going much further into dimensional standardization than has been done in England and America. The object is to secure interchangeability of supplies and machine elements, so that parts of similar apparatus made by different makers may be used without difficulty for similar service. By far the greater part of the German standardization work has been devoted to machine parts, screw-threads, bolts and nuts, standard diameters, systems of limit gaging, etc.—in other words, to purely engineering matters. The Anglo-Saxon mind takes more interest in matters having to do with purchases and contracts, such as specifications for materials and for the performance of apparatus, methods of tests, etc. The German bureau has as yet done very little of this kind of work, although it has been highly developed by some of the German industrial associations, as for example, in the electrical industry. Greater dependence is placed in continental Europe upon theoretical and basic engineering considerations, while the Anglo-Saxon standardization is guided by expediency in adjusting commercial considerations.

Comparison between American, British and German Standardization Work

According to a statement published by the American Engineering Standards Committee, German manufacturers will go much farther in yielding apparent temporary commercial advantages for the sake of advancing their national industry as a whole than American or British manufacturers. This is doubtless due to one of the fundamental German traits, that of planning definitely for the future—often for a future far ahead—while the Anglo-Saxon prefers rather to take the step that seems most expedient at the time, sometimes without very careful consideration of the effects of that step in the long run.

It appears that the work done in Germany is woven very intimately into the industrial fabric. In the work of standardization, the central organization has 5000 firms as cooperating members. There seems to be a striking analogy in the present standardization there and the research work of a generation ago. Whatever estimate one may place on the role played by German industry in general, everyone agrees that research was fundamental to the marked success of the German chemical industries. Apparently the Germans are expecting standardization to prove equally important in their general industrial development.

A complete copy of the report on industrial standardization in Germany, prepared for the American Engineering Standards Committee by its secretary, will be sent to anyone interested upon application to the committee, 29 W. 39th St., New York City.

REPORT ON AMERICAN MACHINE TOOLS IN GREAT BRITAIN

According to a special report recently received by firms in this country who are members of the American Chamber of Commerce in London, the market in Great Britain for American machine tools, once a very good one, now scarcely exists. The factors responsible for this depression are carefully gone into, and interesting comments are made regarding the likelihood of a decreased market for American tools even when trading conditions shall once more have become normal. The report also reviews the state of the British machine tool industry, and discusses the effect of German competition both in Great Britain and in Europe. Hints as to marketing American machine tools are given, and manufacturers in the United States who are considering the British market are advised to consult the American Chamber of Commerce in London, which is always ready to give the benefit of its experience in these matters. Full details are available only in the report which has been sent to members, but concerns interested can obtain copies by writing to the American Chamber of Commerce in London.

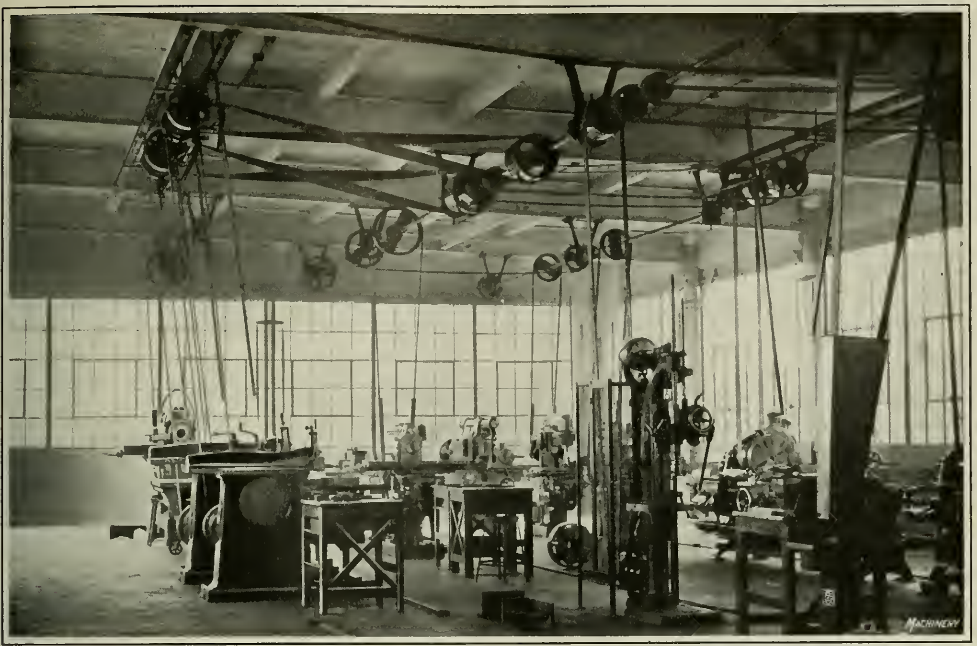
The Latvian Government has adopted a law effective for a period of five years (until April 1, 1926) whereby all industrial machinery and equipment intended for the reconstruction of Latvian industries or the establishment of new industries will be admitted into the country free of duty.



Reclaimed Leather Belting

Use of Salvaged Leather Belts Reinforced with Woven Cotton Fabric

OLD, stretched-out, oil-soaked leather belting can be freed from grease and dirt, and, with proper treatment, can be reclaimed for efficient service. This salvage work is being done commercially with satisfactory results. At an expenditure of 50 per cent of the original cost of leather belting, the life of a belt may be almost doubled without impairing its efficiency. The Syracuse Belting Co., of Syracuse, N. Y., manufacturer of reclaimed belting under the trade name of "Nu-Bilt," uses a process of reclaiming that is quite simple. The secret of the method lies in providing a suitable fabric as a backing to reinforce the scrap leather; the backing must be such that it will not produce an unequal amount of stretch between the leather and the reinforcing material. Solid woven cotton belting is the material used by this company as a backing. It is furnished by the manufacturers in coils of 500 feet, and is then stretched over rolls and held in tension while it is being coated on the side that is to be cemented to the leather with a specially prepared sizing cement. This is allowed to dry thoroughly and set the stretch before being removed from the rolls. It is then free from any further appreciable elongation.

In the process of reclaiming oil-soaked and discarded leather belts, the oil and the grease are extracted previous to applying the fabric backing of woven cotton belting. In treating ply belting, the original plies are separated and each thickness used separately, so that double or triple the amount of reclaimed belting is obtained. The old belting is cleaned in a bath of naphtha in which it is thoroughly soaked. It is then removed from the bath, artificially dried, and passed between rolls to squeeze out the grease that is not removed by the naphtha bath. The leather is next sized for uniform thickness on a leather belt machine, using a knife for scraping off the uneven surface. The belt is afterward hand-scraped to remove any dirt that might not have been scraped by the machine.

The edges are then squared up, or when making narrow belting from wide belting, cut into strips by drawing the belting over a knife. The winding and measuring machine in which this work is done has a straightedge for guiding the leather and producing strips having parallel straight sides. This is of the utmost advantage when making wide belts from narrow ones, which is commonly done by simply building out the width by laying the narrow pieces side by side on fabric backing of the desired width. Sections as short as one foot may be used to piece out a belt. After being treated, the leather is coated with high-grade cement, applied to the flesh side, against which the stretched and sized woven belting is laid while both are run through a press. After the cement between the fabric and the leather has thoroughly set, the edges must be finished to remove all unevennesses. This operation is similar to the edging of old leather, using a winding and measuring machine.

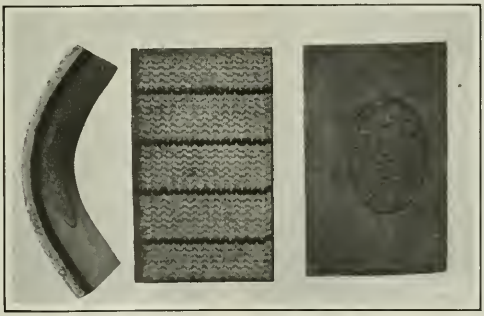


Fig. 1. Reclaimed Belting showing Face and Edge

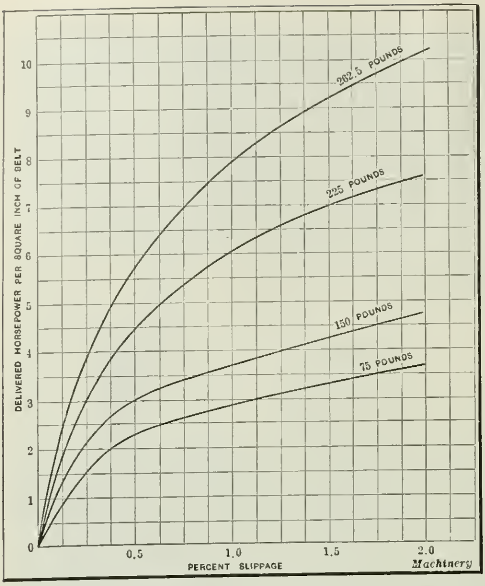

Fig. 2. Chart showing Horsepower of Reclaimed Leather Belting running at a Speed of 1000 Feet per Minute and having Different Initial Tensions

Efficiency in Power Transmissions

It will be realized that the finished product is practically free from further stretch, so relacing to take up slack is not often necessary. Some sections of reclaimed belts are shown in Fig. 1. The reclaimed belting is very pliable, enabling

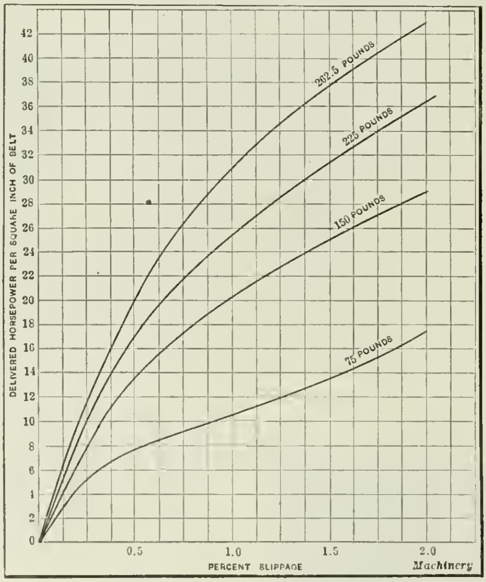

Fig. 3. Chart showing Horsepower of Reclaimed Leather Belting running at a Speed of 3000 Feet per Minute and having Different Initial Tensions

the belt to hug the pulleys closely and transmit horsepower effectively. When operating where oil is likely to get on the belts, the fabric backing acts as a wick and absorbs oil that would otherwise penetrate through a leather belt and ultimately cause slippage. Leather does not readily absorb mineral or vegetable oils. "Nu-Bilt" reclaimed leather belting is run with the hair side of the leather to the pulley, and the woven belting outward.

A series of tests conducted in the engineering department of Cornell University shows that reclaimed belting is efficient as a transmitter of power. Of course, varying humidities on different days affect the results of different tests, because climatic changes cause the initial tensions to change. This element made it desirable to conduct the tests for a sufficient number of days so that it would be possible to strike a fair average from the values obtained under various climatic conditions.

A 4-inch "Nu-Bilt" belt was used in making the tests, and three series of tests for determining the delivered horsepower at the surface speeds of 1000, 3000, and 5000 feet per minute were made, each at initial tensions of 262.5, 225, 150, and 75 pounds per square inch of belt section. The horse-

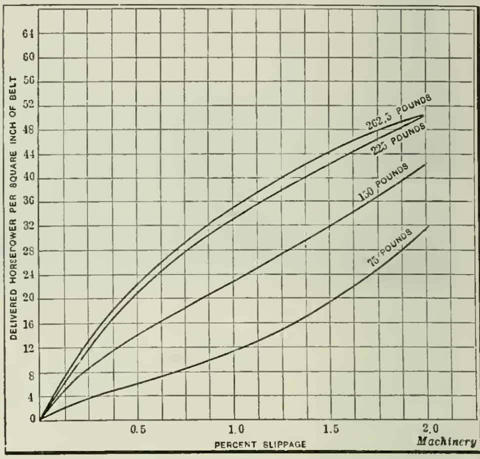

Fig. 4. Chart showing Horsepower of Reclaimed Leather Belting running at a Speed of 5000 Feet per Minute and having Different Initial Tensions

power developed and the percentage of slippage for each of these tests were plotted and curves drawn. The developed horsepower corresponding to slippages of 0.5, 1, 1.5, and 2 per cent was then taken from these curves, and these values

TABLE 1. HORSEPOWER TRANSMITTED BY RECLAIMED BELTING

Percentage of Slip	Initial Tension, Pounds per Square Inch			
	262.5	225	150	75
Test No. 1—1000 Feet per Minute Belt Speed				
0.5	5.72	4.45	2.98	2.28
1.0	7.90	6.04	3.71	2.87
1.5	9.18	6.97	4.23	3.30
2.0	10.14	7.57	4.73	3.69
Test No. 2—3000 Feet per Minute Belt Speed				
0.5	20.1	17.1	13.7	7.6
1.0	31.2	25.4	20.2	10.4
1.5	37.6	31.4	24.9	13.4
2.0	42.8	36.3	28.4	17.3
Test No. 3—5000 Feet per Minute Belt Speed				
0.5	22.5	21.3	13.8	5.9
1.0	35.1	32.6	22.4	10.9
1.5	44.25	42.5	32.1	19.3
2.0	50.1	50.3	41.9	31.4

Machinery

averaged, the results being presented in Table 1. These averages are shown plotted in Figs. 2, 3, and 4 for each of the three belt speeds. The curves are marked to show the tensions used in plotting the average in each case.

Slippage and Strength of Reclaimed Belting

The generally accepted Barth and Sellers formulas give certain horsepower values for different belt speeds and tensions. For a double-ply belt running at 1000 feet per minute, the Sellers formula gives 7.5 horsepower per square inch of belt section, and the Barth formula, 5.4 horsepower; at 3000 feet speed per minute, Sellers gives 18 and Barth 14.2 horsepower; at 5000 feet per minute, Sellers' rating is 22.7 and Barth's 13.6 horsepower. The higher values of Sellers are generally applicable to lineshaft belting, and the Barth values are those commonly used as a basis for machine tool belting from countershafts. These ratings were used to select the slippage values in the three charts shown in Figs. 2, 3, and 4, and this enables these data to be tabulated in the manner shown in Table 2. The values in the table are arranged so that a definite comparison of the amount of slippage for each of the four initial tensions under belt speeds of 1000, 3000, and 5000 feet per minute, may be made.

TABLE 2. SLIPPAGE PERCENTAGES OF RECLAIMED BELTING

Belt Speeds, Feet per Minute	Initial Tension, Pounds per Square Inch				Initial Tension, Pounds per Square Inch			
	262.5	225	150	75	262.5	225	150	75
	Sellers Rating				Barth Rating			
1000	0.89	1.93	....	....	0.45	0.77	....	....
3000	0.43	0.54	0.98	....	0.37	0.38	0.51	1.58
5000	0.51	0.55	1.00	1.66	0.28	0.27	0.48	1.32

Machinery

Although tests were run at an initial tension of 75 pounds per square inch, this low tension is not commonly used in practice except when the tension of the belt has dropped due to stretch. This initial tension would rarely be used with reclaimed belting owing to the fact that its stretch is negligible and it will maintain a high tension.

Tension Test for Breakage

Two breakage tests between two-ply leather and "Nu-Bilt" belting were made for the Brown-Lipe-Chapin Co., Syracuse, N. Y. In one test the reclaimed product broke at a stress of 4050 pounds per square inch, and the leather at 4900 pounds per square inch; in the second test the breaking points were 3900 pounds per square inch for "Nu-Bilt" and 4150 for the double leather. In the first test the elongation in reclaimed leather was 0.10 inch per inch of length, and for leather 0.215 inch; in the second test the respective elongations per inch of length were 0.095 and 0.21 inch. It will be noted that the stretch of the leather belting was more than double that of the reclaimed belting. The results of the second test indicate that there is but slight difference in the strength of the two belts.

Application of Reclaimed Belting

Reclaimed belting is used in a large variety of installations in many of the largest plants in the country, where it is reported to be rendering excellent service. Such machines as turret lathes, automatics, and milling machines are equipped with belting of this kind, and it is also said to be particularly satisfactory in connection with motors and grinders.

In Fig. 5 is shown the application of a 6-inch "Nu-Bilt" belt which is used for driving the top head of a 12-inch molding machine made by the American Wood Working Machinery Co. The machine is in operation at the plant of the Wilson & Green Lumber Co., Syracuse, N. Y. Another installation of this belting is shown in Fig. 6. This view was taken in the plant of the Endicott Forging & Mfg. Co., Endicott, N. Y., where the belting is being used for driving Bradley hammers. It will be seen that the belt is running from a flanged pulley to a pulley on the lineshaft. A belt guide is employed, but the edges of the belt are not curled or frayed to any extent.

One section of the plant of the Greiner, Semon, Lowry Co., Syracuse, N. Y., is shown in the heading illustration. This view shows the main drive motor, as well as shapers, drilling machines, engine lathes, and milling machines, all being driven from the lineshaft by "Nu-Bilt" belting.

WHAT IS NORMAL BUSINESS?

During a recent trip through the West the writer asked a considerable number of machine tool manufacturers for their definition of "normal business." One said three times the amount (in value) of their sales for 1914; another two times; another 50 per cent more; another twice their average annual sales for 1910, 1911, 1912, and 1913; another suggested that if the sales curve were taken for the ten years preceding 1915 and continued through the six years following, not at the war prices or output, but at the average increase for the preceding ten years, the point reached by the curve at the present time would represent present normal business. For purposes of comparison it seems simpler in each case to use a value basis and to allow for the difference in price between the periods to be compared.

Now comes the Manufacturers' Association of Connecticut, which has worked out a method as follows: Each plant should determine the number of employes required to operate its present equipment and the number of regular working hours per week. The product of these two gives the number of man hours per week when the plant is in "normal" operation. To estimate the percentage of normal at which the plant is actually operating at a given time, the actual average number of employes at that time, multiplied by the actual number of working hours gives the total of man hours. The proportion this bears to the normal number of man hours will indicate the percentage of normal at which the plant is operating. Instead of "normal business" this is really capacity production, and we know that many plants have greater capacity, or more equipment than is required by any reasonable estimate of normal business.

Who has another method?

* * *

THE EFFECT OF HIGH FREIGHT RATES

The general belief that the high cost of transportation is one of the most potent factors in retarding business improvement is strengthened by a consideration of the effect of present freight rates upon the cost of machine tools, which, in common with many other manufactured articles, carry from three to six freight charges on the raw material and the various products that enter into their manufacture, thereby greatly increasing the cost to the purchaser.

The increased cost of transportation as it affects the machine tool business is shown by the following examples of freight charges on machine tools in 1914 as compared with 1921, and also freight charges on some of the principal materials used in the machine tool business—steel bars, pig iron, and coal—Cincinnati being used as a center.

The transportation of an 18-inch by 8-foot lathe to New York now costs $48 against $22 in 1914; a 24-inch by 10-foot lathe, $93 against $42; a 4-foot radial drilling machine, $120 against $48, and a carload of machine tools, $136 against $62. The rates from Cincinnati to Chicago are in about the same proportion, $31 against $14; $59 against $27; $78 against $30.

The effect of freight rates on the cost of material is even more marked. In 1914, a 50-ton carload of steel bars at the mill cost $1100; in November, 1921, it cost $1550, or approximately 40 per cent more; but the freight on this carload of steel had increased more than 110 per cent—from $158 to $334.75. A carload of coal cost at the mine in 1914, contract price, $37.50, and in November, 1921, $70; but the freight to Cincinnati, which was $50 in 1914, rose to $108.15 in 1921.

Freight rates must come down before prices can be reduced generally, and every help that the Government continues to give the railroads to reduce their operating expenses by abrogating unreasonable working rules and by reducing railroad pay to a level with wages paid in other lines of industry will help to benefit all classes of the people.

* * *

RUINOUS COMPETITION

Business conditions have caused the revival of some objectionable trade practices in the metal-working industry which have resulted in almost ruinous competition between manufacturers in various lines. In one instance, recently brought to our attention, four bids were submitted for the manufacture of certain metal products, the lowest bid being $2100 and the highest $2450. Nothing below the lowest bid could have been considered a fair price; yet upon being told the figures, the three highest bidders offered to reduce their quotations, virtually forcing the lowest bidder, in turn, to reduce his figure also, until finally the order was placed with him at $1500.

Through the operation of this pernicious practice the contract was finally awarded to the lowest bidder at less than actual cost, a price-cutting war was inaugurated in which all the manufacturers will inevitably lose a large amount of money, and a new price level was established below the point where there is any profit, the manufacturers having played into the hands of the purchasing agent, who in future will work his advantage for all it is worth.

Times of depression always bring out harmful and objectionable business practices which it sometimes requires years of normal business to eradicate. After much labor and research, manufacturers adopt mechanical standards which they would never think of discarding, and for their own protection they should not rashly discard standards of business procedure, especially in regard to competitive practices.

* * *

UNIONS HAMPERING PRODUCTION

One of the questions that must be settled in the railway shops is the extent to which unions shall continue to be permitted to restrict production. In a railroad shop in the Middle West, machinery was installed that produced from 3000 to 4000 parts a day of one article used in great numbers in railroad work. The makers of the machinery employed, devised an automatic machine capable of producing 20,000 parts a day, which was installed and proved its efficiency; but when it became evident that production would be increased at least fivefold, the unions protested so effectively that the use of the automatic machine was discontinued, and it now stands idle.

When the cost of railroad operation is increased because union labor refuses to permit the use of modern improvements and labor-saving machinery, we all suffer. The railroads increase their rates to cover the resulting loss, other costs rise, industry is hampered, unemployment in other industries increases, and even in the railroad shops themselves there is less opportunity for work, as present conditions show, and so it goes throughout the vicious circle.

While some of the most objectionable of the rules in the National Agreement between the railroads and the unions have been abrogated by the Railway Labor Board, many objectionable features have been retained.

Work and Thrift—Watchwords for 1922

THE New Year opens under clearing skies, national and international. The world is wiser, if chastened, and one thing it is now sure of is that the glory of war is one of humanity's great illusions, and there must be no more of it. And right here in America where the love of peace is a national characteristic and ideal, we have learned that we cannot have it, however much we cherish it, by merely holding aloof from our neighbors. So we have been talking things over with them and find them eager for our friendship and quite willing to reduce their armaments and sign up for universal peace, if assured of our continued interest and good will.

Nor can we trade with neighbors impoverished after a world war in which forty million men were under arms and whole populations enlisted for the production of war munitions. A great wild splurge it was while it lasted, and the bill has hardly begun to be paid yet. But the progress of mankind, political aud economic, since the guns were silenced and the trenches vacated, has been amazingly swift, considering what there was to be done and the debris, turmoil and confusion out of which the victorious no less than the vanquished had to lift themselves.

Serving the industries as MACHINERY does, it is exhilarating to note the marked progress in mechanical methods and devices during the past year or two. It is not the spectacular discovery, or even the application of some new force or element, that immediately and directly benefits the mass of mankind, but the thousand and one ideas and improvements developed in prosaic mechanical practice, which improve, multiply and cheapen the manifold products of industry and thus increase the measure of comfort among the people. Wonderful is the flying machine and great must be its future, but of greater direct benefit to the greatest number is a good washing machine made cheap enough for the poorest. Along this line the country is moving, and no industry shows greater progress in the details of design and construction which make for greater power and speed in production than the fundamental machine tool industry which it is MACHINERY's privilege to serve.

Following the great and unprecedented activity of the war period in which this basic industry was greatly expanded in order to accomplish its vital work for the production of munitions there have been nearly two years of stagnation. One of the last of the industries to recede from the peak, it is one of the last to turn toward prosperity again. Small tools and accessories, the vanguard of the metal-working industry in the forward march, are doing a better business, and in other lines of industry various branches are well along the road to prosperity. The machine tool industry serves them all, and when the turn has come for them the turn for this basic industry cannot be far away.

It is a fact that after every depression recovery in the machine tool industry has been more rapid than was expected. There is not a great deal of war machinery to be released, either government or private, and there is a great deal of "hold-back" in buying of shop equipment. The world never stands still; consumption goes on incessantly, and the purchase of machine tools as well as commodities of every description must follow the inexorable law of supply and demand. The year 1921 will stand out a heavy black mark in the annals of the machine tool industry, but that is behind us, and 1922 will unquestionably lay the basis for a period of prosperity in this industry.

The industry has its troubles like every other, but is operated by practical people who know how to work definitely for practical results. They are not much given to theory, except the theory that underlies and makes possible modern mechanical practice. They believe in work. A great many good people believe that religion will save the world; others think prohibition can, or did think so; socialism in all its varieties has many advocates; but MACHINERY believes with the Machine Tool Industry, that the sovereign remedy for social and economic ills is just plain hard WORK, plenty of it—and THRIFT. Evidences multiply that people generally are returning to these fundamentals. The year 1922 should be a great year for men and for nations endowed with horse sense.

New Type of Thread Plug Gage

A THREAD plug gage of a design embodying a number of new features, which is manufactured by the Hartford Tap & Gauge Co., Hartford, Conn., is shown in the accompanying illustrations. This gage can be supplied in a number of different combinations, as for example, with a standard thread plug gage on one end of the hollow handle, and an over-size thread plug gage on the other end, or with a thread plug gage on one end and a plain plug gage of the same diameter as the tap drill used in producing the hole in the work, on the other end. The handle may also be provided with only one gage and used as a single-end gage. The thread of gages generally wears first on the end that enters the hole in the work, and so provision is made for reversing the threaded plugs as they become worn so that they will have a longer life.

Each plug is mounted on a screw which has a head of approximately the same diameter as the bottom diameter of the thread on the plug. This screw fits into a nut held in the handle by means of a taper pin, as shown in Fig. 2. The threaded plug is rigidly attached to the handle by tightening the screw. The taper pin is first driven back so that its large end projects about 5/16 inch from the side of the handle; then the screw is tightened with an ordinary screwdriver, after which the taper pin is again driven into the handle until the large end extends approximately 1/16 inch. Thus the taper pin is driven a distance of about ¼ inch. The driving of the taper pin into place causes the nut to be drawn back into the handle and creates a tension in the screw so that the gage and the handle are held tightly against each other. A small pin driven into the ends of the handle projects into a small slot on the face of the gages. This locks the members together in such a way that they will not work loose.

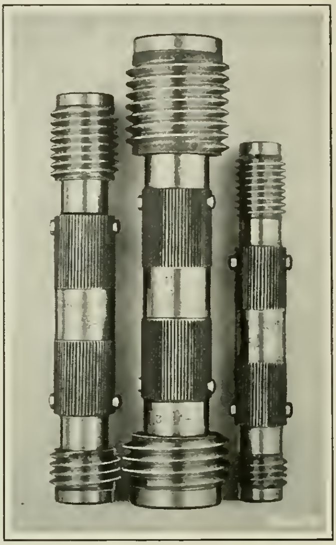

Fig. 1. Reversible-end Thread Plug Gages

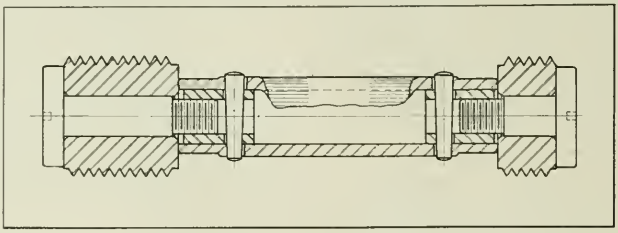

Fig. 2. Sectional View showing the Method of attaching the Threaded Plugs to the Hollow Handle

All parts of the gage, including the taper pins, are hardened. The thread on both ends of the plugs is milled off until a full form is reached. This will be seen by referring to the gages illustrated in Fig. 1. By this construction, any dirt that happens to be in a hole to be gaged will be scraped off by the thread of the plug as the latter is inserted in the hole. As the handle is hollow, the gage is comparatively light in weight, and by making the diameter of the screw heads approximately the same as the diameter of the bottom of the thread on the gage ends, it is unnecessary to provide a special pilot for the plug.

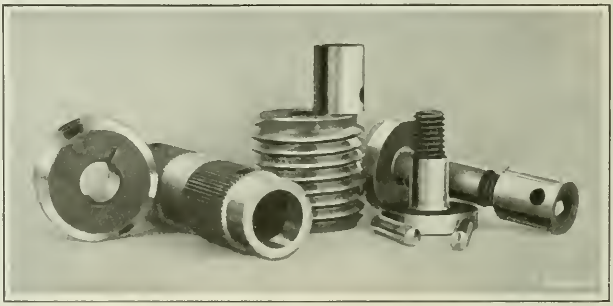

Fig. 3. Parts of the Hartford Tap & Gauge Co.'s Thread Plug Gage

Although the first cost of a gage of this design is more than that of a solid gage, the possibility of renewing the gage ends and using the handle, screws, nuts, and taper pins indefinitely is an economy in cases where a gage is subjected to severe use. The thread plugs are finished without lapping by means of a new grinding method known as the "Hanson process" producing a fine finish and threads of accurate form. The gage ends are manufactured in various sizes from ½ to approximately 6 inches in diameter, and with U. S., V, Acme, and Whitworth threads. This new type of thread plug gage was designed by B. M. W. Hanson.

The more rigid requirements in interchangeable manufacture which prevailed during the period of the war, and which since then are being more and more adhered to in many lines of manufacture for peaceful pursuits, have increased the demand for accurate gaging means, and mechanical men generally will be interested in the details of new designs.

* * *

On December 16 the Keller Mechanical Engraving Co., Brooklyn, N. Y., through its vice-president, Jules Dierckx, presented to President Harding a bronze medallion bearing on one side the portrait of the President and on the other side an expression of the sentiments of the times. The original of the medallion was modeled in wax by Frederick Kaupmann, Jr., and from a mechanical point of view the reproduction is unique in that the dies were cut on an automatic machine and not by hand, as is the usual practice. The occasion commemorated the twenty-fifth anniversary of the founding of the Keller Mechanical Engraving Co.

Reducing Costs by Continuous Milling

CONTINUOUS circular milling presents one method by which production costs can be reduced to the minimum in milling when the work lends itself to ready loading and unloading on a rotary fixture without stopping the machine, and when the operation may be accomplished as the parts are conveyed by the rotating table past the cutters. The efficiency of continuous milling as regards the average amount of time required for machining a part will be emphasized in this article, which illustrates a number of operations of this class performed on single- and double-spindle milling machines of the vertical continuous type, built by the Newton Machine Tool Works, Inc., Philadelphia, Pa. The distance between the spindles of double-spindle machines varies, but in each case it is sufficient to permit long pieces to be completely rough-milled before a finishing cut is begun on the same part. Owing to the fact that the work is turned on the axis of the fixture as it is presented to the cutters, a shearing action of the cutters is produced, which accounts for the high rates of feed obtainable.

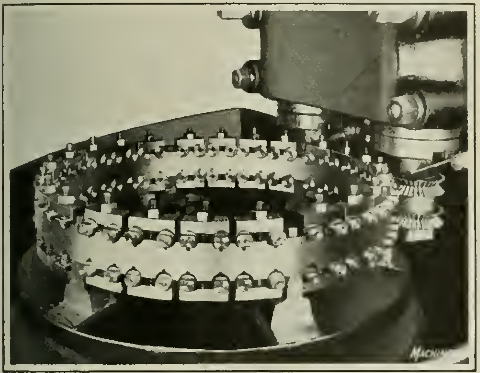

Fig. 1. Operation in which One End of Camshaft Thrust Blocks is flatted and beveled

Fig. 2. Fixture for holding One Hundred Connecting-rod Bolts on a Single-spindle Machine

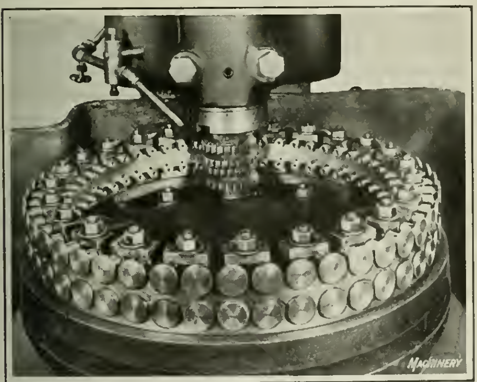

Fig. 3. An Operation on Valve Lifters, the Cutter-spindle heing located within the Work Fixture

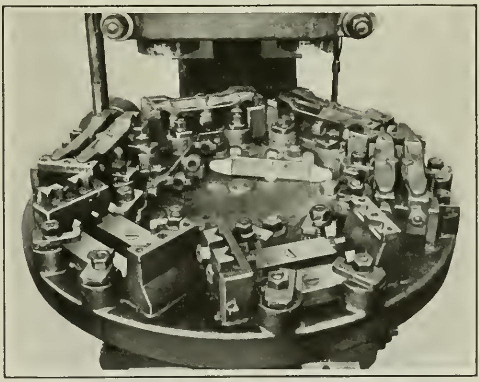

Fig. 4. First Operation on Valve Rocker-arm Brackets in which the Bottoms are machined

In the examples to be presented, the possible production per hour, the average production per day based on an efficiency of 90 per cent, and a piece cost based on a labor rate of 70 cents per hour will be given. An operation in which a double-spindle machine is employed to advantage is illustrated in Fig. 1; this consists of milling camshaft thrust blocks. The fixture holds ninety-six pieces at one time, and as they are traversed past the set of cutters on the first spindle, flats are machined on the top and bottom of the projecting ends. The second set of cutters bevels the front ends of these flats. In this operation the table feed is 5 inches per minute, so that 413 pieces may be machined per hour or 2973 per eight-hour day, based on the efficiency previously mentioned. The average labor cost per piece is 0.19 cent. It will be seen that four blocks are clamped in place by means of one bolt which controls two clamps. The pieces are seated in rounded grooves, and the shoulders on the opposite ends to those machined bear against the inside of the fixture, so that the work projects the required amount.

Automobile connecting-rod bolts have the head milled flat on one side and beveled on the other in the operation illustrated in Fig. 2, which is accomplished on a single-spindle machine equipped with four cutters. The fixture has a capacity for 100 bolts, and four pieces are held in place by two clamps and one bolt, as in the preceding operation. In this case the bolt heads register against the outside of the fixture. The table feed is 8 inches per minute, and a production of 625 pieces per hour is possible, or an average production of 4500 pieces per day, the labor cost being 0.13 cent per piece.

Another 100-piece fixture is illustrated in Fig. 3, which shows an operation on the small ends of valve lifters. In this case the milling cutters are inside the fixture, whereas in the preceding examples they were located outside. The table feed in this operation is 12½ inches per minute, so that a production of 1194 pieces per hour is obtainable, or an average of 8600 pieces per day. This brings the labor cost per piece to 0.065 cent.

An operation on cast-iron valve rocker-arm brackets is performed on a machine provided with the rotary fixture shown in Fig. 4 in which the ends of the pieces are clamped in V-blocks drawn together by means of a bolt, while other clamps bear against bosses on the work. The operation consists of milling the feet and a boss on the bottom of the brackets. There are six stations on the fixture, each of which holds two pieces. At a table feed of 15 inches per minute, the production per hour is 120 pieces or 864 pieces per day, the labor cost being 0.65 cent.

A second operation on the valve rocker-arm brackets, which is somewhat more complex than any of the others described, consists of machining the faces of three bosses. This set-up is not illustrated. The fixture accommodates twenty-two brackets, the pieces being seated on the surfaces machined in the operation illustrated in Fig. 4. While the three boss faces at one end are parallel with each other and those at the other end are also parallel, the faces of both sets are not parallel. On account of this condition only three faces can be machined in one traverse past the cutters, the other three being milled by reversing each bracket for a second traverse. By this method the twenty-two pieces are completed in two revolutions of the table, and with a feed of 4 inches per minute a production of thirty-five pieces per hour is possible. At the rate of 252 pieces per day, the labor cost per piece is 2.22 cents.

A fixture designed for holding cast-iron covers for a pump gear-box is shown in Fig. 6. The covers are surface-milled at the rate of 18 inches per minute, which gives a production of 114 pieces per hour or 821 pieces per day, at a labor cost of 0.68 cent per piece. The portion of the castings projecting into the fixture is forced against a steel plate by means of an adjustable steel plate, actuated by a screw.

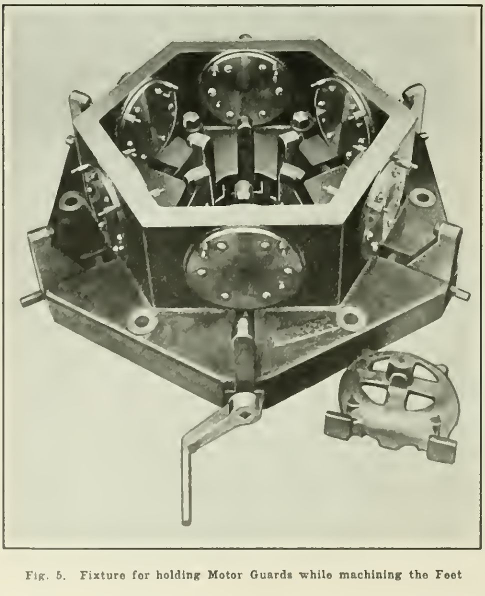

Fig. 5. Fixture for holding Motor Guards while machining the Feet

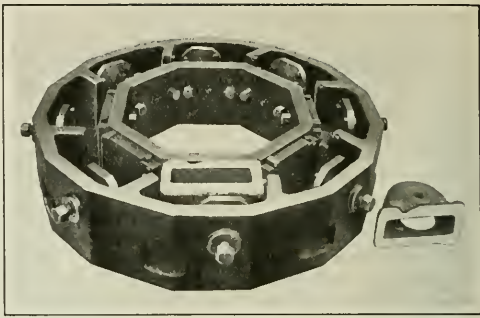

Fig. 6. Fixture designed for holding Covers for Pump Gear-cases

The fixture presented in Fig. 5 is employed in the continuous milling of end shields for electric motors, one of these parts being shown in front of the fixture. An internal surface of the work is machined to fit circular plates attached both to the outside and inside of the fixture, and at each station two parts are held on these surfaces by two clamps operated through a single screw that is turned by means of a crank-handle. The operation for which this fixture is employed consists of milling the feet of the shields, and this is accomplished at a feed of 30 inches per minute which gives a production of 313 pieces per hour or 2254 per day, at a labor cost of 0.25 cent per piece.

* * *

STANDARDIZATION AS A MEANS OF CUTTING PRODUCTION COSTS

Simplification is probably one of the most important means of cutting production costs, but it cannot be accomplished by the individual manufacturer without the wholehearted support of the financial, sales, and production executives. To obtain the greatest reduction in cost it is necessary, however, that such simplification be carried beyond the plant of the individual manufacturer to include the entire industry. Cooperative simplification between manufacturers, or standardization, can be carried out most advantageously through the medium of trade organizations.

In the automotive industry the Society of Automotive Engineers, functioning through its standards committee, has made possible this coordination of effort which has resulted in the application of standards and consequently the cutting of production costs to a great extent. Additional standards, each representing a possibility of reduced costs, will be acted upon at the standards committee meeting on January 10 in the Engineering Societies' Building, New York City. Sixteen divisions representing different fields in the automotive industry and parts or material manufacturers will present over thirty proposals for adoption as standards. The iron and steel division will submit a complete revision of the present iron and steel specifications. The revised report is based on a great number of laboratory tests carried out throughout the country. The following parts and materials are included in the various reports: Ball bearings, roller chains, sprocket cutters, generators, insulated cable, starting motors, carburetors, fan belts and pulleys, mufflers, running boards, iron and steel specifications, non-ferrous metal specifications, rod-ends, lock-washers, pressure gages, pneumatic tires, clutch facings, tire pumps, and three-joint propeller shafts.

* * *

The Danish Government is reported to have discontinued negotiations looking toward a trade agreement with Russia, while Sweden still continues to bargain with the Soviets in the hope of securing a satisfactory commercial treaty. Norway has concluded a commercial treaty with Soviet Russia.

Mechanical Engineers' Annual Meeting

THE keynote of the annual meeting of the American Society of Mechanical Engineers, held December 5 to 9, in the Engineering Societies' Building, 29 W. 39th St., New York City, was the prevention of waste in industry. A great many of the papers read before the society pertained to this subject. The address by the retiring president, Edwin S. Carman, dealt with the subject of industrial relations, and great stress was laid upon the necessity of paying greater attention to the human factor in industry. The engineer must not only concern himself with scientific and mechanical facts, but must broaden his views as to his position in industry, so as to aid in the solution of the greatest problem now requiring attention in the field of production. Some common ground must be found between employer and employe, and the engineer must fit himself to be able to aid in formulating the proper means whereby this can be accomplished.

Salvaging Industrial Waste

The machine shop division had prepared a program of three papers, all of which awakened a great deal of interest. The subject of salvaging industrial waste was dealt with by J. A. Smith, general superintendent of the General Electric Co., Schenectady, N. Y. Attention was called to the great amount of waste in ordinary machine shop operation, due to not taking care of metal and other material waste. Furthermore, a great deal of waste is due to negligence of repair and maintenance work. The author emphasized the fact that systems must be set up governing the distribution and repairs of the various classes of small tools so that the consumption of these will be regulated within certain defined limits of economy and efficient service, in accordance with production requirements in the shop.

It is good practice to make regular monthly inspections of machine tools and equipment, and make a record of these inspections, in order that repairs may be made promptly at a minimum of cost before the damage becomes more serious or breakdown ensues, with increased repair expense and added delay to production. The record is valuable as showing the relative cost of maintenance and the relative life of service of various makes of tools. It is often good economy to replace a tool showing high maintenance cost with a new tool of some other make, and thus save both expense and delays to production. In all cases of replacements and repairs, valuable parts should be salvaged and made use of on other jobs of repair work, wherever practicable.

In supplying small tools to the shop, much can be accomplished in the way of reducing expense by efficient methods of distribution and collection. A system of regular inspection of tool-rooms, tool cupboards, benches, and areas around machine tools should be established in all departments. Tools not needed for immediate or current use should be promptly returned to stock, and those needing repair put into shape for further requirements. This is particularly important in the case of high-speed-steel tools where the cost is relatively high by comparison, and a single idle tool may represent a good many dollars of tied-up capital. By a properly organized system of distribution and collection, the inventory of tool stocks carried may be greatly reduced, expenditures for new tools curtailed, and those in use in the shops kept more constantly in active service.

The author also laid emphasis on the fact that the question of profit should not always be a deciding factor in considering the saving of materials, but that operations must be conducted with a broader view of saving everything which may he of value whether immediate, direct profit is gained or not. The manufacture and supply of raw materials depends so often upon the supply of various kinds of scrap and waste that it is most essential that consideration be given to the country's needs as a whole and that efforts at salvage work be not limited to the desire for immediate profit. Indirectly benefit will be received through reduced cost of raw stocks, because of the abundance of original materials which are thus created.

Still another phase of salvage work which is distinct and apart from the field of salvaging metal scrap and other factory wastes, is the saving of time and human effort, and of mental and physical energy. Profitable manufacturing requires that we build up our organizations both in offices and in the factory with a view to concentrating directive effort, eliminating duplication of orders and instructions, establishing unity of purpose, system in method of procedure, and cooperative effort on the part of all employes, whether serving in official capacities or in the lower grades of mechanical and physical labor.

Waste in the Machine Industry

An address that aroused a great deal of enthusiasm because of its relation to the human rather than the engineering side of shop operation, was that by J. J. Callahan, general manager, Passaic Metal Ware Co., Passaic, N. J., on "Waste in the Machine Industry." In this address Mr. Callahan pointed out that if the management of any industrial undertaking desires the cooperation of its employes, this can be obtained by creating a spirit of mutual confidence and by arousing the interest of the employes in the success of the business enterprise by giving them an opportunity to take an active interest in the development and application of improved methods and facilities. He gave numerous examples of successful application of such cooperation both in the plant with which he is connected and in other manufacturing establishments. An article explaining in detail the plan that Mr. Callahan has installed in his own shop in Passaic, was published in November, 1919, MACHINERY, entitled "Representative Government in a Manufacturing Plant."

The Art of Milling

A paper giving particulars of an investigation undertaken at the University of Michigan for the purpose of finding a rational basis for the action of a milling cutter was presented by Professor John Airey, Ann Arbor, Mich., and Carl J. Oxford, mechanical engineer, National Twist Drill & Tool Co., Detroit, Mich. In this paper it is shown that metal is removed more efficiently with thick chips than with thin chips. It follows from this that, other conditions being equal, including speed and feed per minute, the cutter with the fewest teeth gives the greatest efficiency. However, it is evident that the efficiencies of two cutters with different numbers of teeth are equal, provided the table feeds be adjusted so that the same feed per tooth is effected. This gives a definite working theory on the influence of spacing.

It is definitely established that for a given material, tooth shape, and sharpness, thickness of chip is the sole criterion of the efficiency with which metal is removed in milling and that increase of spacing over that required for free cutting is a handicap. Present-day high-powered cutters have several times the chip space needed. Limitation of machine power has doubtlessly been the chief factor in giving a false bias to the influence of spacing. Formulas for determining the number of teeth for a known diameter of cutter and for determining the depth are included in the paper, as well as a geometrical construction for obtaining the best shape of tooth.

The authors pointed out that the industrial value of scientific analysis applied to basic shop processes appears to be little appreciated when that analysis is contrasted with investigations carried on to improve the design of the manufactured product. This is explained partly by the cleavage between the engineering department and the operating department in almost all plants. It is also partially explained by a shrinkage in the significance of the term "engineering" until it means "design" only, when used in a quantity-production atmosphere. This is either the cause or the effect of our engineering schools keeping out of touch with production proper, and consequently research energy is lavished on all features of design, each minor side issue usually having its full quota of devotees.

In contrast to this, research endeavor covering basic shop processes appears to be badly neglected. Taylor, in this country, and Nicolson, in England, have done classical work in the field of lathe-tool action. There is much to be done, and many fundamental shop processes are yet untouched. A plea is here made that our engineering schools devote the same intensity of attention to shop processes that they now devote to design. The economic results to industry would be greater though not so spectacular. If a hole can be drilled more quickly or a surface can be milled more rapidly, then the cost of practically all classes of finished products is affected. This is true of improvements in all basic shop processes, whereas improvements in design benefit only a limited field—just one class of finished product. The economy accruing from improvements in shop processes, being distributed over a larger territory, is less spectacular, and this, indirectly, may account for the decreased attention given to it.

In the art of milling, the only published investigations have been handled by machine tool builders. Attention has in consequence been focussed more on the machine than on the cutter. This paper describes an attempt to investigate the fundamental principles underlying the action of milling. The investigation described in the paper was instituted in May, 1920, by the National Twist Drill & Tool Co., and this company furnished the financial support throughout. Experiments have been conducted in the engineering shops of the University of Michigan, at the plants of the National Twist Drill & Tool Co., the Lincoln Motor Co., and the Hudson Motor Car Co. The greater part of the work was done at the University of Michigan. A complete copy of the paper may be obtained from the American Society of Mechanical Engineers, 29 W. 39th St., New York City.

PROPOSED BIG STEEL WORKS IN INDIA

According to information given out by W. H. Rastall, chief of the Industrial Machinery Division of the Department of Commerce, there has recently been incorporated in India by Bird & Co. of Calcutta and Cammell, Laird & Co., of Sheffield, a new concern known as the United Steel Corporation of India, Ltd., with a capitalization equivalent to $60,000,000 to $100,000,000 depending on the exchange calculated. It is believed that this development is of great importance to the future of the iron and steel industry in the East, it being proposed to establish, as soon as possible, works on a large scale near the deposits of iron, coal, and limestone in India. The cost at the works is said to be greatly below what has to be paid in other steel-producing countries, and for this reason it is believed that India will be able to produce the cheapest steel in the world. Cammell, Laird & Co., Ltd., are acting as advisors to the corporation, and are responsible for the design and erection of the works as well as of hiring employes. The plant is designed to produce 600,000 to 700,000 tons of pig iron, and the steel works and rolling mills are capable of producing 450,000 tons of finished steel a year. As a first step, however, it is proposed to erect a unit of half this capacity.

INDUSTRIAL CONDITIONS IN FRANCE

By MACHINERY'S Special Correspondent

Paris, December 10

The machine tool market is very quiet, and there is practically no buying. The only demand is for special machines, of which a few are being sold. Hence the production in the French machine tool shops is at a low level, and in the St. Etienne district, especially, a number of plants have reduced their working hours. The machine tool builders are particularly affected by the uncertainty of the policy which will be adopted by France in its dealings with Germany. Many French buyers of machine tools are deferring their purchases until German machines may be imported into France without difficulty.

At the present time, only special machines find a market, but some of these are selling steadily. This is particularly true of swaging machines, which have been placed on the market by three French manufacturers—Jouve, 3 rue de l'Orme, Paris; Chanay, 32 rue du Plat, Lyons; and Groslambert, rue de Vesoul, Besancon. These machines have given very good results.

The Allied Machinery Co. of France, 19 rue de Rocroy, Paris, has just installed in its Cail factory at Denain, one of the "Quickwork" shears built by the Quickwork Co., St. Marys, Ohio, which is said to be the only machine of its kind in France, and which has been arousing considerable interest among French engineers on account of the work of which it is capable.

The Norton Co. has built a large factory at La Courneuve, and is now supplying grinding wheels in all sizes from this plant. The quality of these wheels is exactly the same as that of the wheels formerly imported from America, the raw materials being imported from the United States. Fenwick Frères, 8 rue de Rocroy, Paris, because of the prohibitive exchange rates with America, have taken the agency of a Belgian manufacturer of grinding machines.

General Conditions in the Metal-working Field

In general, there is a slight improvement in the metal-working industries. Slowly but steadily the plants are starting up. There has been an increase in the demand for labor in the metal-working field in the vicinity of Paris. The scale of wages at present, based upon an eight-hour day, is as follows: Unskilled labor, 14 francs; machine operators and helpers, 22 to 24 francs; milling machine and lathe operators, 27 to 28 francs; blacksmiths, boilermakers, structural iron workers, 26 to 29 francs; highly skilled mechanical workers, 30 to 33 francs.

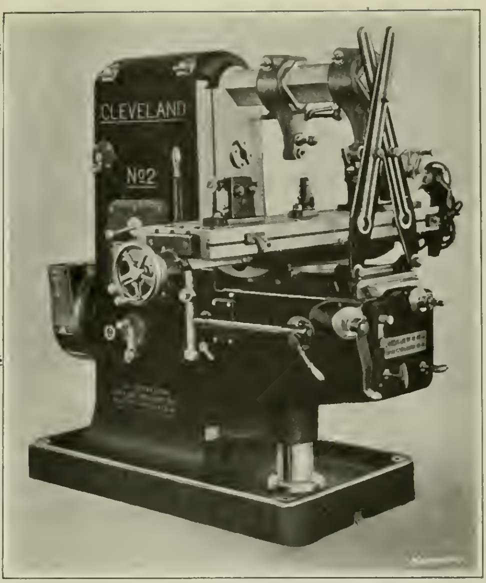
It is stated that a number of large French steel works have jointly opened negotiations with Italian works for delivery to Italy of large quantities of steel billets to be rolled into the finished product by Italian mills. The Italian Government approves of this arrangement, and a reduction is being considered in the custom duty for imports of this kind into Italy.

Considerable business is expected from the electrification of the railroads, some of the large railroad companies of France having already started to negotiate important orders in the electrical field. The Thomson-Houston Co. is figuring on a contract to manufacture 200 electric locomotives for la Compagnie d'Orléans. The same company is at present engaged in the manufacture of material for sub-stations for the Midi railroad, and is negotiating with the Paris-Lyons-Mediterranean road for similar material.

Construction Mecanique Francaise (Anciens Etablissements Cail) at Denain (Nord) is working on an order for 100 large locomotives to be completed and delivered in the course of the coming year. This company now employs 3500 men, and the production has reached 90 per cent of the pre-war output. The restoration work at Denain has proceeded rapidly, and when the new buildings have been completed the industrial plants of the city will have a larger capacity than before the war.

Design of the Cleveland Milling Machine

A Detailed Description Covering the Important Features in Design



THE efforts to produce machines to meet, in the best way possible, the demands for adaptability to a large variety of work, ease of operation, rapidity and accuracy of production, and length of service, have been largely responsible for the evolution of standard machine tools to the present-day designs. By these constant efforts the milling machine has advanced to its present stage of development. The heading illustration shows a modern machine of this type—the Cleveland milling machine built by the Clark-Mesker Co., Cleveland, Ohio. A patent covering the distinctive features of this machine has just been issued and, in view of this, it is believed that a description of the design will prove of interest to those engaged in machine tool design and to users of machine tools.

Construction of the Column and Over-arm

The column and base of the machine consist of a one-piece semi-steel casting adequately ribbed to give a rigid construction. As shown in Fig. 1, the lower portion of the column on the inside is formed into a chamber in which is kept a supply of coolant for the cutters, the coolant being conveyed to the cutters through the medium of the centrifugal pump *B* which is driven from the main driving shaft *A* through bevel gears and a vertical shaft. By driving the pump directly from the main shaft the supply of coolant to the cutters is automatically cut off when the machine is stopped. The bracket for the pump and its driving shaft is suspended from a rib which separates the coolant chamber from the compartment occupied by the main driving shaft and the speed-change gearing. A gasket is placed between the flange of the pump bracket and the rib so as to prevent oil leaking from the upper compartment into the coolant chamber. The pump forces the coolant to the cutters through piping which may be seen in Fig. 3, the coolant being later returned from the table to the chamber through a hose. The coolant chamber is filled through an opening in the right-hand side of the column which is provided with a suitable cover.

A feature of the machine is the square over-arm, the main advantage claimed for this design being that it provides a positive alignment of the arbor supports and the arbor with the other machine members. The over-arm is held snugly in the column by a cap having 90-degree V-grooves which mate with similar grooves in the column proper. The cap is aligned on the column through the use of a taper gib and dowel-pins, and the over-arm is clamped in place by binding members *C*, Fig. 1, each of which has two cylindrical parts connected by a screw that projects from the left-hand side of the column. These cylinders have beveled surfaces on the ends in contact with the square over-arm, and clamp the latter when the bearing surfaces are drawn against it by rotating the binding screw. The two arbor supports are clamped to the over-arm in a similar manner.

Lubricant for the various gears in the upper compartment of the column is supplied through opening *D*. The compartment should be filled to a level midway across a gage glass on the left-hand side of the column, which may be seen in the heading illustration below the main driving shaft. To fill to this level requires approximately five gallons of oil, but it is only necessary to do this about twice a year. A fine mist of oil is created in this compartment when the machine is running, due to the revolution of the gears.

The Spindle Driving Arrangement

Power to the cutter-spindle, the knee-elevating mechanism and the table feeds is transmitted through shaft *A*, Fig. 1, from the constant-speed pulley *E* which drives shaft *A* by means of friction clutch *F*. The pulley is mounted on the hub of the clutch-driving member, and this entire unit is supported by a bracket bolted to the rear of the column. Clutch *F* is controlled by levers *A*, Fig. 3, on each side of the column, located close to the table. The drive from the main shaft to spindle *G*, Fig. 1, is through a set of change-gears which ends in two gears keyed to the spindle. This arrangement furnishes sixteen speeds in geometrical progression, in either direction.

Power is transmitted from the driving shaft to the first gear *H* in the speed-change train, either direct through clutch *L* or through three bevel gears, *I*, *J*, and *K*, and clutch *L*. The clutch is keyed to shaft *A*, and when it is brought in mesh with the sleeve on which gear *H* is mounted, the latter is driven in a direction opposite to that in which it revolves when the drive is through the bevel gears previously mentioned. Clutch *L* is operated by a lever on the left-hand side of the column, which may be seen in the heading illustration adjacent to the oil-gage. With this arrangement only one speed, in either direction, can be transmitted to shaft *M*, Fig. 1, this being accomplished by means of the gear at the rear end of shaft *M* which meshes with gear *H*.

Two sliding gears *U* and *V* on shaft *M* and four gears which are held stationary axially on a sleeve *N* that revolves on a shaft enable any one of four speeds to be transmitted to the sleeve. From this sleeve power is transmitted to shaft *O* through two pairs of sliding gears *W* and *X*, which mesh with gears keyed to sleeve *N*. Sliding gears *W* and *X* have clutch teeth on both ends, and when gear *W* is pushed to the rear, the clutch teeth on this end engage similar teeth on gear *Q*, thus driving this gear directly.

When the sliding gear is brought to the front its teeth engage those of clutch *P* so that gear *Q* is driven through the clutch and the sleeve on which the clutch and gears are mounted. Similarly sliding gear *X* drives gear *R* either through the clutch teeth mounted adjacent to this gear or through clutch *P*. Gears *Q* and *R* mesh with gears keyed to the spindle, and as gear *Q* is mounted on a sleeve, and gear *R* really consists of a sleeve with teeth cut on one end, when either of these gears is transmitting the drive, the other rotates idly on shaft *O*. The sliding gears on shafts *M* and *O* are operated by ball-joint levers *A*, Fig. 4, located on the left-hand side of the column. The forks operating the sliding gears are made interlocking so as to prevent the engagement of both pairs of gears at one time.

Adjustment of the Spindle

The spindle is flanged at the front end, and the face of this flange has a keyway into which may be inserted hardened steel jaws for driving arbors and face mills. Wear on the front and rear spindle bearings may be compensated for by adjusting nut *S* (Fig. 1) at the rear end of the spindle. The spindle may be hand-operated by turning wheel *T*, which is a convenient feature when boring jobs and some milling operations are being performed. Positive locking of the spindle is effected through a small crank-lever on the left-hand side of the column near the rear, which may be seen in the heading illustration. This locking device cannot be operated while the machine is running, and neither can the main driving clutch *F*, Fig. 1, be brought into contact with its driving member when the spindle is locked. The positive locking feature enables the operator to remove arbor nuts without difficulty. The draw-in bolt *Y* provided for holding arbors or cutters in the socket end of the spindle may be rotated by applying a crank-handle on the rear squared end.

The Knee-elevating Mechanism

Reference to Fig. 2 will show that the gearing for elevating or lowering the knee and feeding the saddle and table is all contained in the knee, the latter consisting of a main casting gibbed to a dovetail slide on the column, and a casing *A* in which the major portion of the gearing is contained. This construction enables ready unit assembly and facilitates lubrication of the transmission members, as a sufficient quantity of oil can always be kept in casing *A* for some of the feed-gears to dip into. Power is transmitted to the knee-elevating and table-feeding mechanisms from shaft *A*, Fig. 1, through bevel gears *a* and *b*, and spur gears *c* and *d*, gear *d* driving the extremely wide faced spur gear *B*, Fig. 2. The extreme width of gear *B* is necessary on account of the vertical movement of the knee. Gear *C* also meshes with gear *B* and transmits power to shaft *D* through bevel gears, the drive being connected and disconnected by operating clutch *E*, which is controlled by a lever on the left-hand side of the knee. When clutch *E* is in engagement with bevel gear *F*, the rotation of shaft *D* is in the opposite direction to that in which it revolves when the clutch is in engagement with gear *G*. This arrangement enables the knee to be elevated or lowered, the saddle fed to the front or rear, and the table to the right or left.

From shaft *D* power for operating the knee mechanism is transmitted to sleeve gear *H* through trains of feed-change

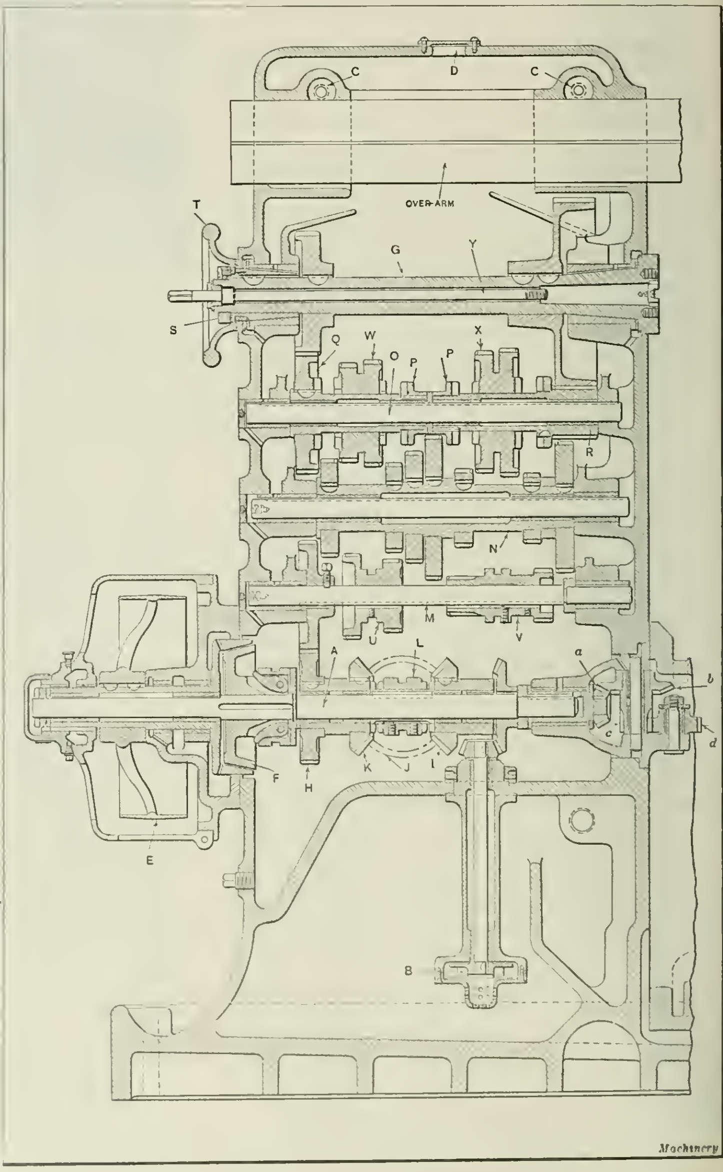


Fig. 1. Cross-sectional View of Column of Cleveland Milling Machine, showing the Main Drive and the Drive to the Spindle and Centrifugal Pump

gears which are connected by either of sliding gears I or J and which drive gear K mounted on a sleeve on shaft L. Power from gear K is transmitted to gear H by engaging the teeth of clutch M with those of the clutch member mounted on shaft L adjacent to gear K. Gear H drives its mating bevel gear V on the top of the elevating screw N. The threads of this screw engage those of nut O which is held in a post mounted on the base and is automatically lubricated. The knee is raised or lowered according to the direction in which the screw is rotated. The main knee casting has a bearing on the post in which the screw nut is mounted. Gear V has teeth on the upper side as well as on the lower, the upper teeth meshing with a pinion that may be rotated by hand by turning crank B, Fig. 3, when the power feed is disengaged.

Saddle and Table Feeds

Sixteen feeds to the saddle and table in geometrical progression are provided through the change-gearing in the knee; these are obtained by operating handles on the front of the knee as shown at C in Fig. 3. The saddle is adjustable on a dovetail slide on the knee, and is fed across the knee by means of a screw engaging a nut cast integral with the saddle, the screw being driven direct through the gearing in the knee or turned by hand when handle Q, Fig. 2, is revolved. This handle is applied to the square end of the screw which is located as shown at D, Fig. 3. The clutch for the power feed is operated by a handle on the right-hand side of the knee. Automatic operation of this clutch is also provided to stop movements of the saddle at predetermined points. The crank for feeding the saddle by hand is disengaged from the screw when this member is power-fed.

On the top surface of the saddle is mounted a swivel-head R, Fig. 2, and on the latter is mounted table S. The saddle and swivel-head are correctly assembled with reference to each other by means of a hardened annular ring which seats in a recess in the upper surface of the saddle and which furnishes a bearing for the head. Clamps are supplied to maintain the head in any desired angular position, and the base of the head is graduated to facilitate such settings. The drive from the feed-change gearing to the table is through a train of spur gears which drive shaft P, and then through bevel gears which connect shaft P to the table screw located at W. The vertical shaft U on which two of the bevel gears are mounted is located at the center about which head R swivels. The table screw engages a stationary nut on the swivel-head.

A clutch on the feed-screw engages and disengages the screw from the power drive. This clutch is actuated by lever T through a gear segment and forked lever. When the clutch is disengaged, the table may be hand-fed by revolving handwheel E, Fig. 3, or crank-handle F. The clutch can be disengaged automatically after the table has moved a desired amount, by an adjustable trip secured to the T-slot on the front side of the table, which strikes a projection on lever T, Fig. 2. The bevel gear on shaft P and those on shaft U are held in a bracket supported by the saddle, the gear on shaft P being free to slide so that it can follow the movements of the saddle. Easy traverse of the table is facilitated by means of rollers with which the swivel-head is equipped, and which keep the bearing surfaces amply lubricated.

Additional Features

Among the most important requirements of a milling machine are convenience and rapidity of operation, and in the Cleveland machine these are obtained by locating all control levers at the front and by having all mechanisms controlled either by a lever or a handle. The graduated dials provided on all adjusting screws are large in diameter. A rotary table can be mounted on the regular table, and in such an event the drive to the rotary table is supplied through an extension shaft and universal joints which connect this table to a train of gears on the right-hand end of the regular table, power being transmitted to this train of gears from the table feed mechanism. Although the machine illustrated is intended to be driven from a lineshaft by a constant-speed pulley, it may be arranged for motor drive in approximately two hours, the machine having been designed with this in view. A Morse silent chain transmits the power when the machine is driven by motor.

A machine equipped for cutting teeth in a rack is illustrated in Fig. 5. A special bracket A is attached to the face of the column, this bracket supporting a cutter-spindle at its outer end. This spindle is positioned at right angles to the machine spindle, and thus is parallel with the table, when this member is at right angles with the knee. The cutter-spindle of the rack attachment is driven from the machine spindle through spiral gears. A form cutter is used in cutting the rack teeth, and a tooth is produced each time the rack is fed transversely past the cutter by operating the saddle feed. After a tooth has been formed the rack is indexed longitudinally to suit the pitch through gearing B on the end of the table, which is connected to the table feed-screw. This gearing is actuated by operating handle C which has a plunger that engages a notch in a one-notch index-plate

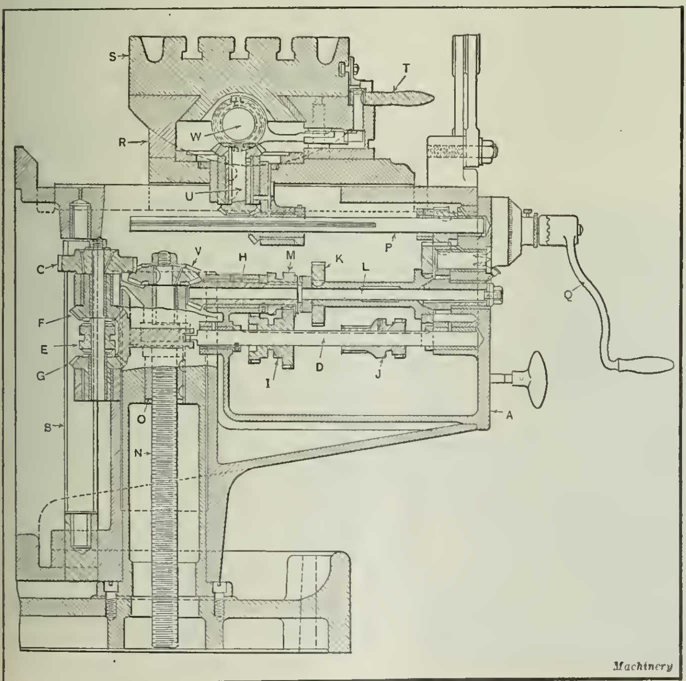

Fig. 2. Sectional View, showing the Important Mechanisms in the Knee

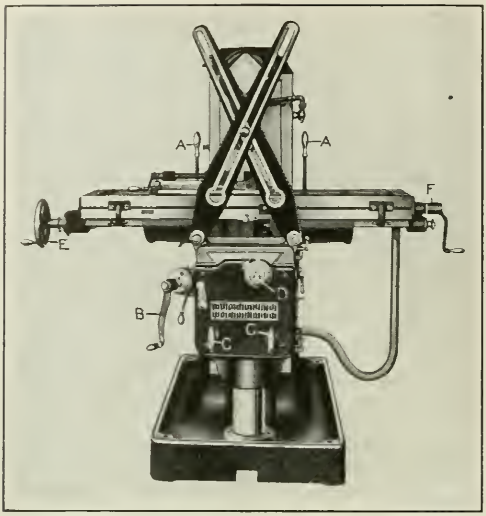

Fig. 3. Front View of the Machine, illustrating the Arrangement of the Arbor Supports

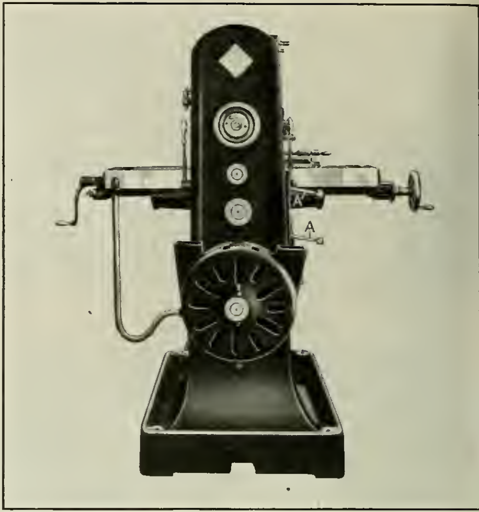

Fig. 4. Rear View of the Machine, showing the Bracket supporting the Driving Pulley

mounted on the same shaft as the top gear in the train. One movement of the handle causes the table and rack to be indexed the necessary amount.

Slotting Attachment

A slotting attachment may also be supplied to meet the requirements of diemakers and toolmakers and for use in shops where there is not sufficient work to justify the purchase of a regular slotting machine. This slotting attachment is firmly clamped to the dovetail slide of the column and located in position on the column by means of two pins at the top of the attachment base. The frame which carries the ram is graduated and can be swiveled through 180 degrees. This permits it to be used in the horizontal position without interfering with the stroke of the ram. The ram is of rectangular section and gibbed to provide adjustment for wear. Its stroke may be set for any length up to 4¾ inches. At the lower end of the ram is attached an adjustable tool-block made of hardened steel V-jaws, which will accommodate tools from ¾ to 1 inch in size. The drive to the crankshaft which actuates the ram is direct from the milling machine spindle through a coupling. Lubricant is supplied to the slide surfaces of the attachment by an oil-cup on the front of the ram and vees which convey the oil while the ram is in operation.

* * *

According to figures published in a recent Commerce Report, there were 558 plants in the United States in 1919 engaged in the manufacture of machine tools and metal-working machinery. The combined value of the products of these plants for that year was $248,573,000. The exports amounted to a value of $58,507,942, of which $22,627,477 represented machine tools.

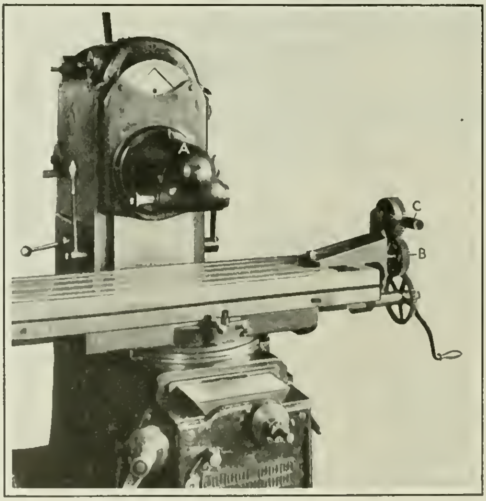

Fig. 5. Attachment for cutting Teeth in Racks

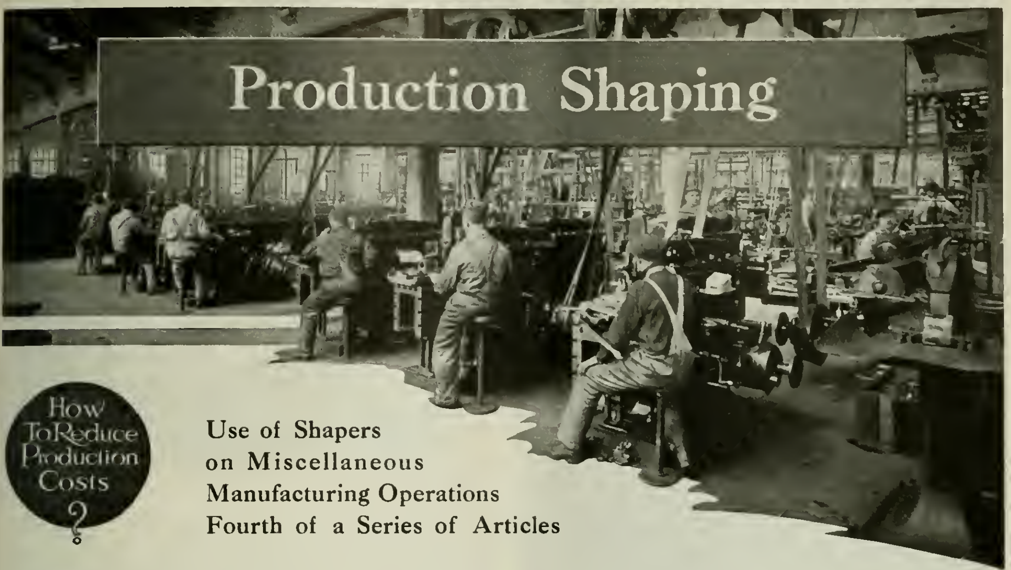
POLISHING FLUTES OF REAMERS

Flutes of reamers, taps, and other similar small tools are not usually polished in regular production work, but are ground with solid wheels. For this operation, according to *Grits and Grinds*, the Norton Co., Worcester, Mass., has found that alundum wheels 2 to 6 inches in diameter, by ¼ to ½ inch thick, grain 60 or 80, and grades O to Q, will give satisfactory results. Some manufacturers, however, polish the flutes of taps and reamers, and for this work a felt or leather wheel is generally used, unless the work is exceptionally large, when a canvas wheel is more satisfactory, since it will hold the abrasive better and give greater production. On the smaller sizes a leather wheel is considered best from the cutting standpoint, and it is also as good as other kinds for finish. Leather wheels are made from a good quality of oak tan leather, and they should be approximately 6 or 8 inches in diameter by ¼ or ½ inch thick.

Care should be taken to see that the polishing wheel is true, and if necessary it should be turned true before setting up with grain. When this is done, a sizing of good glue should be applied and left about two hours to dry. Then two coats of glue and abrasive are put on and left to dry over night. Before using, the grain on the sides of the wheel should be dressed off with a piece of broken grinding wheel.

The sizes of wheels and also the grain to use depend largely upon the sizes of the work to be polished. For large work a wheel of 60 or 80 grain will give good results, while for smaller sizes a wheel of about 120 or 150 grain is satisfactory. If a still better finish is required, grain 200 with Tripoli or oil can be used. This work is done free-hand.

Production Shaping



How To Reduce Production Costs ?

Use of Shapers on Miscellaneous Manufacturing Operations
Fourth of a Series of Articles

ALTHOUGH the principal field of application of shapers is in tool-room and experimental and repair shop work, machines of this type are now being used for many detail operations which must be performed in the manufacture of metal parts. For instance, one well-known maker of firearms has twenty-five crank shapers in the production departments of his plant, and this is but one of many examples that could be cited. The following article illustrates and describes the performance of miscellaneous manufacturing operations on the shaper, and will tend to emphasize the applicability of a machine of this type as a standard form of equipment for production work.

Application of the Tilting Table Flap for Shaping an Inclined Surface

Fig. 1 illustrates a typical application of the tilting table flap of the shaper built by the Potter & Johnston Machine Co., of Pawtucket, R. I. This construction provides for obtaining a specified angular relationship between the under surface of a piece of work that rests on the shaper table and the top surface that is being planed by the cutting tool. In this case, the piece to be machined is a cast-iron gear guard, the feet of which are bolted down to the table by means of clamping straps. By tilting the table flap, the top surface of the gear guard is finished at the required angle with the plane of the feet.

Use of Swiveling Table for Shaping Two Surfaces at an Angle with Each Other

Still another adjustment furnished on the Potter & Johnston shaper to provide for obtaining definite angular relationships between two surfaces of the work is illustrated in Fig. 2. The piece shown on the machine is a cast-iron bracket on which two surfaces are shaped at an obtuse angle to each other. The shaper table is carried on a pivotal support, so that after one surface has been finished, the table

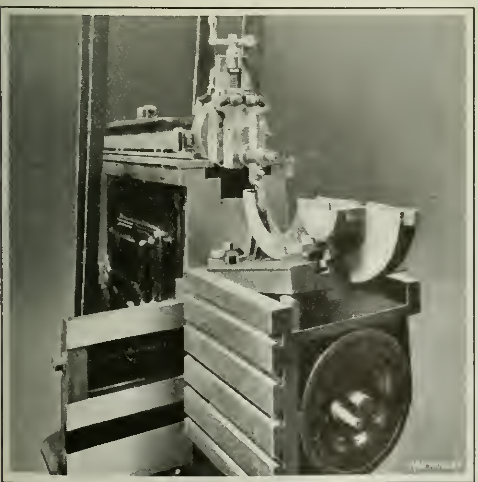


Fig. 1. Application of the Tilting Shaper Table Flap for obtaining a Specified Angular Relationship between Two Finished Surfaces on the Work

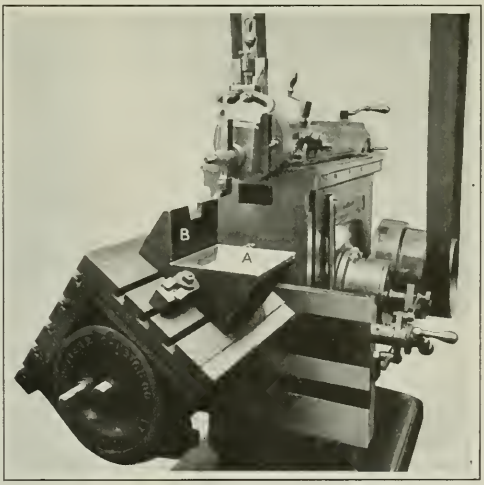

Fig. 2. Application of the Swiveling Table for obtaining a Definite Angular Relationship between Two Finished Surfaces on a Piece of Work

can be swiveled through any required angle for finishing a second surface at a specified angle to the one previously machined without resetting the work. In the present case, surface *A* was finished first, after which the table was swung over to the position shown for shaping surface *B* with a vertical downward feed of the tool. The shaper tool is forged with an offset in order to avoid any interference between the tool and the work. It will be seen that the casting is strapped down on the shaper table.

Shaping Both Sides of a Wide Slot Simultaneously

The piece of work illustrated on the machine in Fig. 3 is a sliding block used on a piston-turning machine. The operation consists of finishing the two vertical walls *A* of a wide slot, with a specified clearance between them, on a

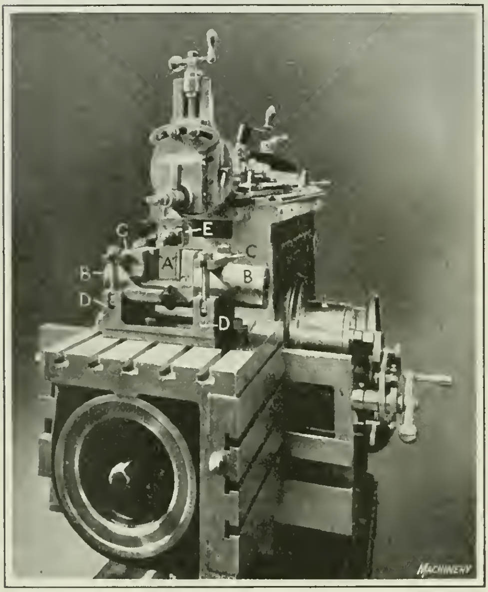

Fig. 3. Use of a Duplex Tool-holder for finishing Two Sides of a Wide Slot simultaneously

Potter & Johnston shaper. This job is interesting for two reasons. The two trunnions *B* have been turned before the piece comes to the shaper, and they are utilized as locating points by having a V-block fixture bolted to the table with straps *C*, which hold the trunnions down in the vees *D*. With the work located in this way, the two sides *A* of the slot are finished simultaneously by means of a tool-holder *E* that supports two cutter bits extending in opposite directions. The slots in which these bits are carried in the tool-holder, are inclined sufficiently so that the points of the tools will operate without interference between the tool-holder and the work.

Cutting Long Keyways on the Shaper

In cases where it is required to cut long keyways, or spline grooves, the shaper may often be employed advantageously. Such a case is shown in Fig. 4, where the shaft is held in a vise bolted to the table of a shaper built by the John Steptoe Co., of Cincinnati, Ohio. The work is done with a tool of the same width as the keyway or spline groove,

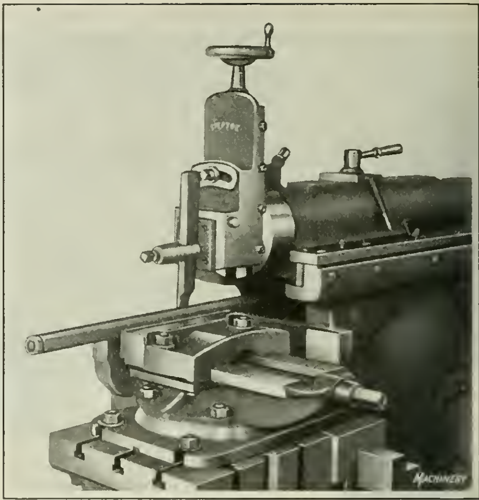

Fig. 4. How the Shaper is used for cutting a Long Keyseat

the latter being produced by feeding the work up to the tool until the groove has been sunk into the work to the required depth. If an exceptionally smooth finish is required on the sides, it may be found desirable to take a second cut with a slightly wider tool.

Many men of experience in the planning of machining operations would regard this as a job for which the milling machine would be peculiarly well adapted. Local conditions would naturally affect the results that could be obtained, but on either type of machine the setting up time would be approximately the same, and it is probable that there would be little difference between the actual time required to form the groove with either a milling cutter or a shaping tool.

Shaping Wobbler Rolls

An interesting operation showing the application of shapers on work other than machine tool parts is illustrated in Fig. 5, which is a close-up view of one end of a very heavy steel wobbler roll on which it was necessary to plane the semicircular grooves that are used for driving

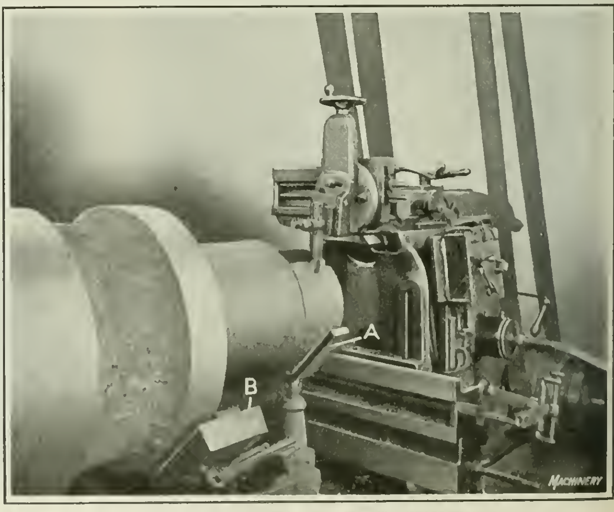

Fig. 5. How a Traverse-head Shaper is used for cutting Integral Key

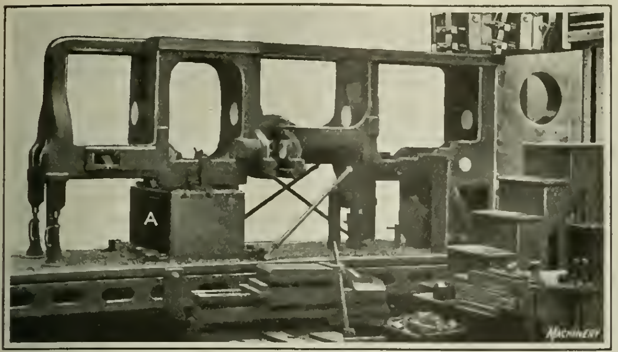

Fig. 1. Automatic Screw Machine Frame Casting set up for planing

the roll. The operation is practically impossible to perform except by using a shaper that is adapted for this work. In this particular instance, the roll was brought to the machine by a crane and set in the proper position with the inner end supported by a cradle *A*, which is mounted on an adjustable jack to locate the work. The cross-rail and table of the shaper were removed as will be seen in the illustration.

The shaper is provided with a traverse head having automatic horizontal and vertical feeds similar to a planer, and has sufficient adjustment to make it possible to plane the wobbler grooves without difficulty and in much less time than by any other method. In some shops where motor-driven shapers are used, it is found easier to transport the shaper to the work on account of the great weight of some of these rolls.

* * *

PLANING OPERATIONS ON PARTS OF NATIONAL ACME AUTOMATICS

Figs. 1 and 2 show the set-up of the frame casting for a National Acme multiple-spindle automatic screw machine on a Cincinnati planer. It will be seen that the casting is of rather unusual size and of such a shape that there would be considerable danger of distorting it by the pressure of the planing tools, unless adequate precautions were taken to avoid such trouble. Before starting to set up the casting, each of the bosses in which shaft bearings are subsequently to be fitted, has been carefully laid out, so that these fixed points on the work may be used in setting the planing tools, thus making sure not only that all planed surfaces on the casting will be properly cleaned, but also that these faces will be correctly located relative to the other fixed points.

The casting is first located by means of a supporting block *A*, which is secured to the table of the planer. This block is employed when the casting is inverted for planing the base; when standing on its own base, no special support of this kind is required, because there is a uniform flat face for the casting to rest on. However, regardless of whether the work is standing right side up or upside down, there are numerous points at which it is necessary to provide additional support to prevent springing the casting out of shape under the pressure of the cut; this is accomplished by the use of jacks, as shown in the illustrations. Adequate support is furnished by this means, and by the use of end-stops, straps, and packings usually employed in the performance of planing operations.

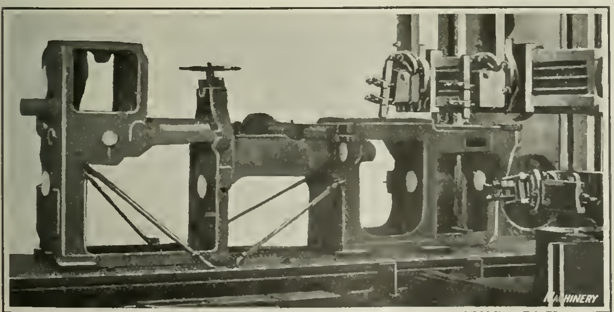

Fig. 2. Casting shown in Fig. 1, set up in the Reverse Position

Planing the Dovetailed Bearing in a Cross-slide Block

In Fig. 3 a finished cross-slide block for a National Acme automatic screw machine is shown at *A*, and this illustration also shows the way in which a string of these castings is set up on a G. A. Gray planer for planing one of the dovetailed bearings of these blocks. The castings are clamped against a parallel bar fixture by means of bolts and fingers. Sheet-metal guards *B* are placed over the ends of the clamping fingers to protect the finished surface of the work. In this operation, the point of interest is the provision which is made for finishing the angular under-cuts of the dovetailed bearings. This is accomplished by setting the tool-head at an angle so that the tool point can be fed down the inclined side of the work. The tool is forged with an offset point which enables it to operate without interference between the side of the tool and the work. In performing this operation, the method of procedure is to first cut a slot of rectangular cross-section, and then to perform the under-cutting operation as shown. The material is cast iron, and this job is performed with a feed of 1/64 inch per table stroke and a cutting speed of 36 feet per minute.

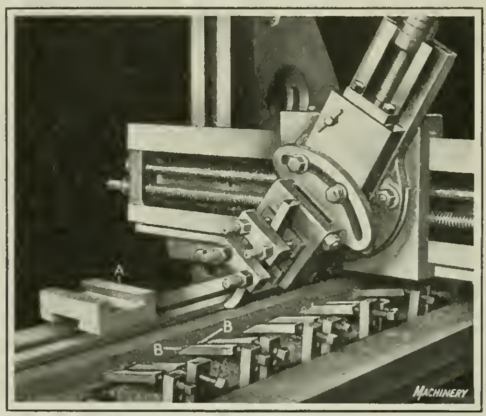

Fig. 3. Planing Dovetailed Bearing in Cross-slide Blocks for National Acme Automatics

* * *

Great improvements are being effected in the French railway system, according to an item in a recent Commerce Report, and the rolling stock now includes about 1000 locomotives and 50,000 cars more than before the war. Traffic has increased, and 40,000 cars, on an average, were loaded daily during September.

HOW THE MACHINE TOOL SALESMAN CAN SERVE THE INDUSTRY

By a Machine Tool Sales Manager

Rumors—good, bad, and indifferent—surge through all industries. Some of them are based on facts, many are not. At the present time there is a rumor circulating in many industries to the effect that manufacturers are trying to meet the demand for lower prices by lowering the quality of their products. It is impossible either to confirm or contradict this rumor, in so far as it concerns *all* the different industries of the country; but it is a matter of great consequence if such a rumor should be circulated in regard to the machine-building industries in general, and the machine tool industry in particular. Whether such rumors invade the industry and are allowed to circulate depends largely upon the viewpoint and activity of the salesman.

With all due credit to the efforts of catalogue and trade-paper advertising to create quality ideas in the minds of the buyers, it is the spoken word of the salesman that leaves the lasting impression. The machine tool salesman, of course, will always say that the particular machines that he represents have greatly improved; but he sometimes implies that the machines of his firm are the only ones about which this could be said. Then he is followed by another salesman who represents another machine, which is the "only exception." There can be only one effect upon buyers of such an attitude. The impression is created that there must be some ground for the untrue rumors, and this will prove injurious to the industry.

No salesman would want to plant favorable impressions which are likely to grow into orders for his competitors, but he should never forget that his firm is part of his competitors' industry, and that no permanent gain can be made by reflecting unfavorably in any way upon that industry. Suppose that he is selling lathes. He will make a much stronger impression by admitting that all lathes have made rapid progress within the last few years. They are all improving, for the machine tool industry can never stand still, and his own firm had to hustle to keep their usual place in the lead. To hold their lead they secured the best engineers and made improvement after improvement. It is true that another salesman will come along with another leading lathe, but is it not better to have several claiming to be the best builder, instead of having all condemn every machine except their own?

The Old-time Shop Mechanic

In one respect machine shop mechanics are like ball players of bygone days. Just as the old ball player likes to tell how much faster the old game used to be played, so the old-time mechanic likes to praise old-time workmanship, and tell how certain old-time machines "made as they used to make 'em" were better than those made today. This is a pitfall which the machine tool salesman must take care to avoid in these times. It would be easy at the present time to help spread the thought that machine tool workmanship really has not improved, or having improved, is now yielding to a different tendency. Yet, if the salesman permits himself to agree with these statements, he is showing himself ignorant of the remarkable advance of recent years, and by ignoring well-known facts is doing a great injury to the industry in which he is engaged.

It is true that machine tools have always been built with a great deal more care than a great many other lines of machinery, and old-time machines have some very good workmanship. But today the gears are made of steel—perhaps hardened steel or alloy steel—many of the parts are ground to size, and modern measuring tools have reduced the working limits and made perfect alignment the rule, whereas formerly it was an exception. The machines of today are heavier, they have more power, and they perform more and better work.

The Question of Lower Prices

For the last six months the great problem for all business men has been to establish confidence in business, and it may be said that this has been accomplished. As individuals we are all determined that prices are to be lower. We know that food, clothing, and other standard articles of consumption should and will come down in price, but for such articles there is generally a standard of quality, which for the same classes of goods is the same today as it was ten or twenty years ago. In the machine tool industry a different condition exists. Machine tools will continue to improve, and the machine tool salesman should impress that upon the minds of his customers. It is doubtful if there is another industry in which quantity is as subordinate to quality as in machine tool building. The first thing that is demanded of a machine tool is quality. The prices of machine tools will never recede to the pre-war levels, because of the improvements that have been made both in design and workmanship during recent years. The machine tool salesman who casts a reflection upon the workmanship of the product of any reputable machine tool builders whose products may compete with his is doing an injustice to the entire machine tool building industry.

The best service that the machine tool salesman can render today is to give useful and accurate information as to the products of the entire industry. The impressions that he allows to remain in a prospective customer's mind will be passed on to others, and he should check any impressions that may create an unfavorable opinion of the industry.

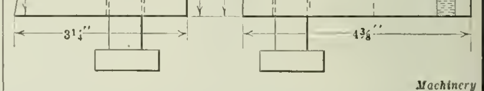
CLAMP FOR PLANER WORK

By JOE V. ROMIG

A clamp or pinch-dog, which is intended for holding flat work on a planer table, is shown in the accompanying illustration. It will be noted that the 60-degree tooth of the clamping member *A* lies in a higher plane than the axis of the bolt *C*. When in use, the body *D* is clamped to the table in such a position that the 60-degree tooth of clamp *A* will be in contact with the side of the work. When screw *B* is elevated, a downward and inward pressure is exerted on



Clamp for Planer Work

the work by the point of the 60-degree tooth. In some cases it is advisable to cut a shallow notch in the work with a chisel for the reception of the clamping tooth. When used on work having finished surfaces, a smooth block of metal is placed between the tooth of the dog and the work.

It is obvious that clamps of this type are intended to be used in pairs, so that a clamp on one side of the work will be located directly opposite a similar clamp on the other side. The clamping-bolt slot in the base of the fixture is long enough to permit the dog to be attached to the planer table in almost any position. The device can be located on parallels in order to obtain the desired clamping action on high work. The body *D* may be made of cast iron, and the clamping member *A* of hardened and drawn tool steel.

Feeds and Speeds as Production Factors

By ALBERT A. DOWD, President, and FRANK W. CURTIS, Chief Engineer, Dowd Engineering Co., New York City

How To Reduce Production Costs ?

ALL manufacturers agree that correct cutting speeds and feeds of machines are essential to maximum production, but there are comparatively few who give the matter sufficient consideration. If the production and the establishment are large, the little losses here and there due to incorrect speeds and feeds may make a total loss of thousands of dollars in the course of a year, and even in a small factory, the loss in production will result in a considerable loss in money. Manufacturers often do not make any great effort to keep machines up to their maximum output, because it is thought that the changes necessary may interrupt production and cause a still greater loss. Also, past experiences in changing feeds or speeds may not have proved successful, due to the poor judgment of the man engaged on the work.

Importance of Recording Speeds and Feeds

There is in all probability no more important factor in production work than the use of correct feeds and speeds, and yet, admitting that each manufacturer wishes to keep his machines running at 100 per cent efficiency, he is not always willing to take the proper steps to insure such a condition. A lathe may be turning a piece of work at too slow a speed and a request may come from the foreman of the department to install a larger pulley on the lineshaft in order to obtain the desired increase of speed. A similar job may be in process in another part of the factory at a different speed and feed without the foreman knowing about it, because he has no supervision in the other department. He may not even know the correct speed at which the work should be revolved to insure the greatest efficiency, but realizes that the production is not what it should be.

An occurrence like this reveals the importance of keeping a record of machine speeds and feeds employed throughout the entire shop and those used on every piece of work which has been made. With a carefully kept record and proper supervision of the machines to see that they are producing as they should, there is no reason why one lot of parts being machined today, should be produced at a slower rate than another lot of the same kind made several months ago. In addition to this, there is always the possibility that production can be increased more or less if the man in charge of setting feeds and speeds conscientiously does all he can to obtain the highest production. This brings us to an important point in the discussion—the selection of a competent man to set all speeds and feeds.

Selection of the Right Man to Set Speeds and Feeds

In determining a man's qualifications for the position, a number of matters must be taken into consideration in order that no mistake will be made by picking out a person likely to use poor judgment or antagonize the department foremen. Mechanical knowledge over a broad field is an essential item, and this knowledge should be of a thoroughly practical nature gained not only by actual shop practice but also by study and analysis. A clear-thinking man having a critical turn of mind, yet not hasty or of the egotistical type, will usually be found to be best for this kind of position. Another essential quality is the ability to determine whether a machine is at fault in not giving sufficient production or whether the loss is due to castings being too hard, or other conditions. In a shop of normal size, one man should have charge of all speeds and feeds, and none of these should be changed in any department without a written order from him. Naturally, this could not apply at first, as it would interrupt production and cause a great amount of trouble.

Installing a System of Recording Speeds and Feeds

In the installation of a system of this kind, the first step would be to make a list of all machines with complete data regarding speeds and feeds for each, their location in the factory, their factory number, etc. Much of this information should be easy of access through the tool engineer, other heads of departments, and factory records. It is advisable to file record cards according either to the type of machine or the department, as may be found most suitable for ready reference. A card suitable for this kind of record is shown in Fig. 1. If a machine is kept continually on a given piece of work, it may be found more convenient to incorporate all data about the speeds, feeds, and rate of production on the card record of the machine. However, as the majority of factories use machines on more than one piece of work, a record of each piece with the details of each operation may be found more useful. A great deal depends upon conditions in the factory, and the system should be devised according to their requirements.

Fig. 2 shows a card which can be used to record facts about the work itself, such as the machine on which a given operation is performed, the speed and feed used, and the rate of production obtained. A single card should be used for each operation, and complete details regarding the production should be given in such a form that it will serve

CHART SHOWING CONDITIONS WHICH GOVERN SPEEDS AND FEEDS

Machine Tool	Size: Heavy or Light Condition: Good or Bad Style: Old or New Right Machine for Nature of Cut
Material	Annealed, Hard, Medium, Soft Too Much Stock to Remove Shape of Work Proper Heat-treatment
Tool Used	Grade: Steel, Stellite Properly Ground Properly Held and Supported Properly Hardened Size: Large Enough to Carry off Heat Number of Pieces per Grind
Lubricant	Necessary or Not Composition Flowing Correctly Flow Large Enough

as a guide in setting up the machine and operating it when the same work is again placed in the shop. After these cards have been prepared, shop tests can be instituted gradually, each machine being tested according to the work it is doing in order to be sure that this is being accomplished in the best manner and in the least possible time. When making the tests a record should be kept of the old and new speeds and the resulting gain in production. Such records will be found of great value, as they not only show the gain in production, but also the method used to obtain the result. If the same job is put through the factory at intervals any deviation from the standard time originally set should be accounted for.

Factors to be Considered in Setting Speeds and Feeds

In analyzing the conditions that affect the setting of speeds and feeds, it will be found that the four following factors are particularly important: the machine tool used for the operation, the material to be cut, the cutting tools employed, and the lubricant used. Each of these factors should be carefully considered from several angles, and as any one of them often affects the others, the engineer should consider the problem in general in connection with each factor, if best results are to be obtained. The accompanying chart will assist a man new to the work to reach a decision regarding the various essential points. The order in which the different factors are mentioned is the logical sequence for a rapid analysis of conditions, although it is possible to start at almost any point, provided certain requirements are known to be correct.

Machine Tools—The machine tool for a given piece of work should be selected with care to make sure not only that it is the ideal type for the work, but also that it is in good condition. High production with the necessary accuracy cannot be obtained unless the equipment is in first-class shape, and a great deal of trouble is caused by an attempt to turn out a high-grade product with inefficient equipment. Modern machine tools are to be preferred to the older types for several reasons: They are more convenient to operate, and have more power and greater range; hence, they will turn out work more rapidly and with greater precision. The man in charge of speeds and feeds should recommend the substitution of newer types of machines for those which are obsolete and which, as a consequence of their condition, cause production to fall below normal.

Material to be Cut—After the machine tool selected for an operation has been found to be in suitable condition to perform its part of the work, the material to be machined should be considered. Steel, cast iron, and brass should not be cut at the same speed and feed. Cast iron may be chilled, hard, medium or soft, all of which conditions require a different rate of speed and feed. So also brass and aluminum vary in their composition and must be cut at suitable speeds and feeds. Tests should be made of the material to be cut, and if found far from normal it should be returned to the foundry or forge shop for proper treatment. If work comes through the factory with some pieces hard, others medium, and some soft, a machine cannot be expected to turn out a uniform product at established rates of speed and feed.

Certain kinds of material can only be brought into a uniform condition by annealing, and when this is the case care must be taken to see that the work is thus treated before it is placed in production. On some classes of work it may be found that the finish allowance is too great and that it would be better to change the pattern so that the cutting action will be less severe. The shape of the work also has some effect on the speeds and feeds which can safely be used, as a part which is very thin and fragile or one on which the cutting action is interrupted, will not permit the same speeds and feeds that might otherwise be employed.

Cutting Tools and Lubricant—The next step is to note carefully the cutting tools and lubricant used. These two items are shown separately on the chart, but they may often be considered together. Sometimes a heavier tool or one made from different material will result in an increase in production; for example, a stellite tool may be substituted for one of high-speed steel with an appreciable gain in production, although stellite would not always be found entirely suitable. On certain classes of materials and kinds of cutting, substantial gains can be made by the use of the tool best suited to the work. The length of time which a tool will run without grinding is a fairly reliable guide as to whether it is suited to its work or not; however, the most economical tool is not always that which stands up the longest, as it may be better to grind it several times a day if an increase in production will result. A common lathe tool, for example, may reasonably be expected to require regrinding oftener than a form cutter, which would perhaps need a special attachment in order to grind it properly. The latter may also require considerable time for setting up, while the former can be located and clamped readily.

A heavy tool carries away heat from the cutting point more rapidly than a light one; hence it is used where heavy cutting is required. The use of various kinds of lubricants often shows that a tool will stand up longer with one than with the other, and when this is the case, it is obviously more economical to use the compound which shows the greatest efficiency. In cutting threads, for instance, oil gives better results than soda water or other compounds. Some materials can be cut wet or dry, but usually one method is better than the other, and whichever it is, it should be used if circumstances will permit. A lubricant serves two purposes—it reduces the friction and cools the tool. Both of these functions should be considered in selecting a lubricant.

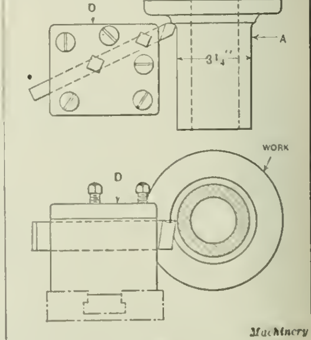

Fig. 3. Job on which Savings were effected by altering the Design of the Toolpost

Setting the Speeds and Feeds

After a number of tests have been made on different classes of work and kinds of materials, it will be found an advantage to make up tables of the results so that they can be used in the future for setting speeds and feeds on new work. It is essential to have these tables in such shape that they can be referred to readily; therefore, a cross-index which refers to a number of actual tests on cast iron, steel, brass, etc., is of value in connection with the tables. A great many points regarding speeds and feeds have been mentioned in order to bring out their value in relation to the general subject. We could easily go a step further and state that cast iron can be cut at a surface speed of 50 feet per minute, mild steel at 80 feet, and brass and aluminum at 200 feet, but such information would serve no useful purpose except to give an approximation of what can be accomplished under normal conditions, and we should then be obliged to determine what a normal condition is.

Cutting speeds for various materials can be found in any mechanical handbook, but any kind of rule of this sort must be flexible. Cast iron may be cut at speeds ranging from 30 to 150 feet per minute, depending on the quality of the material, depth of cut, finish desired, tool used, feed of machine, and other matters which have been mentioned. Other metals and alloys can also be cut at widely different rates of speed and feed, depending on the circumstances. The proper cutting speeds and feeds for a given piece of work are those which will produce it within the required limits in the shortest possible time and what these speeds and feeds should be must be determined to a great extent by tests and by the most careful supervision. The maximum speeds and feeds cannot be obtained by calculation, although comparative records are a great help in this connection. The highest and best production is obtained through a capable man who is always in the shop and who is never satisfied with results until assured that the limit has been reached.

Savings made Possible by Increasing Rate of Feed on a Lathe

A few specific examples of actual savings effected by giving attention to the speeds and feeds of machines will illustrate the value of proper supervision of this work. Fig. 3 shows a flanged cast-iron piece *A*, which is finished in a turret lathe, the flanged portion being held in chuck jaws. Tool *B* is used for turning the cylindrical surface of the piece, the length of the cut being 5 inches. The original method of holding the tool was by means of a standard tool-post *C*, and the depth of the cut was 1/16 inch, the feed 0.020 inch per revolution, and the speed 50 feet per minute. The length of time needed to make the cut was 4.54 minutes.

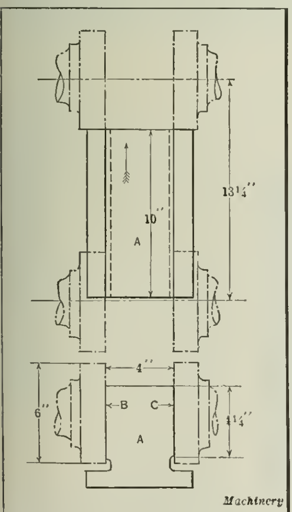

Fig. 4. Job on which a Reduced Speed and Increased Feed aided Production

The foreman of the department considered this satisfactory, as he had found that a coarser feed produced chatter, but the man in charge of the speeds and feeds considered the time too slow. In tests he tried a speed of 65 feet per minute, with the result that there was considerable chatter and the tool was soon ruined. He then decided that the method of holding the tool was largely responsible, as it was not suited to withstand heavy cutting, and so, a heavy special tool-post *D* was made which permitted a heavier feed to be taken without appreciable vibration. Now, a speed of 50 feet per minute is employed and a feed double that previously possible, or 0.040 inch per revolution. By this means, the time of the cut has been reduced to 2.27 minutes. The time required to make the change was thirty minutes.

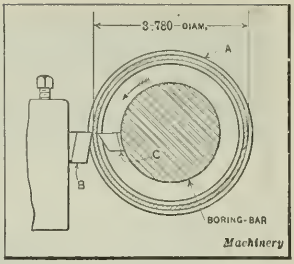

Fig. 5. Example in which Stellite Tools were substituted for High-speed Tools

Increasing Production on a Milling Job by Reducing Speed and Increasing Feed

Another example is presented by Fig. 4 which shows a steel billet *A* that is face-milled on two sides *B* and *C*. The amount of stock removed is 3/32 inch on each side; the length to be cut, 10 inches; the total traverse of the table, 13¼ inches; and the diameter of the cutters, 6 inches. The original speed of the cutters was 80 feet per minute, the table feed 0.100 inch per cutter revolution, and the time required for the cut 2.55 minutes. It was decided that the cutting speed was too great, as the cutters did not stand up as they should. Therefore, their speed was reduced to 60 feet per minute, and the table feed increased to 0.200 inch per revolution. The new time of production was 1.65 minutes, and the cutters kept sharp a much longer time. This example illustrates the savings possible in milling operations by a judicious selection of feeds and speeds. Generally slow speeds and coarse feeds are better for milling operations, but this is not always so. Chatter in milling may often be remedied by a suitable change in feed or speed or both. A little experimenting along these lines will prove of value, as chatter is fatal to good workmanship, and causes loss in production and injury to the tool equipment and the machine.

Savings Effected by a Change in Tools

Occasionally more suitable speeds and feeds can be set for a job by changing the tool or its general shape. This matter, however, should be approached with caution, and unless an analysis determines conclusively that the tool is at fault, it would not be found advantageous to change it. Fig. 5 shows a ring pot *A* that is simultaneously turned eccentric by tool *B* and bored by tool *C*. Both of these tools were formerly made of high-speed steel, but they did not stand up well on account of the hardness of the material. On an average only six pieces could be turned and bored before regrinding of the tools was necessary. The speed of the work was 37.1 feet per minute, the feed was 0.035 inch per revolution and the production per eight hours was 65 pieces. Some of these would not pass the inspector on account of the tools being slightly dull and, therefore, not producing the work within the required limits.

Stellite tools were substituted for the others, and the speed was increased to 39.6 feet per minute and the feed to 0.042 inch per revolution, with the result that the tools machined 140 pieces before regrinding was required. The production increased to 89 pieces per eight-hour day, the gain amounting to 36.9 per cent. From this example it is plain that a change in a tool may increase production in some cases. The great variety of conditions encountered make it impossible to give hard and fast rules for this kind of work, but great gains can be made if care is taken in the selection of the right man for the work, giving him the authority to make necessary changes in feeds and speeds and, in this way, making him solely responsible for the work throughout the factory.

Furnace Design and Fuels Suitable for Treating Drop-forgings

IN the articles published in November and December MACHINERY, a number of examples of modern drop-forging practice were illustrated and described, together with the dies used in producing them. In the present article, the practice followed in heat-treating drop-forgings and the equipment employed will be discussed, with special reference to furnace design and kinds of fuels commonly used.

As a general statement it may be said that annealing will improve the reliability of any forging, although it is not necessary to anneal all forgings; in fact, there are a great many that are never annealed and that give satisfactory service without such treatment. As a rule, small parts need not be annealed except, perhaps, to make them easier to machine. Low-carbon steel parts that are to be casehardened should first be annealed to overcome the tendency of the forgings to warp during the casehardening process. If they are not to be casehardened, straight carbon steel forgings of not more than 0.30 per cent carbon are rarely annealed unless by so doing subsequent machining will be facilitated.

Complications have arisen in connection with the heat-treating of steels during recent years due to the ever-increasing use of alloy steels of a great variety of compositions. These complications have been met by the advances which have been made in the metallurgical field, which have resulted in better control arrangements for the heat-treating department. The practice now followed in modern plants is to rely wholly on the directions issued by the metallurgist for handling steel in the furnace, and in quenching and tempering, to obtain the physical qualities desired in the finished forging.

When it comes to the actual heat-treating, it is necessary that the man in charge be capable and experienced in the operation of the furnaces, so that he can intelligently carry out the instructions of the metallurgical department. The human element enters into the process to a considerable extent, and hence the methods may vary somewhat from the recommendations of the technical expert. It is noticeable that rarely can two shops be found which carry out the identical heat-treating instructions in the same manner, which, of course, is due to the human element, and for this reason rather wide tolerances are permitted in the heat-treating specifications.

Fig. 1. Observing Conditions in Heat-treating Furnace

Refining the Grain Structure Preparatory to Hardening

As the steel leaves the hammer, the grain is large and it should be refined by annealing. Before dependable results can be assured, every precaution must be taken to obtain steel which will conform exactly to the specifications recommended by the metallurgical department for the particular service required. Working to specified temperatures is of little value unless the analysis of the steel is known. The temperatures for annealing and hardening and all data referring to the heat-treating of steel are furnished by the steel manufacturers in some cases, although the most satisfactory results are those obtained when the steel is made to the analysis furnished by the purchaser's metallurgist or chemical engineer.

The annealing process consists of heating the steel slowly and uniformly to a few degrees above the lower critical point (usually about 1600 degrees F.) and allowing it to cool without being unduly exposed to the atmosphere. This can be done either in the furnace or in suitable cooling pits. Perhaps the most satisfactory results will be obtained with the intermittent pusher type of annealing furnace. This is equipped with a mechanical device for intermittently advancing the plates on which the work rests into the heating chamber a few inches at a time. The heat in the chamber may be so regulated that as the work advances into the furnace it will be subjected to a gradually increasing temperature, and as it approaches the discharge end of the furnace the temperature will gradually decrease. The temperature in the center of the chamber is, of course, the proper annealing heat. By this means absolute uniformity is assured, and as the work is delivered from the discharge end it is dropped into baskets or other suitable receptacles where it is left until it has cooled completely.

Treatment after Annealing

If the steels are of the straight carbon class, they should be heated, after annealing, to the proper temperature for hardening and then quenched and drawn to the required hardness. In general, the heat-treatment of drop-forgings is based on the same principles as those that govern other steel parts, although there are a few special conditions that arise in handling steel in this form. The higher the carbon content, up to 0.90 per cent, the lower the quenching temperature should be. Likewise, nickel has a similar effect to carbon in lowering the upper critical temperature of iron. The method of heat-treating medium sized chrome-nickel steel forgings employed in a plant engaged in the manufacture of airplane motors is as follows: The forgings are gradually and uniformly heated to from 1425 to 1500 degrees F. and held at this temperature until thoroughly soaked. They are then removed from the furnace and quenched in warm water, maintained at a temperature of 115 to 120 degrees, for a period of twenty seconds. The forgings are drawn immediately at 1000 to 1200 degrees F., depending on the exact chemical analysis of the steel. The practice of drawing immediately after the quenching overcomes the tendency of the steel to crack. In some other plants the practice differs from that described in that chrome-nickel forgings are quenched in oil instead of in water.

Types of Furnaces

Of the three designs of fuel-burning furnaces—muffle, semi-muffle and car-bottom—it is probable that the semi-muffle type is the most economical to operate from the standpoint of fuel consumption. The muffle type furnace, although furnishing an even distribution of heat, requires more fuel consumption to penetrate the refractory lining of the furnace and reach the work. The car-bottom type of furnace is advantageous in charging and discharging, but in recharging, the bottom of the car becomes cold and must be reheated with each charge, resulting in the consumption of an increased amount of fuel. The car-bottom type of furnace is excellent for annealing large quantities of parts, for which work uniform results can always be had with this style furnace.

City gas is a satisfactory fuel for the muffle or semi-muffle type of furnace, and with this fuel the flame is short and the distribution of heat good. However, the cost of artificial gas is so high, that it is never used in localities where natural gas is procurable. Oil-burning furnaces are provided with burners and a low-pressure air line for atomizing the oil. By regulating the supply of air, the amount of oxidation which will occur, when burning oil, can be controlled and a soft flame obtained.

Anthracite coal as a fuel is still used in certain types of furnaces, but with varying results. The flame is not a highly oxidizing one, and in this respect the fuel has some advantages. Powdered or pulverized coal which has been passed through a fine 200-mesh screen and blown into the combustion chamber at low pressure may also give good results. The best success with pulverized coal will be obtained in small furnaces.

While oil- and gas-burning furnaces are used extensively in modern heat-treating departments, the application of electricity to the heating of furnaces is the most recent method in use, especially where the temperature must be under more absolute control than can be obtained in fuel-burning furnaces. Furnaces of this type are ordinarily of comparatively small size, so that there are certain limitations to their use for heat-treating large work. The electric furnace is best where results of an exacting nature are required, and in the continuous type of furnace electricity is almost invariably employed. The power cost, however, is high, and in some localities where large power companies do not exist, it is almost prohibitive. Control equipment must be used; this consists usually of a relay system, actuated by pyrometers, which produce electric contact with a switch or operating mechanism by means of which the

Fig. 2. Battery of Heat-treating Furnaces for Drop-forgings

supply of electricity is regulated. The pyrometer, of course, registers the heat only in that part of the furnace in which the thermo-couple is located, and is used by the furnace operator principally as an aid in judging the temperature of the other parts of the heating chamber.

Two methods of heating an electric furnace may be used —the electric arc and the resistor. For heat-treating purposes, the electric arc is not suitable, because the heat is not distributed properly, and the gases developed by the arc have a detrimental effect on the work. The resistor type of electric furnace is therefore invariably used, but it is limited by the amount of heat that the metal of the resistor will withstand. Under ordinary circumstances this temperature is about 2000 degrees F., so that for most commercial heat-treating purposes it is suitable, since a temperature as high as this is rarely required. A resistor of chrome-nickel alloy is highly satisfactory, although carbon and graphite resistors are being used considerably with some success. Resistors made of other materials than those mentioned are inferior and will not be found satisfactory.

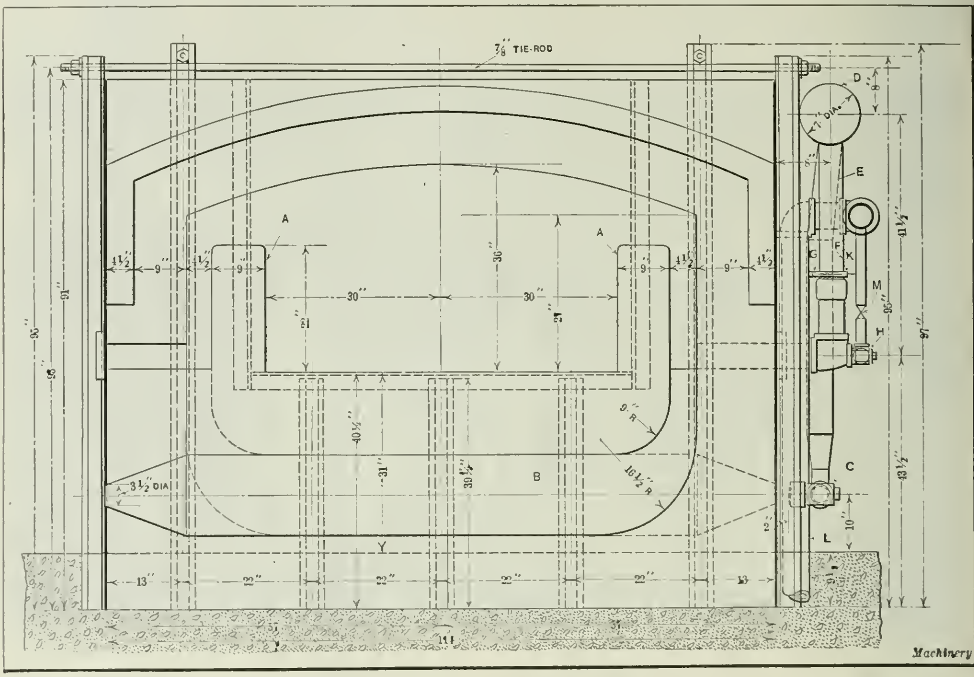

Fig. 3. Design of Combination Oil and Gas Furnaces shown in Fig. 2

Furnace Equipment and Design

In some plants where the work is small and is pot-annealed, the furnaces are installed in a pit so that the hearth is on a level with the floor of the heat-treating department. (See the heading illustration.) This facilitates the loading of the furnaces and the removal of the pots, and in such a case the arrangement is preferable to one where the hearth is elevated.

In designing a furnace, the kind of fuel which it is advantageous to burn should be kept in mind, this of course being influenced by local conditions. The heating chamber should be designed so that the radiant energy from the arches will fall on the work being heated, but not so that the flame will come in contact with the work. If large work is being heated and is laid directly on the hearth of the furnace, care should be taken to select a refractory material for the hearth, which will withstand the destructive effect of dragging the work back and forth. A cheap grade of firebrick, machine made, will be found suitable for this purpose, because it is hard and resists friction. The walls may be lined with any of the commercial furnace linings, but they need not be as hard as is required for the hearth.

The continuous type of furnace, in which a conveyor carries the work through, is especially suitable for handling small work. This same principle of automatic heating, when the parts to be treated are comparatively large, is incorporated in the intermittent type of furnace. This arrangement provides for advancing the work to a certain section of the furnace and after it has acquired the proper temperature, advancing it still farther, intermittently, until the work has been properly heated. Continuous and intermittent heat-treating furnaces may be heated by electric current, although a fuel fire is more commonly used.

A battery of heating furnaces used in the heat-treating department of a large drop-forging concern is shown in Fig. 2. This drop-forging plant has a rated monthly output of 1800 tons, and for handling this work there are eight of these large furnaces, the proportions and design of which are shown in Fig. 3. These furnaces are a combination gas- or oil-burning type of special design. The protective walls *A* are arranged so that the heat will radiate from the arched roof, thus providing a semi-muffle construction which affords ample protection for the work. There are four combustion chambers *B*, equally spaced under the furnace hearth. These are fed by gas burners *C*, two on a side, arranged alternately and connected directly with the supply pipe (not shown in the illustration). The blast line is located at *D* and runs the depth of the furnace. There are suitable valves for regulating the gas flame located along the gas line. The blast for the gas burner is regulated by dampers *G* in pipes *E*, and when gas is not used, is shut off and the air for the oil burners *H* admitted through dampers *K* located in pipes *F*. The oil supply pipes *L* are laid underground. The admission of oil to the burners is regulated by valves located at *M*.

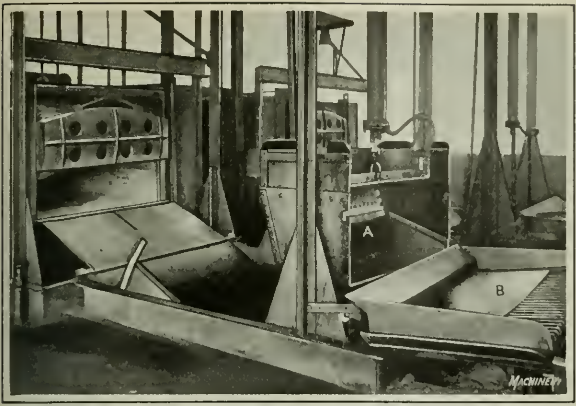

Fig. 4. Front View of Furnace, showing Chute leading to Quenching Tank and Air-operated Shovel

These furnaces are equipped with four pyrometers each, with leads to a central control station. The man in charge of the control station is required to notify the furnace men of the temperature of each furnace and the proper time for drawing the heats. This is done by means of a telautograph, so that as the temperatures are written down by the man in charge of the instrument, this reading will be duplicated at each of the stations which are located in different parts of the heat-treating room, as well as in the laboratory. This enables not only the furnace man but also those in the laboratory who are interested in the progress of any particular lot of forgings being treated, to keep in close touch with the heats. These readings are taken every twenty minutes so that the progress of the heating can be closely watched.

It will be seen that the furnace hearth is above the floor level, which is a desirable condition when comparatively large pieces are being heated. This arrangement makes it possible for the parts to be pushed out at the opposite end of the furnace on the floor where they can either be permitted to cool, or immediately picked up and placed in a convenient place for subsequent treatment. A portable hoist is provided for this purpose. The quenching tanks, which are located in front of the furnace, are equipped with gratings for holding the work. These gratings are operated by an air hoist as may be seen at the left in the extreme background of Fig. 2.

The facility with which work of this kind can be handled will be understood by reference to Fig. 4. Here a front view of a furnace is shown, with the door raised and a chute in position, down which the heated work slides into the oil quenching tank. The scoop or shovel *A* rides in a suitable framework, and is operated by compressed air. The air cylinder is shown in the illustration, as well as the supply hose for admitting the air to the cylinder. The construction of the shovel is such as to permit it to be swung on trunnions and scrape the bottom of the tank, like one-half of a grab bucket. The forgings are deposited from the shovel on the grating *B*, allowing the oil to drain back into the tank. The depth of the tank is about four feet.

In addition to these furnaces and their quenching tanks, this department is also provided with a number of small furnaces for casehardening and cyaniding small work and for various hardening requirements.

General Notes Relating to Heat-treatment

The variation in the compositions of steel makes it practically imperative to follow the fixed rules regarding time requirements in heat-treating the various types of steel. The experiences of the man in charge, in connection with the recommendations of the metallurgist, are usually followed. The work should be heated to about the same color as the refracted light from the furnace walls, which, in connection with the use of pyrometers, will enable the heating and drawing time to be closely approximated.

As a means of assisting in keeping a record of various parts which have been heat-treated so that a precedent for handling similar work may be had, the practice is followed in one shop of making a "prolong" on each forging to be subsequently cut off and used as a test piece. After the heat-treatment has been completed, the "prolong" is cropped off and numbered to correspond with the piece from which it was cropped. All or a portion of this is machined into various types of test pieces, and these are tested to see if the forging meets the tensile and impact requirements. The parts are not permitted to leave the heat-treating department until satisfactory results have been obtained from the tests. It has often been found necessary to reheat the forgings as a result of information obtained from the tests, in order to obtain the desired physical qualities in the forgings. These test pieces are filed away for future reference when similar work is being treated.

Accessories Required in a Heat-treating Department

In addition to the furnaces and quenching tanks, there should be included in the department a medium-sized open frame drop-hammer for use in correcting excessive distortions due to heating, particularly if the work is long like an axle or crankshaft. A hammer of this type will reduce materially the amount of subsequent straightening necessary, and for crankshafts is really essential. There is usually space enough in a corner of the heat-treating department to accommodate the accessory equipment. This equipment will include, besides the hammer, an air compressor which furnishes air for operating the grating hoist cylinder for the quenching baths (if this equipment is used), a blower for the furnace blasts, a straightening machine, and a machine for testing hardness.

Fig. 5 shows a Metalwood straightening machine used for the final straightening of such parts as camshafts and crankshafts. This machine employs an anvil which is operated by air pressure. The crankshaft is supported between centers on the table of the machine, so that it may be turned as required to locate the shaft when applying pressure. Fig. 6 illustrates the use of the Brinell machine for testing the hardness of a motor truck axle. The machine is enclosed in a closet, when not in use, so as to protect it from varying atmospheric conditions, which are so noticeable in a heat-treating department. By this means, a higher degree of dependability can be placed on the results obtained in making the test.

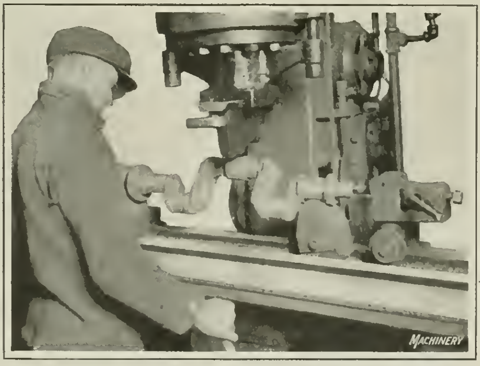

Fig. 5. Straightening a Crankshaft Forging

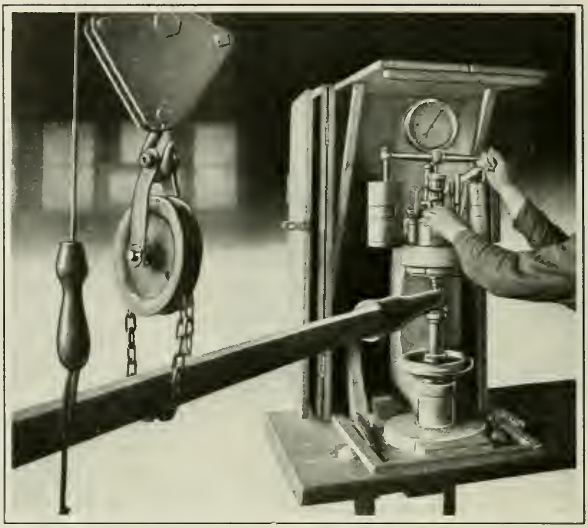

Fig. 6. Motor Truck Axle being tested by Brinell Hardness Testing Machine

After the drop-forgings have been heat-treated, they are transported to the cleaning department in which the tumbling barrels, pickling solution tanks, and sand-blasting equipment are installed. If the forgings are to be machined subsequently, they should be pickled in a dilute solution of sulphuric acid, or other suitable bath. Small parts may be cleaned by tumbling, which is an effective method of removing the scale and fins from the surface of the forgings. Large parts cannot, of course, be tumbled, and if a sand-blasting equipment is not available, the parts may be gone over with a wire brush to remove the scale. However, sand-blasting is the most effective method of handling all sizes of work.

MACHINERY is indebted to the Union Switch & Signal Co., Swissvale, Pa., and to J. H. Williams & Co., Brooklyn, N. Y., for their cooperation in preparing the series of articles of which this is the last.

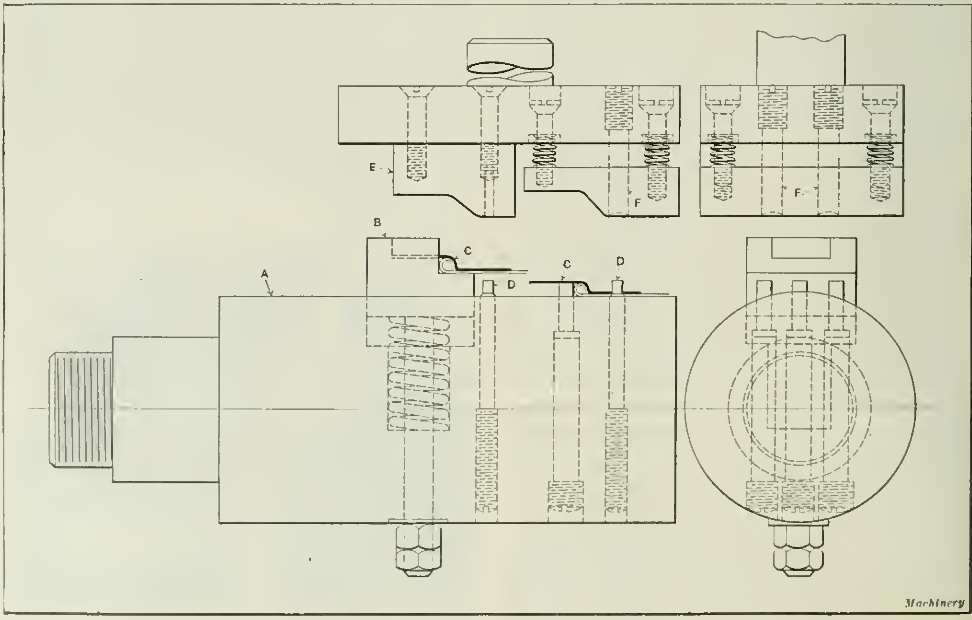
RIVETING DIE

By D. C. OVIATT

The riveting die illustrated is used for attaching ears to tin pails. The cylindrical horn *A* is attached to the power press, extending out horizontally so that the pail may rest on it while the ears are being riveted in place. The pail is abutted against the spring gage block *B* as shown in the illustration, and the ear *C* laid on it in the proper position for riveting. The rivets *D* are set in suitable depressions in the horn, these depressions being formed by special long screws which do not extend quite to the circumference on the horn. To permit the depth of depressions to be maintained regardless of wear produced in the riveting operation, it is merely necessary to adjust the screws to the proper depth. The upper member carries a punch-block *E* which, on the descent of the press ram, forces the gage-block and the work which it supports down until the rivets have pierced the pail and ear. The second position of the pail, with the ear partly assembled, is shown near the end of the horn. The ear is supported by spring pins during the riveting operation which takes place with the work located in the second position. The riveting punches *F* are protected by a spring-backed guard block which, when the press ram descends and the rivet is set down, rests on the ear and acts as a shock absorber.

Work of this kind is usually done on a regular horning press that is arranged especially for the performance of rivet-setting operations of this nature, but such a press is not required when dies constructed according to the general design illustrated are employed.



Die used on Power Press for riveting Ears to Pails

A Railroad Shop Organized for Efficiency

Equipment and Methods Employed in the Angus Shops of the Canadian Pacific Railway Co. Montreal, Canada—Second of Two Articles

By EDWARD K. HAMMOND

IN the first installment of this article, which appeared in the December number of MACHINERY, the general arrangement of the Canadian Pacific Railway shops at Montreal, Canada, known as the Angus shops, was described, and a plan of the shops was shown. It is the purpose in the present installment to show designs of jigs and fixtures used, and to outline some of the methods that have made it possible to reduce costs in the Angus shops.

Design of Multiple Jigs and Fixtures

With a view to bringing production conditions in a railroad shop as nearly as possible into line with those that obtain in the best manufacturing organizations, the jigs and fixtures in the Angus shops have been designed, wherever possible, to provide for a multiple set-up of engine and car parts. As a case in point, consider the equipment shown in Fig. 1, which is used for planing all flat external surfaces of locomotive cylinders. By using a fixture of this kind two castings can be set up at a time, and a number of pairs of cylinders, depending on the capacity of the planer, can be handled in a single operation, thus substantially increasing the rate of production.

The method of procedure is quite simple. The cones *A* are provided with steps to enter the finished bore of cyl-

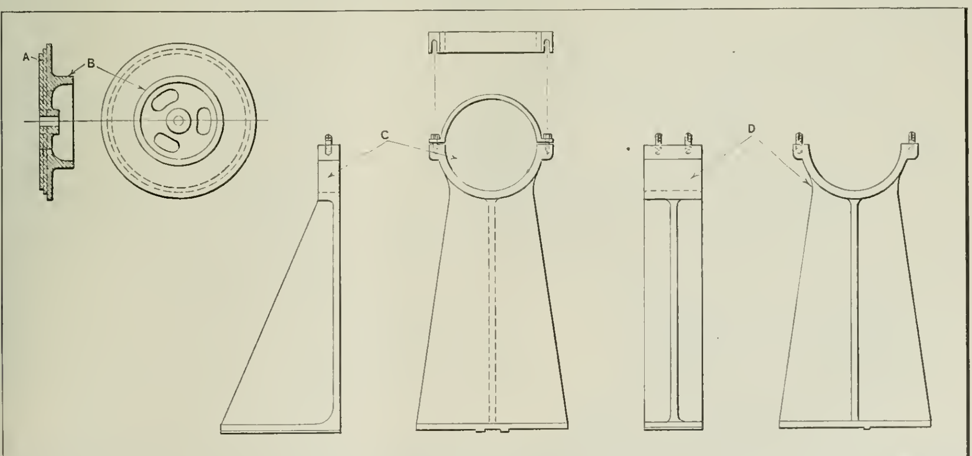


Fig. 1. Fixture used in planing Locomotive Cylinders, which is designed to hold Two Castings at a Time

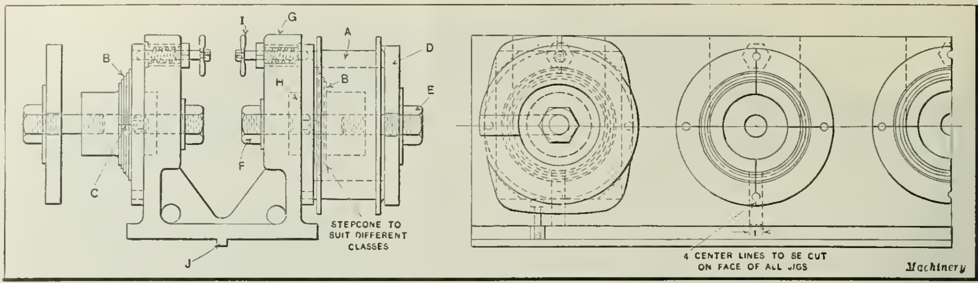

Fig. 2. A Multiple Planing Fixture for Use in machining Main- and Side-rod Brasses

inders of various sizes, and these cones have hubs *B* which enter sockets *C* in the supporting members. Each fixture consists of three parts, namely, two end pieces *C* and a center support *D* that is also arranged to hold a pair of cones *A* projecting one at each side. Obviously, three supporting members arranged in this way have cones *A* in each end of a pair of cylinders. The work is located and leveled up for finishing the joint, frame fits, and other surfaces that have to be planed, according to standard practice. The advantages of such an arrangement are the speed with which the job can be set up and the reduction of planing time that can be effected by the simultaneous handling of a number of castings.

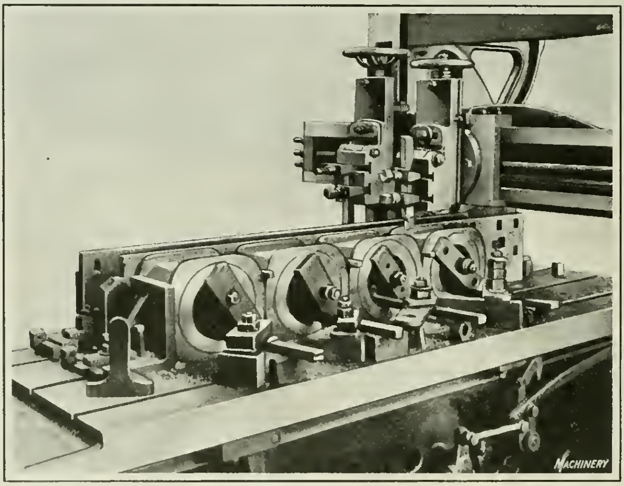

Fig. 3. Gang Planing applied to Rod Brasses

Fixture for Planing Main- and Side-rod Brasses

A better example of economical fixture design is illustrated in Fig. 2, which shows an equipment for use in machining the sides and flanges of bearing brasses for locomotive main-rods and side-rods. In this illustration, one of the pieces of work is shown in position in the fixture at *A*, where it will be seen that stepped cones *B* are furnished for the purpose of handling different sized pieces of work which are previously bored so that the finished hole may be utilized as the locating point.

This fixture is arranged to carry the castings in two rows, and ten pieces of work may be set up at a time. The method of operating the fixture is as follows: After casting *A* has been placed over cone *B*, the line of the joint on which the two halves of the bearing brass are sweated together is brought into coincidence with a graduation line *C*, so that the faces of the bearing brass may be properly finished relative to this joint. Then strap *D* is tightened by means of a cap-screw *E*. When ten cast-

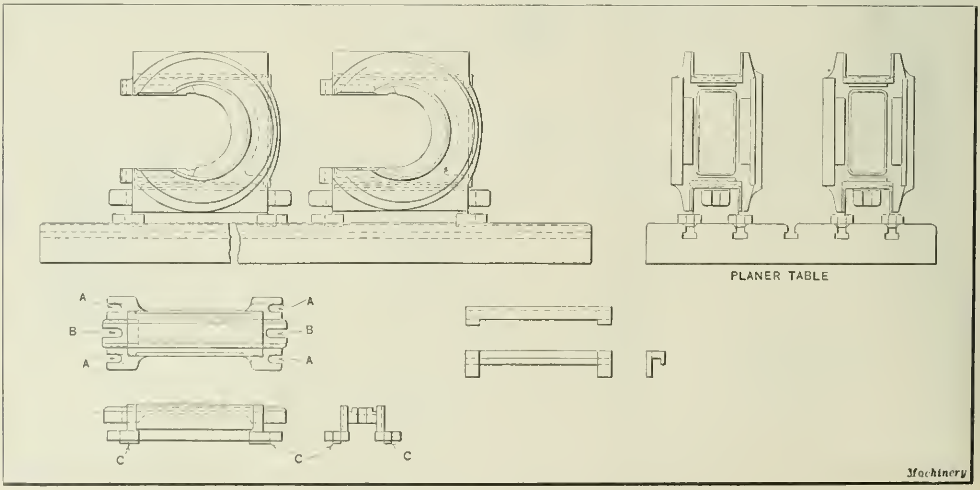

Fig. 4. Multiple Fixture for planing Locomotive Driving-boxes

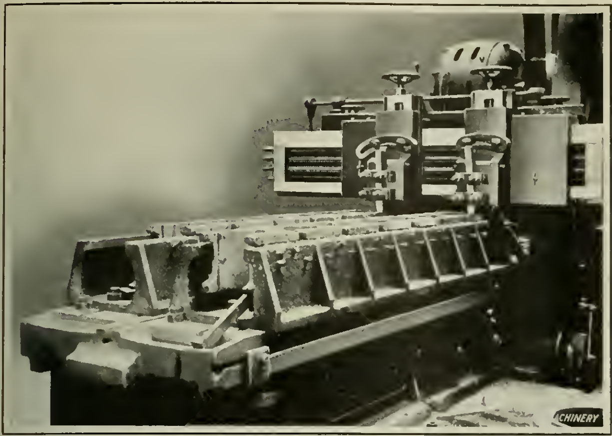

Fig. 5. Planing Two Parallel Rows of Engine Truck Boxes

ings have been set up in this way, the planing operation can be performed on the top face of each piece, two planer heads on the cross-rail being utilized so that the rate of output may be speeded up as much as possible.

After one side of each brass has been finished in this manner, a cap-screw *F* is loosened at the back of each fixture, so that cone *B* and the work carried by it are slightly released from the finished face of bracket *G*, against which each work-holding fixture is tightened. At the back, cone *B* is provided with a boss *H* that enters a socket in bracket *G*. After cap-screw *F* has been loosened, index-pin *I* is withdrawn from the hole in the back of cone *B* and the work is turned through a quarter revolution, after which the index-pin is allowed to snap back into position in the next hole. Then cap-screw *F* is again tightened. After each of the ten pieces of work has been reset, the planer-hand is ready to machine the next face on the castings. Four such sequences of operations are required to complete the job. This fixture is located on the table by a tongue *J* which enters one of the T-slots. Fig. 3 shows a row of rod brasses on the planer.

Fixture for Planing Driving-boxes

For planing the shoe and wedge faces of driving-boxes, the arrangement of the work on the planer table is similar to that employed in the case of the bearing brasses handled on the fixture shown in Fig. 2. However, the design of the fixture used for handling this work is quite different. In the present case, each piece of work is held in a separate fixture, the form of which is best shown at the lower left-hand corner of Fig. 4. Here it will be seen that the fixture consists of a member similar in form to a piece of channel iron, with three slots at each end.

The fixture is clamped to the planer table by bolts passing through the four slots *A*, and the driving-box casting is clamped down on the fixture by means of bolts passing through the two slots *B*. The number of castings set up at a time varies according to the type of locomotive on which they are to be used. Three pairs of boxes are set up in two rows, when the boxes are of the type used on eight-wheel locomotives, while in the case of six-wheel locomotives the boxes are planed with two pairs set up parallel to each other. After the shoe face has been planed, this finished surface is used as a locating point in setting up the work to plane the wedge face. The fixtures are provided with tongues *C* that enter T-slots in the planer table. The chief advantage of fixtures of this kind is that they are quite inexpensive to make and still enable a substantial saving of time to be effected through the application of the multiple principle of setting up the work.

The method of planing engine truck boxes is shown in Fig. 5. Two rows are planed at the same time, and the type of fixture used is clearly shown in the illustration.

Device for Casting Bearing Brasses on Shoe and Wedge Faces of Driving-boxes

Driving-boxes for locomotives used on the Canadian Pacific Railway are equipped with brass bearings on the shoe and wedge faces. After the boxes have been planed, the brass bearings have to be put in place, and reference to Fig. 6 will show that dovetailed anchorages *A* are planed in the driving-box to hold the brass securely. A better idea of the arrangement of the fixture *B* will be obtained by reference to Fig. 7, which shows the device in detail. It consists of three lateral members *C*, *D*, and *E*, which are assembled to form the composite plate, and two cross-strips *F* and *G* which carry bolts that hold the lateral members together.

Plates *C* and *E* are tapered in one direction and *D* is tapered to an equal degree in the opposite direction, so that when the three are assembled they form a single plate with parallel edges. Strips *F* and *G* are slotted in such a way that bolts passing through them have the necessary play to allow the center plate *D* to be adjusted by tapping a head *H* which is welded on it for that purpose. By slightly loosening the bolts and then tapping this head, plates *C* and *E* may be extended or drawn together so that they just fit the space in the driving-box. Conical-headed screws *I* rest against the planed shoe or wedge face of the driving-box, thus holding the plate at a sufficient distance from the box so that a brass bearing of the required thickness may be cast. The entire device is held in place by putting a heavy piece of iron against it while in position in the driving-box;

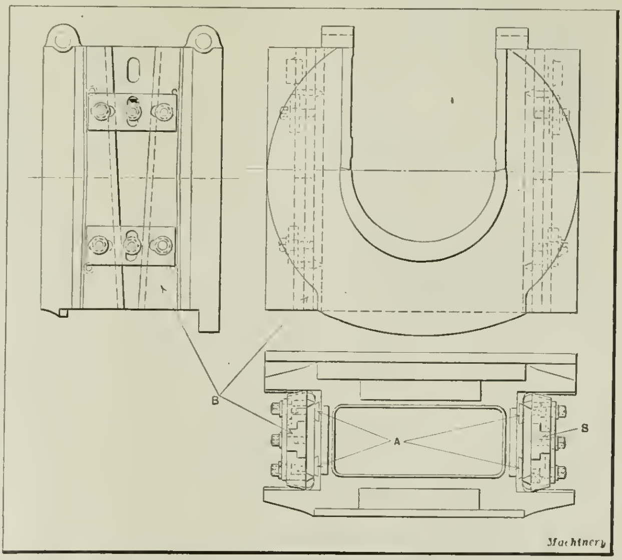

Fig. 6. Driving-box and Fixture used when casting Brass Bearings on the Shoe and Wedge Faces

and the space at the bottom, as well as the joints between the edges of the plate and the flanges on the driving-box, is luted with fire-clay to prevent the brass from running out.

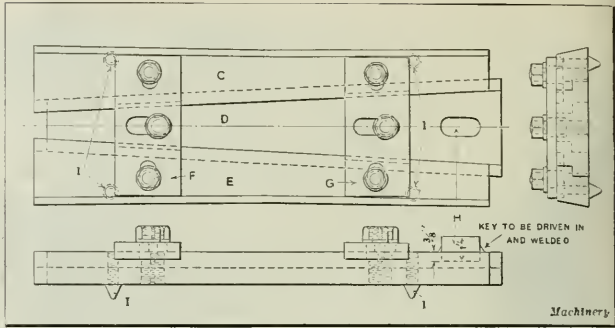

Fig. 7. Fixture used for casting Brass on Shoe and Wedge Faces of Driving-boxes.

Drill Jig for Replacing Dry-pipe Sleeves

Removing a sleeve from the end of a dry pipe in order to substitute a new one is not so simple an operation as fitting a new sleeve, because the new holes in the sleeve have to be drilled in alignment with the old ones previously made in the end of the pipe. To provide a convenient means for performing this operation, a jig shown in Fig. 8 has been developed, which is strapped into place on the table of any sensitive drilling machine. The jig consists of two arms, one of which carries a spring-pin *A* that enters successively the holes in the old dry pipe, while the other arm carries a drill bushing *B* that is located directly over the spring-pin. When the drill is fed down through this bushing, it produces a hole in the sleeve, the position of which coincides with that of the hole in the old dry pipe. After one hole has been located and drilled in this manner, the pipe is turned until pin *A* enters the next hole, after which the corresponding hole can be drilled in the new sleeve. By this method very little time is required to drill a series of holes, the location of which might otherwise cause considerable trouble.

Method of Handling the Labor Problem

Two measures have been adopted in the Angus shops which have been quite effectual in overcoming difficulties with labor. One of these is the application of a system of employe representation. The other is the use of what is known as a "contract" system to encourage industry on the part of the workers and to afford an opportunity for exceptionally industrious or capable men to earn more than the normal hourly rate of pay. This contract plan works out as follows: A so-called "contract price" is fixed for each job, and each class of workers in the plant is paid a specified scale of wages, which is guaranteed. All men working on contracts are credited daily with the cash value of the work done, and they are charged with the amount represented by their wages while on that job. All shop men are paid every two weeks, and once a month they receive as a bonus any difference between the amount earned on their contracts and the amount of the wages which have been charged against the job. According to this system, it is possible for good men to earn 20 or 25 per cent over their regular rate of pay.

Duties of the Contract Foremen

In carrying on this work, there is one contract foreman to approximately every seventy-five contract workers—in many cases less, never more. They are selected from the best mechanics in the shop and placed on the monthly payroll. Their duties are twofold: First, to recommend to the general supervisor of piecework, contract prices for the different jobs; and, second, to inspect the finished work and to credit the men with the number of pieces that pass inspection. It is important to note that these contract foremen are entirely independent of the shop supervision. In conducting their work, if they see ways in which they believe that the efficiency of an operation could be improved, it is their duty to go to the foreman of the department and make a recommendation for the change. If the change is not made within a reasonable time, the contract foreman takes the matter up with the head of his department. In this way, a constant check is kept on the plant's productive efficiency and weak points do not long remain undetected.

* * *

As an indication of the difficulty of selling American machine tools abroad, the following figures will prove of interest. A shaper of American make selling at $720, dealer's price, F.O.B. New York, is copied by an Italian manufacturer who delivers the machine in Paris, duty and transportation charges paid, for $465. The freight and delivery charges on the American machine would add about $75 to its cost in France, and in addition the import tariff would have to be paid. Even though it is understood that the copy of the American machine is not equal, in quality, to the original, it is clear that when the copy is sold for about one-half the price of the American machine in Paris, the advantage is with the copy.

Grinding Multiple Spline Gages

By C. F. SCHLEGEL

The following method of grinding multiple spline gages having six or more splines has been used successfully by the writer. The fact that fifteen or twenty multiple spline gages with limits of 0.0002 inch in both size and spacing of the splines were ground by this method without the loss of a single gage gives evidence of the accuracy of the method. A description of the procedure in grinding a gage with six splines, such as shown in Fig. 1, will make the method clear. First grind the outside of the gage on a cylindrical grinder, leaving the work a little over size for finish-grinding, and of a dimension which permits the circumference to be easily subdivided without using complicated fractions. Next mount the gage on centers and on a surface grinder, indicating both the top and the side of the gage to insure accurate alignment, and taking care not to subject the work to any strain when securing it to the center head.

Now grind the gage surfaces S between the splines by employing the center head to rotate the work while moving the table forward and backward. To finish these surfaces, it is necessary to go over the gage two or three times to insure concentricity of the surfaces with the axial center line. An angle-plate A is mounted firmly on the table of the grinding machine, care being taken to see that it rests close against the outside surface of a spline which is located in a horizontal plane passing through the axis of the gage. The face of the angle-plate must be set true or parallel with the axis of the work, and also at 90 degrees from the surface of the table.

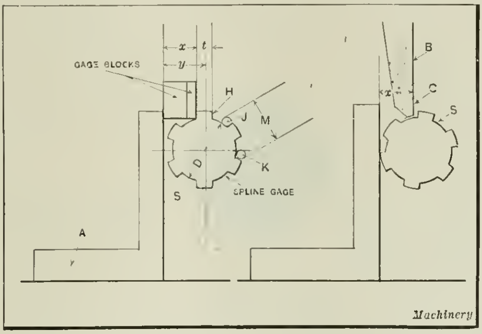

Fig. 1. Method of locating Work and setting Wheel for grinding Spline Gages

A saucer wheel B, dressed off on the periphery and side as shown in the illustration, is set 0.002 inch above the body surface S of the gage, the grinding face C of the wheel being set at a distance x from the face of the angle-plate. The grinding machine table is next moved back sufficiently to permit the gage to be revolved by means of the center head until a spline is brought approximately central at the top, making the distance x, shown in the view at the left, Fig. 1, 0.004 or 0.005 inch less than $y - \frac{1}{2}t$. Without raising or lowering the wheel, grind the side of the spline until dimension x equals $y - \frac{1}{2}t$. The cross-feed of the table is used in performing this grinding operation, and size blocks are employed for gaging dimension x.

The machine table is then moved forward and the gage revolved a sufficient amount to allow the grinding wheel to enter the next space. The side of the second spline is then ground, using the center head to feed the work to the wheel. The accurately ground wires J and K are placed in contact with the ground sides of the two splines as indicated. The side of the second spline should be ground until a micrometer measurement over wires J and K shows that this distance is only 0.0001 inch less than the calculated dimension M. Dimension M is calculated as follows: Add to diameter D the wire diameter; multiply by the sine of 180 degrees divided by the number of splines; add the product to the wire diameter. Expressed as a formula,

$$M = (D + d)\left(\sin \frac{180 \text{ deg.}}{N}\right) + d$$

in which d equals diameter of wire and N the number of splines. Care must be taken to keep the wheel in a free-cutting condition, and the distance from the faceplate to the face of the wheel, as indicated by dimension x, should always be maintained, the wear on the wheel being compensated for by means of the table cross-feed.

The spline gage is next revolved until the two ground splines are in the position indicated in the view at the left, Fig. 1, with the rods J and K in contact with the ground sides. Two adjustable dial indicators F and G, Fig. 2, are then mounted on a toolmaker's surface gage as shown, and adjusted until both indicators show a reading of approximately zero when the ball points pass over their respective rods J and K. The ball point of the upper indicator should pass over the rod J a little in advance so as to enable the workmen to easily read both indicators correctly. All clamping screws should next be tightened, and the indicators adjusted to read exactly zero when their contact points pass over the rods.

The spline gage should then be revolved so as to bring the next or third spline into the grinding position. This spline should be ground until both indicators F and G register zero. The work must, of course, be tested frequently during this operation by placing wire J in contact with the surface being ground, and revolving the work until it reaches the gaging position indicated in Fig. 2. This method of grinding and testing is employed in grinding one side of each of the six splines. The distance between the ground faces of the first and sixth spline will undoubtedly be a little greater than that between the faces of the other splines, say 0.0018 inch greater. Therefore, the distance between the ground faces of the other splines should be increased by 0.0003 inch. With the spline gage set so that the lower indicator shows a reading of zero when the gaging point passes over the ground face of the second spline, proceed to adjust the indicator so that it will show a dial reading of minus 0.0003, or in other words so that 0.0003 inch must be removed from the second spline in order to have both indicators again register zero. The sides of all six splines should then be reground in the manner previously described until all the spaces are exactly equal. It may be necessary to repeat these grinding operations three or four times before the required accuracy of spacing is obtained. Should the space between the ground sides of the sixth and first spline be a little less instead of greater than that required, it is only necessary to find the average discrepancy for each space, adjust the lower indicator so as to lengthen the distance between the two indicator points the amount required to rectify this error, and regrind the gage as previously described.

By taking a very light cut on the side of the first spline, any slight error can be rectified, thus minimizing the danger of spoiling a gage. In finishing the other sides of the splines, size blocks are used that have a total thickness equal to $y - \frac{1}{2} t$ to adjust the work. These blocks are placed between the face of the angle-plate and the ground side of the spline as indicated in the view at the left, Fig. 1. The grinding wheel is then brought into contact with the side H, and the spline ground to the required thickness. During this operation care must be taken to have the corner of the wheel from 0.001 to 0.002 inch above the surface of the body of the gage. The table cross-feed is, of course, employed for feeding the work to the wheel during this operation.

By moving the table in or out a little so that the spline, if pressed against the wheel, will be at an angle of about 1 degree, it is possible to finish-grind the gage so that it will have sharp corners where the sides of the spline and the body surfaces of the gage meet. In performing the latter operation, the gage can be revolved to bring the spline away from the wheel, and the wheel lowered until its edge just makes contact with the surface of the body of the gage. Then, while the work is being moved forward and backward, it can be carefully fed up to the wheel by revolving the index-head, this operation being completed when the edge of the wheel meets the base of the spline. The final

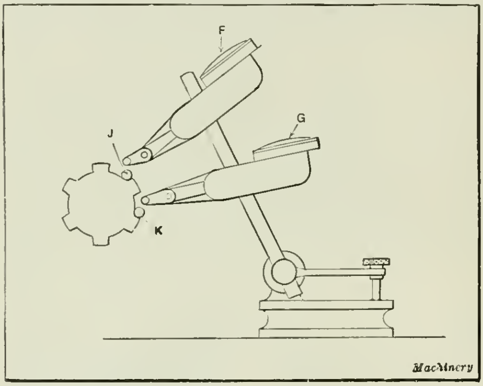

Fig. 2. Indicators used in testing Spacing of Splines

operation is that of finish-grinding the outside in a cylindrical grinder.

The method described can also be used for grinding index-plates having six or more index points or notches. For this work, the angle-plate is located as shown in Fig. 3. Instead of using size blocks, as in the case of the spline gage, it is possible to use micrometers for measuring dimension x in order to obtain the correct relationship between the sides of the notch and the center line of the work. The back face of the angle-plate must, of course, be parallel with the front face when used in this way. By using two indicators, as previously explained, it is possible to obtain very accurate spacing of the working faces L of the index slots. The other sides or faces M, whether straight or at an angle of 15 degrees—the latter design being preferable—may be correctly spaced by using the index-pin as a gage.

SWEDISH MACHINE INDUSTRIES

Statistics covering the Swedish machine industries for 1917, the last complete statistics published, show that in that year machine tools were manufactured in that country to a value of $12,000,000; oil engines, $10,000,000; agricultural machinery, not including dairy machinery, $8,000,000; woodworking machinery, $3,000,000; paper-making machinery, $3,000,000; steam turbines, $1,500,000; water turbines, $1,250,000; and bicycles, $5,000,000.

DEVELOPING MACHINISTS FOR JOBS HIGHER UP

By ARTHUR McCOMB

Notwithstanding the fact that the subject of developing men for better positions has been discussed frequently from various angles, there is still something further to be said. It is always good policy for a shop department to have at least one good man in the course of development and ready to take the place of the foreman in case of necessity. The average superintendent or works manager generally selects a man from the shop for the position of foreman, and is influenced in his selection by the fact that the man is most familiar with the work, regardless of his knowledge of handling men.

The writer is a firm believer in choosing men from the ranks when it is possible to do so; but he also believes that such men should be given a thorough training for at least a year before taking the job, so that in addition to the regular shop routine, they may become proficient in the handling of men and in maintaining a maximum amount of production with a minimum amount of attention to detail. The writer has worked for several men who have been taken from the ranks but have not received such training. Failing in this important detail and having no one to assist them

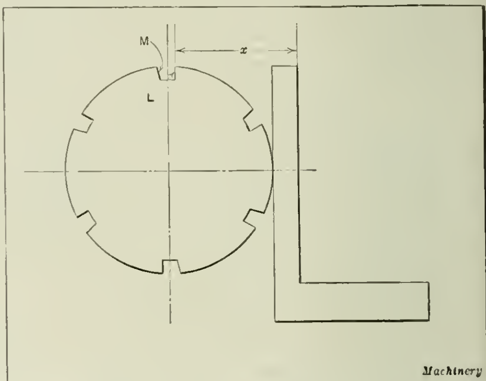

Fig. 3. Locating Index-plate for Notch Grinding

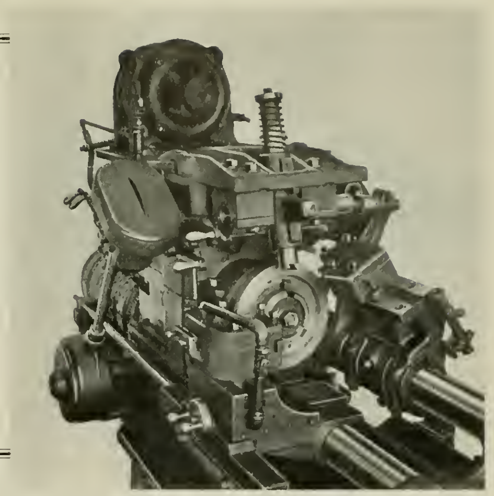
at the time they needed assistance most, these men became discouraged, and were not successful in filling the positions.

Some superintendents do not recognize the fact that there are men in the machine shop of high enough caliber to make high-class foremen. The writer believes that there are, and that there is hardly a shop of any considerable size that does not employ at least one such man who, if given a little encouragement and responsibility, would develop quickly. Responsibility in the development of a foreman is an important factor. Probably much labor trouble could be eliminated by employing a well-trained foreman who understands both the employer's and the workman's point of view, and who is capable of talking and explaining matters to the men in the right way.

The remark is often made that a certain shop cannot compete with some other concern because it does not have the same high-class workmen. The writer does not believe such a remark justified, because he has worked in a number of different machine shops and finds that as far as the men are concerned they are all very much alike. The one thing that makes a big difference is the foreman's organization within his department, and he can develop this organization until he really obtains high-class work with little effort from men who under other circumstances might not be classed as especially capable. This development work of the foreman also helps him to qualify for a higher position.

Cost-reducing Tooling Equipments



Machines and Tooling Equipments Used for Performing Turning, Boring, Facing and Recessing Operations on Automobile Gears

By RALPH E. FLANDERS
Manager, Jones & Lamson Machine Co., Springfield, Vt.

MACHINE or tool designers who endeavor to develop equipments that will enable one operator to run a large number of machines are extending their efforts in the wrong direction when the work must be inserted and removed by the operator. Their aim should be rather to bring out machines which will be so intensive in production that as few as possible will keep an operator busy, the ideal arrangement being one machine to one operator. In the examples of automobile gear manufacture presented in this article, there is one operator to each two machines.

The tooling equipments employed on Fay automatic lathes for turning and facing a stem bevel pinion used in the rear axle drive of an automobile are illustrated in Figs. 1, 2, and 3. This pinion has a projection on the head end which permits it to be driven, in the set-up shown in Figs. 1 and 2, by a hardened and balanced driving plate. The part should have the small end milled, and preferably straddle-milled, so that the end of the projection may be centered to a standard depth, as gaged from the shoulders of the forging. The shank is rough-turned by the tools mounted in the front holder of the equipment shown in Fig. 1, and is necked at the pinion end, and necked and beveled at the small end, by the tools in the rear holder. The formed tool *A*, which necks and bevels the small end, does not come into action until after the turning tool *B* has removed the scale from this end.

The equipment shown in Fig. 2 is employed for the next operation in which the taper surface near the small end is finish-turned by a tool in the rear holder, while tools in the front holder finish-turn the straight portions. The arrows in the various tooling diagrams, show the direction in which the front and rear tool-holders are fed.

On such cuts as those taken by the tools shown in Fig. 1, the work, if properly supported, will stand feeds, speeds, and a number of simultaneous cuts which will consume as much as fifteen horsepower or more, and to be successful in automotive practice the machines should be designed to transmit this horsepower continuously. Since so much depends on the support of the work in determining the output, the question may be raised as to the value of the commonly used driving projection shown, which is of small diameter and lengthens the blank. An alternative scheme that is particularly applicable to parts drilled in the head end is the gripping of this end in a chuck. The chuck drive is the better of the two if it will permit a sufficiently faster cut to compensate for the extra time required in chucking the work.

The gear end of the part is rough- and finish-turned and faced in the next operation, which is performed in a Fay automatic lathe provided with the equipment shown in Fig. 3. The work is gaged lengthwise against the back shoulder of the pinion by abutting this surface against a hardened collar carried on the faceplate fixture. The small end of the part is supported on a spring center, the fixture being slotted to allow the work and driving dog to drop into place. Tool *C* on the front carriage rough-turns the face of the gear, and tool *D* finish-turns it in the same continuous feeding movement. The rear tools do not come into action until the roughing cut has been completed, so that their finishing corners do not become injured by rough scale. In all finishing operations performed in the Fay

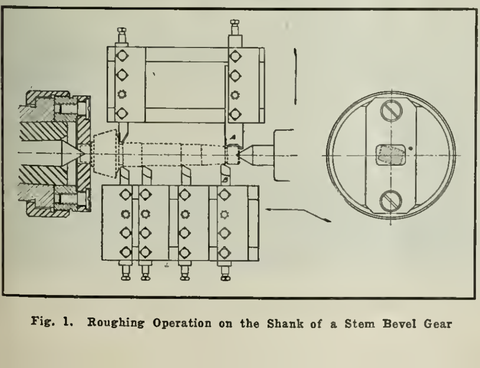


Fig. 1. Roughing Operation on the Shank of a Stem Bevel Gear

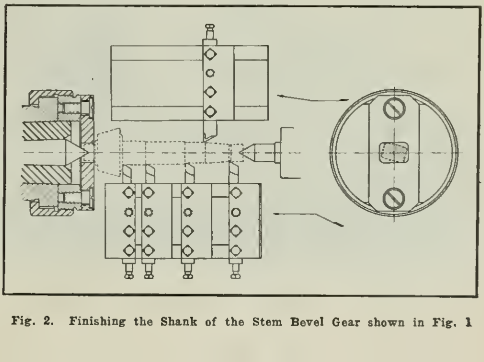

Fig. 2. Finishing the Shank of the Stem Bevel Gear shown in Fig. 1

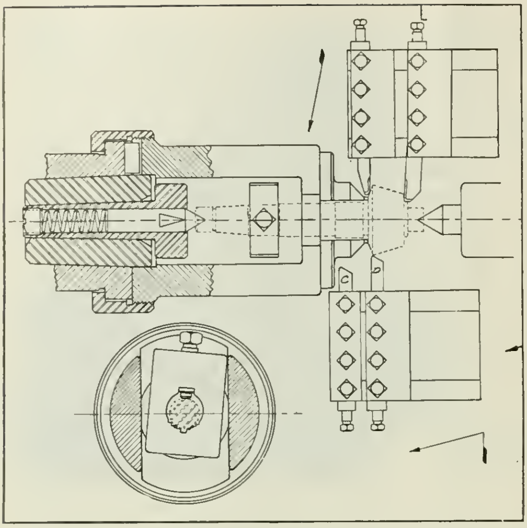

Fig. 3. Rough- and finish-turning and facing the Large End of the Stem Bevel Gear shown in Fig. 1

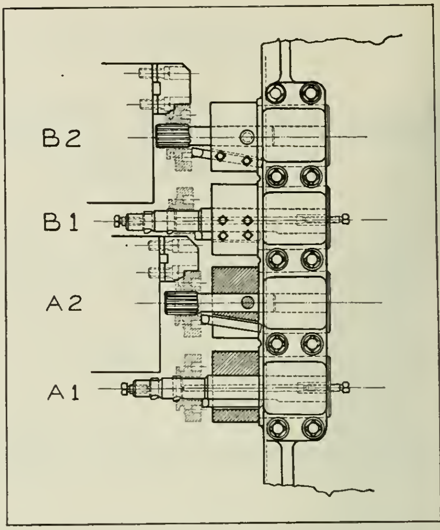

Fig. 4. Tooling Equipment for machining a Transmission Gear on a Double-spindle Production Lathe

automatic lathe, the turning tools on the front holder are relieved automatically on the return travel so that finished surfaces are not scored.

Finishing Two Gears Simultaneously

In the jobs described in the following, the work has a central hole which is finished first in a turret lathe or some similar machine, the finishing operations then being performed in a Fay automatic lathe with the work supported on an arbor. There are certain principles involved in the division of the cuts between two machines and the supporting of the work on an arbor; these are best illustrated by a simple case. In Fig. 7 is shown a job in which the holes in the blanks have been finished and the hubs faced in a preliminary operation. This operation is performed quickly, because the cutting is confined to a small diameter and done at high speed. The blank is held at the periphery so that a firm grip and a true running rim are obtained.

The standard arrangement illustrated in Fig. 7 consists of two machines, three arbors, and one operator. Then while one machine roughs the blanks on one arbor and the second machine finishes the blanks on the second arbor, the operator can change the work on the third arbor. It will be noted that the keyways have also been cut in the work prior to this operation, this provision permitting the heavy drive demanded by the intensive tooling. Simple rim-facing tools are supplied in the rear holder and rim-turning tools in the front holder.

This sequence of operations enables the work to be accurately machined, as it is supported on a true arbor mounted on true centers. The arbors are driven by a swiveling cross-pin, which balances cutting strains and eliminates any tendency of the arbor to spring. Furthermore, as the arbor has a heavy tapered male end supported in a hardened and ground bushing in the spindle nose, the stiffness of the spindle is brought directly into the arbor, and no long and yielding center intervenes. The following conditions give this method the maximum output: The simultaneous roughing and finishing of the work in two machines run by one operator; the simultaneous facing and turning of the work

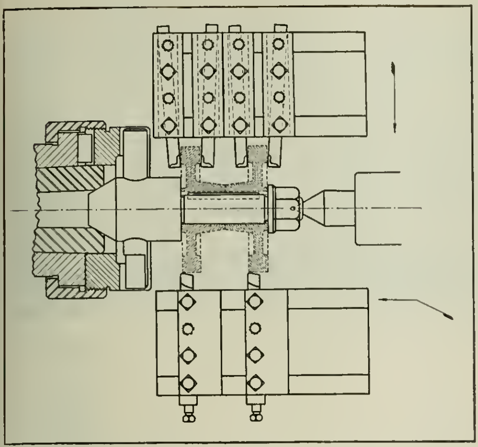

Fig. 7. Tooling Equipment for a Job in which Two Gears are finished at One Time

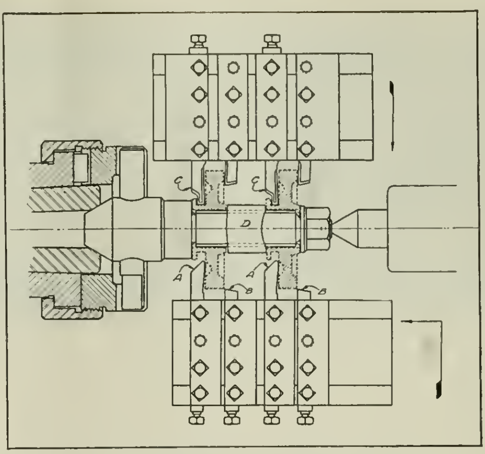

Fig. 8. Use of Spacing Collar to prevent Springing of Arbor when machining Two Gears at a Time

in each machine; the clamping of the work on the third arbor while the machines are in operation; the placing of the work between centers; and, finally, the mounting of two pieces at a time on each arbor, thus doubling the efficiency of the operation.

Tooling Equipments for Transmission Gears
